The number of cases in which the solution of the induction problem can be worked out is very small. Besides those already treated synthetically, one or two more, affording examples of the general method, will be mentioned in the historical summary below. Meantime, we must not omit to mention an extremely elegant transformation theorem, due to J. Neumann,[2] which enables us to deduce the magnetic moment of any body as a whole under the action of any forces whatever, when its magnetization in a uniform field is known.

Let A_1', B_1', C_1' be the components of induced magnetization produced in the body A by the uniform field whose components are $\alpha_0', \beta_0', \gamma_0'$; A_1, B_1, C_1 the magnetization produced in A by any field whatever $(\alpha_0, \beta_0, \gamma_0)$. Let $\int dv$ denote volume integration throughout A; and consider the function

$$U = \int dv(\alpha_0 A_1' + \beta_0 B_1' + \gamma_0 C_1').$$

U is known, since we suppose $\alpha_0, \beta_0, \gamma_0$, A_1', B_1', C_1' to be known. But, since $A_1 = \kappa(\alpha_0 + \alpha_1)$, &c., $A_1' = \kappa(\alpha_0' + \alpha_1')$, &c., we have

$$U = \int dv\left\{\left(\frac{A_1}{\kappa} - \alpha_1\right)\kappa(\alpha_0' + \alpha_1') + \&c. \quad . \quad . \quad .\right\}$$

$$= \int dv(\alpha_0' A_1 + \&c.) + \int dv(\alpha_1' A_1 + \&c.) - \int dv(\alpha_1 A_1' + \&c.).$$

Now the last two terms destroy each other; for they are simply different expressions for the mutual potential energies of the induced magnetism due to $(\alpha_0, \beta_0, \gamma_0)$ and to $(\alpha_0', \beta_0', \gamma_0')$, regarded as separate rigid systems, although coincident in position. Hence we get

$$U = \alpha_0'\int dv A_1 + \beta_0'\int dv B_1 + \gamma_0'\int dv C_1,$$

whence

$$\int dv A_1 = \frac{dU}{d\alpha_0'}, \quad \int dv B_1 = \frac{dU}{d\beta_0'}, \quad \int dv C_1 = \frac{dU}{d\gamma_0'}.$$

[1] See Thomson, *Reprint of Papers on Electrostatics and Magnetism*, pp. 548 *sq.*

[2] *Crelle's Jour.*, xxxvii. 44 (1848). The proof given is a modification of Kirchhoff's, *Crelle*, xlviii. 366 (1854).

For an ellipsoid this gives at once for the components of moment

$$P=\frac{\kappa}{1+\kappa L}\int dv\alpha_0\,,\quad Q=\frac{\kappa}{1+\kappa M}\int dv\beta_0\,,\quad R=\frac{\kappa}{1+\kappa N}\int dv\gamma_0\,.$$

An interesting particular case is that of an infinite cylinder. If P be the component of the moment parallel to its axis, $P=-\kappa\iint dydz\,(V_\infty - V_{-\infty})$. If the inducing system be magnetic bodies at a finite distance, then $V_\infty = V_{-\infty}=0$, and $P=0$. If the cylinder be magnetized by a spiral current i, of n windings, of whatever form, then, r being the radius of the cylinder, $P=4\pi^2\kappa r^2 ni$.[1]

Generalization of the Theory for Isotropic Media in which κ is not constant.—In the above theory we have supposed the magnetic susceptibility to be constant. This is by no means the case in nature, however. It is of importance therefore to consider how the theory must be modified when we assume κ to be a function of the magnetization already induced. Subject to the restriction (obviously necessary for isotropic media) that the resultant magnetization shall coincide in direction with the total resultant magnetic force ($\mathfrak{H}$), the most general assumption that can be made is

Kirchhoff's extension of Poisson's theory.

$$A=f(I)\alpha\,,\quad B=f(I)\beta\,,\quad C=f(I)\gamma \quad . \quad . \quad . \quad . \quad (100),$$

where f is a function depending on the nature of the substance. From these equations, by squaring, adding, and extracting the square root, we get $f(I)/I=1/\mathfrak{H}$, in other words, I, and therefore $f(I)$, are functions of $\mathfrak{H}$. Hence we may write the equations (95).

$$A_1=F(\mathfrak{H})\alpha\,,\quad B_1=F(\mathfrak{H})\beta\,,\quad C_1=F(\mathfrak{H})\gamma \quad . \quad . \quad . \quad (101).$$

It is easy by means of these to introduce the requisite modifications into the general equations of magnetic equilibrium. For the details we refer our readers to Kirchhoff's memoir in *Crelle's Journal*,[2] where the matter was first fully worked out. It will be seen at once that the induced magnetization is in general neither solenoidal nor lamellar.

Cases in which the magnetization is uniform.

There is one important class of cases in which the conclusions arrived at on the assumption that κ is constant still hold, viz., those in which the induced magnetization is uniform. In such cases I has the same value throughout the body, and κ is therefore constant throughout the body *in any one case*, although it differs from one case to another. For example, in the case of an ellipsoid the equations (85) above given for the components of magnetization still hold good, provided we understand κ to be defined by the equation

$$\kappa=F\left[\left\{\left(\frac{\alpha_0}{1+\kappa L}\right)^2+\left(\frac{\beta_0}{1+\kappa M}\right)^2+\left(\frac{\gamma_0}{1+\kappa N}\right)^2\right\}^{\frac{1}{2}}\right] \quad . \quad (102).$$

It is clear, therefore, that by experiments on an ellipsoid placed in a uniform field we could determine the function $F(\mathfrak{H})$, and also test the truth of the mathematical theory. For, A_1, B_1, C_1 being obtained by observation, one of the equations (85) will enable us to determine κ, and the argument $\mathfrak{H}$ can be calculated from α_0, β_0, γ_0 and A_1, B_1, C_1; the test of the truth of the theory would be the agreement of the three values of κ obtained from the three equations (85).

Historical Remarks on the History of the Mathematical Theory.—Although the *Tentamen* of Æpinus, published in 1759, and the discoveries of Mayer and Lambert did much to make clear the exact nature of the problems involved in the modern mathematical theory of magnetism, yet the origin of that theory is usually, and with justice, dated from Coulomb.[3] Not only did the results of his careful and judicious experiments afford the means of bringing a mathematical theory to the test, but the marvellous sagacity he displayed in analysing the phenomena enabled him actually to lay the foundations upon which such a theory could be constructed. After him, Biot[4] and Hansteen,[5] of whose services we have already spoken, are to be reckoned as pioneers. The theory as it now stands was virtually created by Poisson in four of the most admirable memoirs[6] to be found in the whole literature of mathematical physics. In the first two he investigates expressions for the force due to bodies magnetized in any manner; he then applies his formulæ to the case of bodies inductively magnetized but having no coercive force. Although he confines his investigations to the case of isotropic bodies, he is quite aware of the general nature of the consequences of æolotropy, and in fact distinctly predicts as possible the magnecrystallic phenomena afterwards discovered by Plücker and Faraday. The formulæ he gives are practically identical with those given above (p. 248). He works out in detail the solution for the case of a hollow or solid sphere exposed to any system of inducing forces having a potential,[7] and in particular compares the results, when the inducing field is uniform, with the experiments of Barlow. In the second memoir he works out the solution of his equations for an ellipsoid in a uniform field, examining specially the case of an ellipsoid of revolution and its extreme cases (see above, p. 245). At the end of this memoir he discusses the disturbing forces on a compass, arising from the earth's induction on any distribution of soft iron, and shows that the given components of the disturbing force are expressed by linear functions of the components of the earth's force, involving nine constants which depend on the quantity and distribution of the iron. The third memoir, on magnetism in motion, is an attempt to explain the phenomena of the deviation of the magnetic needle caused by rotating metal spheres or disks. Although the physical interest of this memoir was in a great measure destroyed by the discoveries of Faraday as to the true nature of this action, yet, as a piece of profound mathematical investigation, this work of Poisson's is still worthy of study; nor is it perfectly certain that his theory will not after all be required to explain certain residual phenomena. The fourth memoir develops the mathematical theory of the deviation of the compass caused by the iron of ships. After Poisson the most important investigators are Green and Gauss. Green's services have already been alluded to in the article ELECTRICITY; we need only mention here his approximate solution of the problem of the magnetic distribution on cylindrical bars, which gives a formula agreeing with that of Biot. The all-important work of Gauss has already been detailed.

Coulomb. Biot. Hansteen. Poisson. Green. Gauss.

In *Crelle's Journal* for 1848 J. Neumann worked out the solution of the induction problem for an ellipsoid of revolution under the action of any conservative system; and six years later, in the same journal, Kirchhoff worked out the case of a circular cylinder of infinite length. We are not aware that the solution of Poisson's equations in particular cases has been carried any farther, unless we include as new the case of a hollow ellipsoid treated by A. G. Greenhill in the *Journal de Physique* for 1881.

Neumann. Kirchhoff. Greenhill.

The most important contributions to the general theory of magnetism since Poisson are to be found in a series of memoirs[8] by Sir William Thomson, the first of which appeared in the *Philosophical Transactions* for 1851. He divests the theory of Poisson of all particular assumptions connected with the two-fluid theory, and bases it on a

small number of principles drawn from observation. He enters more fully than Poisson had done into the specification of magnetic distribution. He gives simple synthetic solutions of the induction problem for spheres and ellipsoids in a uniform field. He gives for the first time with full generality the theory of induction in æolotropic media, and shows that Poisson's theory thus fully developed leads to all the laws of paramagnetic and diamagnetic action discovered by Faraday, and also to the laws of magnecrystallic action discovered by Plücker and Faraday. The value of his theory was fully recognized by Plücker,[1] and apparently also by Faraday; indeed one of its ablest expositors was Beer[2] the friend and coadjutor of Plücker. The experimenters who followed these masters were less intelligent, and the theory of Thomson was for a number of years misunderstood or neglected, the result being much fruitless discussion in which the true issues were often confused. Of late the theory has obtained wide currency and the adhesion of every physicist worthy of the name. Quite recently Thomson's theory has been further developed in an interesting paper by Helmholtz,[3] chiefly with a view to its application to the phenomena of dielectric polarization.

Plücker. Beer. Helmholtz.

For the benefit of the mathematical reader we append a list of the more important papers on the mathematical theory of magnetism that have appeared recently, and are not quoted above:—

Plana, "Mémoire sur la théorie du magnétisme," *Ast. Nach.*, xxxix., 1854; F. Neumann, *Vorlesungen über die Theorie des Magnetismus*, delivered 1857, edited by C. Neumann, 1881; Riemann, *Schwere, Electricität, und Magnetismus*, lectures delivered in 1861, edited by Hattendorf, 1876; Lamont, "Beitrag zu einer mathematischen Theorie des Magnetismus," *Sitzber. d. Bayer. Akad.*, 1862; L Weber, *Zur Theorie der Magnetischen Induction*, Kiel, 1877, see *Wied. Beibl.*, 1878; Rowland, *Silliman's Jour.*, 1879 (calculation of couple on a body suspended in a heterogeneous magnetic field); Boltzmann, "Magnetisirung eines Eisenringes," *Wied. Beibl.*, 1879; Id., "Ueber die auf Diamagnete wirkende Kraft," *Wien. Ber.*, 1879; Riecke, *Wied. Ann.*, 1881 (approximative solutions of the problem of magnetic induction).

Induction in Strongly Magnetic Bodies.

Experiments of Barlow and Christie.

The earliest experiments bearing on the mathematical theory of magnetic induction are those of Barlow[4] and Christie, who determined the deflexion of a compass needle placed in various positions relatively to spheres of cast iron inductively magnetized by the earth's force. They found that the deflexion α of the compass could be represented by $\tan\alpha = A\sin\theta\cos\theta\sin\phi/r^3$, where θ is the angle between the line of dip and the line joining the centres of the sphere and compass, and ϕ the angle between the plane of these two lines and the plane of the magnetic meridian. It was also found that the deflexion produced by a hollow sphere was as great as that produced by a solid sphere so long as the thickness of the former was not less than the $\frac{1}{127}$th of its radius.

Magnetic screens.

All these results of Barlow and Christie are in agreement with the theory of Poisson.[5] Another consequence of great practical importance follows from the mathematical theory, viz., that inside a hollow iron sphere of any considerable thickness the magnetic force is very small in comparison with the external inducing force. Sir William Thomson takes advantage of this principle to render his marine galvanometers independent of external magnetic force by surrounding them with a tube of soft iron.

Along with the experiments of Barlow we may rank those of Plücker[6] and Dronke[7] as affording us the means of testing the general applicability of the mathematical theory to the magnetization of soft iron. In Plücker's experiments an ellipsoid of soft iron was fixed in a graduated brass ring with its longest and shortest axes (a and c) in the plane of the ring. When the ring was suspended with the longest axis a vertical in the nearly uniform field between the two flat vertical faces of the poles of an electromagnet, the mean axis b set itself parallel to the horizontal line of force; as the point of suspension was moved along the circumference of the ring a point was reached at which the plane of b and a ceased to set parallel to the lines of force, and the plane of a and c began to do so; ω, the number of degrees between this point and the end of the axis a, was observed. The times of vibration, T_a and T_c, of the ellipsoid, when suspended so that a and c were vertical, were then observed. By the theory we ought to have

Plücker and Dronke.

$$\tan^2\omega = T_c^2(b^2+c^2)/T_a^2(a^2+b^2).$$

The value of ω calculated by means of T_c and T_a from this formula was 30° 13′; the value observed was about 29°. The relation connecting T_a, T_b, T_c according to the theory is

$$(a^2+b^2)/T_c^2 + (b^2+c^2)/T_b^2 - (c^2+a^2)/T_c^2 = 0\ ;$$

and the observed values of T_a, T_b, T_c did, in fact, satisfy this equation very nearly. Dronke's experiments on ellipsoids of iron and nickel were of a similar character.

First observations of the deviation.

Deviation of the Compass.—One of the earliest and certainly the most important of the applications of the mathematical theory of magnetic induction was the discussion of the deviation of the compass caused by the magnetism of the iron in ships. This disturbance seems to have been first noticed by Wales the astronomer, who accompanied Cook on his voyages of discovery (1772 to 1779). The same thing was noticed during the voyage of D'Entrecasteaux in search of La Pérouse; and Beautemps-Beaupré, who accompanied him, calls attention to the errors thence arising in the surveying of coasts by means of the compass. Flinders,[8] using the numerous observations made by Wales and by himself, endeavoured without success to construct empirical formulæ for correcting the errors of the compass. He also attempted to correct the errors partially by means of a vertical bar of soft iron placed near the binnacle. Barlow[9] and Scoresby[10] also occupied themselves with the problem.

The unusually great deviations observed during the Arctic voyage of the "Isabella" and "Alexander" in 1818 attracted the attention of Poisson, and gave rise to his memoir on the subject already alluded to. Important as the matter then appeared, it became still more so after the introduction of iron ships. Investigations both theoretical and experimental were made in England by Johnson,[11] Airy,[12] Evans,[13] Smith,[13] &c. It is to Smith that the mathematical theory as it now stands is mainly due.

Causes of deviation.

The cause of the deviation of the compass is twofold; it arises partly from the permanent magnetism of the ship, partly from the temporary or induced magnetism. The permanent magnetism of the ship is acquired for the most part during the process of building. The earth's force acts on the iron, and the constant jarring in the process of construction enables it to induce a considerable permanent magnetization, which the ship carries with her to sea. The quantity and distribution of this magnetism will depend greatly on the build of the ship (whether of wood or of

Permanent and subpermanent magnetism.

iron), and on her position with respect to the magnetic meridian during building. A considerable portion of it is what Airy calls subpermanent; *i.e.*, it diminishes gradually as the ship is worked. This magnetic settling down will take place more rapidly in a steamer which is constantly agitated by the jarring of machinery than in a sailing ship, unless the latter be subjected to shocks from the impact of waves in rough weather. After a time the ship reaches a more or less stationary condition as to permanent magnetism. Along with the phenomenon of subpermanent magnetism has to be classed what is sometimes called the sluggishness of ships' magnetism; this arises from the fact that all the temporary magnetism of a ship which has sailed for some time on any one magnetic course in any one latitude does not at once disappear when the course or the latitude is changed, so that to the permanent magnetism of the ship has to be added a subpermanent magnetism depending on her course and position several days before. It is evident that the cause of disturbance at present under discussion is somewhat capricious, and can only be controlled by constant attention on the part of the mariner.

Sluggishness.

Temporary magnetism.

The temporary induced magnetism depends on the ship's position on the earth, and on her angular position relative to the magnetic meridian; but, so long as the iron in the ship or the position of the compass is not altered, the constants which determine it remain the same; the disturbance can be foreseen, and either allowed for or mechanically corrected with much greater certainty than in the case of the permanent magnetism.

Mathematical Formulæ for the Deviation.—Let the origin be at the centre of suspension of the compass card; and let the axes of x, y, and z be drawn in the direction from stern to head, in the perpendicular direction from port to starboard, and vertically downwards respectively, the ship for the present being supposed to be on even keel. Let P, Q, R be the components of the magnetic force parallel to these axes arising from the permanent magnetism of the ship; x, y, z the components of the earth's force; and x', y', z' the components of the whole force at the centre of the compass card. Then

Poisson's equations.

$$\left.\begin{aligned} x' &= x + ax + by + cz + \mathrm{P} \\ y' &= y + dx + ey + fz + \mathrm{Q} \\ z' &= z + gx + hy + kz + \mathrm{R} \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad . \quad (103)$$

are, according to Poisson's general theory, the fundamental equations of the subject. P, Q, R are constants depending on the permanent, and $a, b, c, d, e, f, g, h, k$ constants depending on the temporary induced magnetism.

Nine rods to represent the induction constants.

By a synthetic process of great interest and importance we may show that the nine constants $a, b, c, d, e, f, g, h, k$ are all independent. For example, if we place a rod of practically infinite length with its end before the binnacle, and stretching forward, or with its end abaft the binnacle and stretching aft, it will give rise to the term ax in x'. If a be negative the rod must be finite and it must run under the binnacle, ending a little fore and aft; again, to represent dx, we must have a pair of infinite rods with their ends to starboard and port of the binnacle, and running fore and aft or aft and fore respectively, according as d is positive or negative; finally, to represent gx, a pair of infinite rods with ends above and below the binnacle, running fore and aft or aft and fore respectively. The reader will have no difficulty in completing the scheme, the rule being that the ends lie in the direction of x', y', or z', and the lengths in the direction of x, y, or z.

From equations (103) the deviation of the compass is expressed in terms of the magnetic or of the compass course as follows. Let H be the horizontal force of the earth; H′ the horizontal force of the earth and ship; θ the dip; ζ the "magnetic course," *i.e.*, the azimuth of the ship's head eastward from magnetic north; ζ' the "compass course," *i.e.*, the azimuth of the ship's head eastward from the direction of the disturbed needle; $\delta=\zeta-\zeta'$ the easterly deviation of the compass. Then

Deviation in term of magnetic and compass courses.

$$\left.\begin{aligned} \frac{\mathrm{H}'}{\lambda\mathrm{H}}\sin\delta &= \mathfrak{A} + \mathfrak{B}\sin\zeta + \mathfrak{C}\cos\zeta + \mathfrak{D}\sin 2\zeta + \mathfrak{E}\cos 2\zeta \\ \frac{\mathrm{H}'}{\lambda\mathrm{H}}\cos\delta &= 1 + \mathfrak{B}\cos\zeta - \mathfrak{C}\sin\zeta + \mathfrak{D}\cos 2\zeta - \mathfrak{E}\sin 2\zeta \end{aligned}\right\} \quad (104),$$

where

$$\lambda = 1 + \frac{a+e}{2}\,, \quad \mathfrak{A} = \frac{d-b}{2\lambda}\,, \quad \mathfrak{D} = \frac{a-e}{2\lambda}\,, \quad \mathfrak{E} = \frac{d+b}{2\lambda}\,,$$

$$\mathfrak{B} = \frac{1}{\lambda}\left(c\tan\theta + \frac{\mathrm{P}}{\mathrm{H}}\right), \quad \mathfrak{C} = \frac{1}{\lambda}\left(f\tan\theta + \frac{\mathrm{Q}}{\mathrm{H}}\right).$$

From (104) we get

$$\tan\delta = \frac{\mathfrak{A} + \mathfrak{B}\sin\zeta + \mathfrak{C}\cos\zeta + \mathfrak{D}\sin 2\zeta + \mathfrak{E}\cos 2\zeta}{1 + \mathfrak{B}\cos\zeta - \mathfrak{C}\sin\zeta + \mathfrak{D}\cos 2\zeta - \mathfrak{E}\sin 2\zeta} \quad . \quad (105),$$

which gives the deviation on any given magnetic course.

From (105) we get by substitution

$$\sin\delta = \mathfrak{A}\cos\delta + \mathfrak{B}\sin\zeta' + \mathfrak{C}\cos\zeta' + \mathfrak{D}\sin(2\zeta'+\delta) + \mathfrak{E}\cos(2\zeta'+\delta) \, (106),$$

an equation connecting the deviation with the compass course.

When the deviation is not greater than 20° or so, then (106) may be replaced with sufficient accuracy by

$$\delta = \mathrm{A} + \mathrm{B}\sin\zeta' + \mathrm{C}\cos\zeta' + \mathrm{D}\sin 2\zeta' + \mathrm{E}\cos 2\zeta' \quad . \quad . \quad (107),$$

where $\mathfrak{A}$, $\mathfrak{B}$, $\mathfrak{C}$, $\mathfrak{D}$, $\mathfrak{E}$, are nearly the natural sines of A, B, C, D, E.

Effect of heeling.

In the above it is supposed that the ship is on even keel. Strictly we ought to take into account both the pitch and the heel of the ship; in practice the pitch is always so small as to be of no consequence, but the heel, especially in a ship under sail, may be very considerable. When the ship heels through an angle i, the deviation is obtained from the above formulæ by writing a_i, b_i, &c., in place of a, b, &c., where

$$\begin{aligned} &a_i = a, \quad b_i = b\cos i - c\sin i, \quad c_i = c\cos i + b\sin i, \\ &d_i = d\cos i - g\sin i, \quad e_i = e - (f+h)\cos i\sin i - (e-k)\sin^2 i, \\ &f_i = f + (e-k)\cos i\sin i - (f+h)\sin^2 i, \quad g_i = g\cos i + d\sin i, \\ &h_i = h + (e-k)\cos i\sin i - (f+h)\sin^2 i, \\ &k_i = k + (f+h)\cos i\sin i + (e-k)\sin^2 i, \\ &\mathrm{P}_i = \mathrm{P}, \quad \mathrm{Q}_i = \mathrm{Q}\cos i - \mathrm{R}\sin i, \quad \mathrm{R}_i = \mathrm{R}\cos i + \mathrm{Q}\sin i. \end{aligned}$$

If the soft iron be symmetrical with respect to the fore and aft central line, and if i be so small that its square may be neglected, then

$$\lambda_i = \lambda, \; \mathfrak{D}_i = \mathfrak{D}, \; \mathfrak{A}_i = \frac{c-g}{2\lambda}i, \; \mathfrak{E}_i = -\frac{c+g}{2\lambda}i, \; \mathfrak{B}_i = \mathfrak{B},$$

$$\mathfrak{C}_i = \mathfrak{C} + \frac{1}{\lambda}\left(e - k - \frac{\mathrm{R}}{\mathrm{Z}}\right)\tan\theta\, i = \mathfrak{C} + \mathrm{J}i;$$

and if δ_i represent the deviation for the given compass course ζ' when the ship heels i to starboard, δ the deviation on the same course on even keel, then

$$\delta_i = \delta + \frac{c-g}{2\lambda}i + \mathrm{J}i\cos\zeta' - \frac{c+g}{2\lambda}i\cos 2\zeta' \quad . \quad . \quad . \quad (108).$$

Constant deviation.

The part of the deviation which depends mainly on $\mathfrak{A}$ is called the "constant deviation"; it can only arise from horizontal induction on soft iron unsymmetrically placed.

Semicircular deviation.

The part depending mainly on $\mathfrak{B}$ and $\mathfrak{C}$, viz., $\mathrm{B}\cos\zeta' + \mathrm{C}\sin\zeta'$, is called the "semicircular deviation" because it vanishes and changes sign on two diametrically opposite compass courses, or neutral points. The principal coefficient of the semicircular deviation is $\mathfrak{B} = (c\tan\theta + \mathrm{P}/\mathrm{H})/\lambda$; $c\tan\theta/\lambda$ arises from vertical induction in soft iron before or abaft the compass; $\mathrm{P}/\lambda\mathrm{H}$ arises from the permanent magnetism of the ship. The second coefficient $\mathfrak{C} = (f\tan\theta + \mathrm{Q}/\mathrm{H})/\lambda$ consists of $f\tan\theta/\lambda$, arising from soft iron unsymmetrically placed, and therefore in general very small, and $\mathrm{Q}/\lambda\mathrm{H}$ arising from permanent magnetism. $\mathfrak{B}$ can be reduced to zero by a magnet placed fore and aft with its centre in a transverse vertical plane passing through the compass, $\mathfrak{C}$ by means of a transverse magnet in a fore and aft plane through the compass.

In wooden ships the courses for which the semicircular deviation vanishes are nearly north and south; but in iron ships they approximate to those points of the compass towards which the stem and stern lay in building.

Quadrantal deviation.

The terms $\mathrm{D}\sin 2\zeta' + \mathrm{E}\cos 2\zeta'$, depending mainly on the constants $\mathfrak{D}$ and $\mathfrak{E}$, are called the "quadrantal deviation." This part is alternately easterly and westerly in the four quadrants, vanishing on four compass courses. $\mathfrak{D} = (a-e)/2\lambda$ is the principal coefficient of the quadrantal deviation; it depends on horizontal induction in symmetrically placed fore and aft or transverse soft iron. It is in general positive, and in that case can be reduced to zero by two transverse rods with their ends symmetrically placed to starboard and port of the compass. In practice two hollow spheres an inch or so thick are used instead of the rods. The other coefficient $\mathfrak{E} = (d+b)/2\lambda$ is in general small, as it depends on horizontal induction in soft iron unsymmetrically placed. It is only when the ship heels that this coefficient is in general of any importance.

Whereas the semicircular deviation depends both on the geographical position of the ship and on the state of its subpermanent magnetism, the quadrantal deviation is independent of both, and can be corrected mechanically once for all, or allowed for by means of tables constructed from observations made in any one place. The amount of the semicircular deviation in England does not exceed 10° for wooden ships of war, but in iron-built ships it frequently exceeds 30° even at the standard compass. The quadrantal deviation in wooden ships does not often exceed 1° or 2°; in ordinary iron ships it ranges from 3° to 7°, but in some armour-plated iron ships of war it has reached as much as $8\frac{1}{2}$° at the standard compass, and 15° for compasses less favourably placed.

The chief part of the heeling deviation is the term $Ji\cos\zeta'$, depending on the coefficient $J=(e-k-R/Z)\tan\theta/\lambda$. This coefficient may be reduced to zero by increasing or diminishing the earth's vertical force by means of a vertical magnet under the compass.

Determination of deviations by "swinging."

The usual way of ascertaining the deviations of a ship's compass is to "swing" the ship gently round so that her head comes into various positions, and to observe with the compass the magnetic bearing of some well-defined distant point (compass mark) on shore. The true magnetic bearing of this point is then ascertained, which may be done by taking the compass ashore, carefully placing it in a line joining the compass mark with the point on board at which the compass was formerly placed, and then taking the magnetic bearing of the mark once more. Care must of course be taken that there is no local magnetic disturbance at the shore station. The differences between the bearings on board and the bearing on shore give of course the deviations for the various positions of the ship's head.

When the deviations have thus been ascertained they may be either corrected by means of tables, by graphical methods, such as the steering diagram of Napier or the dygograms of Smith, or mechanically as we have partially explained. For full details on the subject the reader should consult the *Admiralty Manual on the Deviation of the Compass.*

Thomson's compass.

Of late years Sir W. Thomson has devoted his great scientific knowledge and well-known practical sagacity and inventive skill to the improvement of the compass. By reducing the size of the magnets and increasing their number he has succeeded in reducing Airy's apparatus for the mechanical correction of the quadrantal deviation within convenient bulk, and by lightening the card and suspension of the magnets in a very ingenious manner (at the same time throwing all the remaining weight as much as possible to the circumference) he has reduced the friction on the pivot to a minimum while retaining a sufficiently long period of vibration to secure perfect steadiness. He has also contrived apparatus for facilitating the determinations of the deviation on different courses and of the heeling error.[1]

Experimental difficulties.

The *experimental investigation of induced magnetism* reduces itself mainly to the investigation of the dependence of the magnetic susceptibility κ[2] (or the magnetic permeability ϖ) upon the magnetizing force $\mathfrak{H}$. Confining ourselves to the strongly magnetic metals, iron, nickel, and cobalt, it will be seen presently that κ depends, not only upon $\mathfrak{H}$, but also upon the magnetic condition of the body at the actual moment when $\mathfrak{H}$ is in action, and upon its previous magnetic history. κ also depends greatly on the temperature, on the state of the body as to purity (notably in the case of iron and steel on the percentage of carbon present), and on the temper. Thus, if we make one experiment on a body by magnetizing it in any way, we permanently alter its magnetic properties, and can restore it to the magnetically virgin condition only by heating it to a high temperature; but in this process we are very apt to permanently alter its molecular condition, so that, although magnetically indifferent, it is physically changed. Owing to the fact, already insisted upon, that we cannot infer the magnetic distribution inside a heterogeneously magnetized body from its external magnetic action, and to the fact, presently to be established, that κ varies with $\mathfrak{H}$, it is of the last importance to choose the experimental circumstances so that both the magnetic field and the induced magnetization shall be uniform, or very approximately so. A further necessity for the fulfilment of these conditions arises from the fact that we must in all cases be able to render an account of the effect of the *form* of the magnetized body, because the true argument of κ is not the strength of the original field but the whole force $\mathfrak{H}$ due to the original field and the induced magnetism together.

Importance of uniform magnetization.

Uniform field.

The simplest method for securing a uniform field whose strength can be controlled is to place the body inside a hollow cylindrical coil (usually called the magnetizing spiral), whose length so far exceeds that of the body that the disturbance arising from the ends of the coil may be neglected in the neighbourhood of the body. The results in all cases where the length of the body or core is nearly equal to or exceeds that of the coil are impure, and can only be used with the greatest caution in drawing general conclusions as to the value of κ. The core should always be either exactly or approximately one of the calculable forms, but preferably such that the dimension parallel to the axis of the spiral very much exceeds the others, because in this case the effect of the form is of secondary importance compared with the effect of the susceptibility (see above, p. 245). Thus a very thin cylindrical core is convenient, because the force inside it differs very little from that of the undisturbed field, and any small difference can be easily calculated by supposing the cylinder replaced by a very elongated ellipsoid. On the other hand, a thick cylindrical bar is a bad form of core for the determination of κ, both because the magnetizing force inside it is less than the intensity of the undisturbed field by a large quantity, which it is impossible to calculate, and because the magnetization at the end is not uniform, and the disturbance thereby arising is so great that it may mask the general character of the function κ altogether.

Best form of core.

Disturbances at make and break.

A further question arises as to how far the time during which a magnetizing force acts affects the resulting magnetization, whether temporary or permanent. It is also important to consider the disturbances arising during the make and break of the current in the magnetizing spiral. As the resistance in the circuit is usually small, and the self-induction and capacity sensible, oscillatory currents may arise; to these will correspond oscillatory magnetizing forces, which may even vary in sign. When we consider that the permanent magnetization produced by any force may be very much weakened or even altogether destroyed by a smaller force in the opposite direction, it is evident that we have no right to conclude that these disturbances, especially at break, will be without effect upon the permanent magnetization. In order to elude these difficulties, some experimenters have followed the practice of first establishing the current, then gently[3] introducing the core into its place, and finally removing it before breaking the circuit. In this way the disturbances just alluded to are avoided; but another difficulty is raised, for it is clear that in this operation the core passes through a heterogeneous field before it reaches the final position where the magnetizing force is uniform; different parts of it have therefore been subjected successively to different influences, and we are not at liberty *a priori* to conclude that this fact will not influence the results. Perhaps the best plan would be to place the core in its position, and allow the current to rise very slowly to the maximum value required, and then to fall slowly to zero. This, however, is not the place to dogmatize concerning the best method of experimenting; all that is necessary is to furnish the reader with points of

---

[1] For a description of his compass see art. COMPASS, vol. vi. p. 228. Detailed descriptions of the compass with instructions for its adjustment are issued in the form of a small pamphlet (Maclehose, Glasgow, 1879).

[2] κ is sometimes called by Continental writers the magnetization function. They have also a habit of speaking of the ratio of whole magnetic moment of a body of any form divided by its volume to the strength of the field in which it is placed as the magnetization function for that particular form. This is a most inconvenient practice, and has led to considerable confusion.

[3] Carefully avoiding all shocks or tremors which exercise a very important influence on the induced magnetism, see below, p. 268.

view from which to criticize the experimental results now to be cited.

Lenz and Jacobi. κ constant. In the researches of Lenz and Jacobi[1] the magnetic moment of the core was measured by the induction current in a secondary coil placed upon the magnetizing spiral. A considerable portion of their work was directed to proving principles which we here take for granted, *e.g.*, that the magnetizing force is independent of the thickness of the wire of the magnetizing spiral, of the radius of its windings, and so on. They concluded from these experiments that the magnetization is proportional to the magnetizing force; *i.e.*, κ is constant for a given quality, &c., of metal.

Joule. The experiments of Joule,[2] which were made independently about the same time, led in general to a similar result. His method consisted in measuring by means of a balance the attraction P between two electromagnets actuated by the same current C. If the magnetization of the core were strictly proportional to the magnetizing force, *i.e.*, to the current, then P would be proportional to C^2, and P/C^2 would be constant. In most cases this was so; but in two cases, where the cores of the electromagnets were very thin and the windings more than usually numerous, the ratio P/C^2 was found to decrease as the current increased. **κ decreases for large forces.** This shows that the magnetization tends to a maximum value as the current increases, in other words, that, for very large values of $\mathfrak{H}$, κ decreases.

Müller. Müller,[3] using the method of deflexions, arrived at a similar conclusion. His cores were 56 cm. long and from 9 mm. to 44 mm. thick, his magnetizing spirals from 48·2 cm. to 53·2 cm. long; his results are therefore impure, and the empirical formula by means of which he represents them of comparatively little importance; but the approach to a maximum of magnetization (saturation) is quite clearly demonstrated. **Maximum of magnetization.** He found, in accordance with theory, that if we increase the *external* magnetizing force ($\mathfrak{H}_0$) saturation is more quickly reached in thin than in thick bars. Somewhat similar experiments were made by Von Waltenhofen,[4] who deduces[5] from some of his own experiments with very thin cores, and from the experiments of Müller, Weber, and Dub, 1678 to 2125 mm. mg. sec. units of magnetic moment per mg. of iron as the maximum of magnetization. This would give from 1317 to 1668 C.G.S. units for the maximum magnetic intensity in iron. These numbers, derived from more or less impure results, are merely rough approximations, but they agree very well with those derived at a later date by methods less open to theoretical objections.

Koosen's experiment. The approach to saturation may be very neatly demonstrated as follows.[6] The same current is sent through a galvanometer and through the coil of an electromagnet with a thin core. The electromagnet is so placed that its action on the needle of the galvanometer just compensates the action of the galvanometer coil for a particular strength of current; the needle then points to zero. If now the current be increased, since the increase of magnetization does not keep up with the increase of the current, the action of the coil prevails, and the needle deviates accordingly.

Wiedemann's researches. The most extensive and important of the earlier researches into the general nature of magnetic induction are those of Wiedemann.[7] An epitome[8] of his results, with references to contemporary or preceding researches in the same direction, will put the reader in possession of almost all the more important general facts known until the quantitative experiments of Stoletow, Rowland, and their followers gave a complete account of the general characteristics of the function κ.

Experimental method. In these experiments the method of deflexion was used. The magnetizing spiral was placed magnetic east and west, and in the continuation of its axis was hung a magnetic steel mirror in a thick copper box to damp its oscillations. The deflexions of this mirror, read as usual with a scale and telescope when the core was not in, gave a measure of the current; and the increase of the deflexion on introducing the core gave a measure of the magnetic moment of the core. The cores were cylinders 22 cm. long., 1·35 cm. thick, and the length of the spiral was only 24 cm.,—so that perfectly pure results could not be obtained. To compensate to some extent for the shortness of the spiral, the bars were gently drawn to and fro several times before being placed in the final position for which the reading was taken. In order to measure the permanent magnetism the core was removed, the current broken, the core returned to its former position, and a reading again taken. The conclusions arrived at were as follows.

Maximum of magnetization and turning point. I. When a steel or iron bar is magnetized for the first time by a current C, the temporary moment K produced during the action of the current at first increases faster than the current, then more slowly, and finally tends to a maximum, as shown by Joule and Müller. The period of quicker increase is more marked in long than in short bars; it shows itself even on remagnetizing bars that have been several times magnetized and demagnetized. As C increases, the maximum of K is reached sooner in thin and long bars than in short and thick bars. Between the period of increase of K/C and its period of decrease there is no period of any considerable length for which it is constant. This last fact may be shown by means of the experiment of Koosen described above; viz., if the compensation be made for very small currents, when the current is increased, at first the electromagnet prevails, and the needle goes to one side of zero, then the current in the coil prevails, and the needle returns towards zero, and finally deviates on the other side.

The point at which the ratio K/C has its maximum for any particular electromagnet is called by Wiedemann the "turning point" (Wendepunkt). The turning point relates to the body as a whole, and the value of the external magnetizing force $\mathfrak{H}_0$ for which it occurs depends both on the form of the body and on the nature of the metal. It has therefore no very definite physical meaning. It must be carefully distinguished from the "saturation point." Any element of a body is said to be magnetized to saturation when no increase of the magnetic force can increase its magnetization any farther. It may happen, however, that some parts of a body are magnetized to saturation while others are not. With regard to the turning point, Dub[9] has shown that with similar and similarly wound cores the turning point occurs for the same value of the current. This is of course in agreement with an obvious corollary of the general theory of magnetic induction.[10]

II. In a freshly[11] magnetized bar the permanent moment which remains after the action of the current has ceased at first increases quicker than the producing current; but for stronger currents a turning point is reached; and then the moment increases more slowly than the current, and approaches a maximum.

III. In attempting to destroy the permanent magnetism of a bar by means of a demagnetizing current, it may happen that a current, which, during its action, already

[11] That is, after being heated white hot to destroy all pre-existing magnetism.

Demagnetization easier than magnetization.

produces a temporary magnetic moment of opposite sign, still leaves on ceasing to act a permanent magnetic moment of the same sign as before, although less in amount.[1] On increasing the demagnetizing current still farther the permanent moment is at last destroyed. In this process the permanent magnetism decreases faster than the demagnetizing current increases,—so that *the current required to destroy a given permanent magnetism is less than the current that originally produced it.*[2]

Unilateral property of demagnetized bar.

IV. When a fresh bar has been magnetized with any permanent moment, and then demagnetized by a current $-C'$, opposite to the magnetizing current C, a second application of $-C'$, or of any *weaker* current in the same direction, will not produce a reverse *permanent* moment, although a current C' in the same direction as C *will* magnetize the bar permanently in the original direction more or less strongly. It follows therefore that demagnetizing by an opposite magnetic force, although it may destroy the permanent magnetism of a body, does not render it magnetically indifferent, as heating to a white heat would do. The body remains in fact more easily magnetizable in one direction than in another.[3]

V. In certain cases a fresh bar was magnetized by a current C, and then partly demagnetized; it was then found that a current C was required to bring it back to its original permanent moment.

VI. In another case a fresh bar was magnetized by a current C to permanent moment K, then reduced by a demagnetizing current C' to permanent moment K', then by a direct current C'' less than C brought to permanent moment K''. It was then found that a current C' was necessary to bring it back to permanent moment K'; and this held whether K' was positive, zero, or negative.

Repeated magnetization and demagnetization.

VII. When a bar is repeatedly magnetized and demagnetized by currents of the same intensity, the permanent magnetic moments corresponding to a given force become, to begin with, a little greater than at first; to begin with, they increase faster than the magnetizing force, though not so fast as at the first. The turning point, however, occurs for a weaker current than before. The magnetization obtained with the strongest current gradually decreases a little. The moments left by the demagnetizing current decrease less rapidly than before, so that a current at first capable of demagnetizing the bar altogether leaves after repeated magnetization and demagnetization a slowly increasing residual moment. After a large number of repetitions of the operation of magnetization by a current C and demagnetization by a current $-C'$, the bar finally reaches a constant state, so that each magnetization and demagnetization leaves a corresponding invariable permanent moment. When we pass beyond the limits C and $-C'$, these phenomena are repeated in the same order as before.[4]

Temporary and permanent magnetism in hard and soft steel and in soft iron.

VIII. All the above phenomena are most clearly seen in hard steel, less clearly in soft steel and iron. For small magnetizing forces the temporary moment in hard steel is less than in soft steel, and greatest of all in soft iron. The general rule is, the harder the material the less the temporary and the greater the permanent moment for a given magnetizing force.

IX. If, however, we consider the ratios of the temporary moments in soft steel and iron to the temporary moment in hard steel, all for the same force, then these ratios decrease gradually as the force increases; so that the temporary moment in soft iron reaches its maximum sooner than in soft steel, and still sooner than in hard steel.[5]

Earlier values of κ.

The earliest experiments from which definite values of κ have been calculated are those of Weber.[6] A cylindrical bar, 10·02 cm. long and ·36 cm. thick, was placed inside a spiral so long that the magnetizing force throughout the length of the bar could be assumed to be uniform. The moment of the bar was measured by the method of deflexion, the action of the spiral on the deflected magnet being compensated by means of a part of its own circuit suitably arranged. The intensity of the current in the spiral was found in absolute measure by means of a tangent galvanometer. Assuming that the bar could be replaced by a very elongated ellipsoid, Kirchhoff calculated by means of the theory explained above (p. 249) the values of κ for values of $\mathfrak{H}$ ranging from 29·6 to 248·4 (C.G.S. units), and found that it decreased steadily from 25·0 to 5·6. In the experiments of Von Quintus Icilius[7] bars were used which had been reduced by filing as nearly as possible to the form of ellipsoids of revolution. The magnetic moments were measured partly by the deflexion method, partly by the method of electromagnetic induction. In this last method a secondary spiral is placed upon the magnetizing spiral, and the induced current in it, caused by reversing the magnetizing current, is observed first when the ellipsoid is in the magnetizing spiral, secondly when it is not. When these currents are known in absolute measure, the moment of the ellipsoid can be calculated. The experimenter did not himself reduce his results so as to obtain κ, but contented himself with remarking that the ratio of the whole moment of the ellipsoid K to the strength of the undisturbed field $\mathfrak{H}_0$ reached a maximum as $\mathfrak{H}_0$ was increased, this maximum occurring for smaller values of $\mathfrak{H}_0$ the more elongated the ellipsoid. The true meaning of his results was brought out by Stoletow,[8] who reduced them, and established the interesting fact that, as the magnetizing force[9] $\mathfrak{H}$ increases from very small values, κ at first increases rapidly, then reaches a maximum, and afterwards decreases more slowly. For one ellipsoid κ increased from 30·5, for $\mathfrak{H} = ·24$, to a maximum 120·4, for $\mathfrak{H} = 4·56$, and then decreased to the value 39·4, for $\mathfrak{H} = 30·07$. In another, the initial value was 20·1 for $\mathfrak{H} = ·518$, the maximum value 107·5 for $\mathfrak{H} = 4·92$, and the final value 2·86 for $\mathfrak{H} = 454·1$.

Quintus Icilius.

Stoletow's deductions.

Thalén.

Thalén, adopting a method indicated by Weber,[10] determined the value of κ for small magnetizing forces. Long bars were placed in the axis of a cylindrical coil considerably exceeding them in length. This coil was caused to rotate 180° about a horizontal axis, so that the magnetization induced by the earth's vertical force was reversed relatively to the coil. The current thus caused was meaured by means of the swing of a galvanometer in circuit with the coil; from this (see above, p. 240) the moment of the induced magnetism was calculated; and thence, assuming the bar to be replaceable by an ellipsoid, κ was calculated. From three bars of the same metal each 400·4 mm. long, having diameters of 36·4, 29·94, and 23·87 mm. respectively, the values of κ deduced were 32·32, 31·80, and 32·64. For other specimens of iron he found values of κ ranging from 27·24 to 44·23.

[1] See Poggendorff, *Pogg. Ann.*, 1852.

[2] This result had also been arrived at by Abria, *Ann. d. Chim. et d. Phys.*, 1844; and by Joule, *Phil. Mag.*, 1847, *Phil. Trans.*, 1855.

[3] Similar conclusions were arrived at by Ritchie, *Phil. Mag.*, 1833; Jacobi, *Pogg. Ann.*, 1834; Marianini, *Ann. Chim. et d. Phys.*, 1846.

[4] On the same subject see Joule, *Phil. Trans.*, 1856; also Von Waltenhofen, *Pogg. Ann.*, 1864.

[5] Similar results by Plücker, *Pogg. Ann.*, 1852 and 1855.

[6] *Electrodynamische Maasbestimmungen*, Bd. iii. § 26.

[7] *Pogg. Ann.*, cxxi., 1864. Similar results were obtained by Oberbeck, *Pogg. Ann.*, cxxxv., 1868.

[8] *Pogg. Ann.*, cxlvi. p. 443, 1872.

[9] $\mathfrak{H}$ here means the whole magnetizing force, arising partly from the inducing field and partly from the induced magnetism. Experimenters have needlessly complicated the already complex problem of ferro-magnetic induction by neglecting the all-important distinction between $\mathfrak{H}$ and $\mathfrak{H}_0$.

[10] *Abh. d. Gött. Gesellschaft*, Bd. 6.

Riecke.

A set of observations on ellipsoids of revolution were made by Riecke,[1] by the method just described. The ellipsoids, seven in number, were all cut from the same piece of soft iron, but varied in volume and in eccentricity. The resulting values of κ were found to be independent of the volume of the ellipsoids and of the part of the iron from which they were cut; but, on the other hand, with one slight exception, they increased with the eccentricity of the ellipsoids. Kohlrausch, in communicating these results to *Poggendorff's Annalen*, remarked that they stand in contradiction with the theory of Poisson and Neumann; in so saying he probably considered the constant vertical force of the earth ($\mathfrak{H}_0$) to be the argument of the function κ; but this is not so, as Stoletow points out in the paper already quoted. The actual magnetizing forces are greater in the more elongated ellipsoids; and Riecke's results simply prove that for values of $\mathfrak{H}$ varying from ·031 to ·072 κ increases from 13·5 to 25·4.

Stoletow's experiments.

In order to establish the initial increase of the magnetization function κ beyond all doubt, Stoletow (*l. c.*) made a new set of experiments on a carefully annealed iron ring[2] of rectangular section (exterior diameter 20 cm., interior diameter 18 cm., height 1·47 cm.). The ring was carefully wound throughout with a primary coil of n (=800) windings; over this, in one or more shorter or longer stretches, was wound a secondary coil of n'(=50 to 750) windings. The induction current in the secondary, due to the reversal of a known current i in the primary, was sent through a galvanometer, and thus measured. If E be the electromotive force of this current, then (see above, p. 246) $E = 4nn'i(4\pi\kappa M + P)$, where M and P can be calculated from the dimensions of the ring and its primary coil. All then that is necessary is to know E/i in absolute measure. We refer the reader to the original paper for the details of the measurements. The results are very interesting, and fully confirm the conclusions drawn from the results of Von Quintus Icilius and Riecke. The smallest value of $\mathfrak{H}$ was ·43, and the corresponding value of κ 21·5; the maximum value of κ was 174, for $\mathfrak{H}=3·2$; the last value observed was $\kappa = 42·1$, for $\mathfrak{H} = 30·7$. The temperature varied from 15° C. to 20° C., but it appeared from the experiments that κ did not alter much for moderate changes of temperature. In figure (34) is given a transcription of the curve that represents the results of

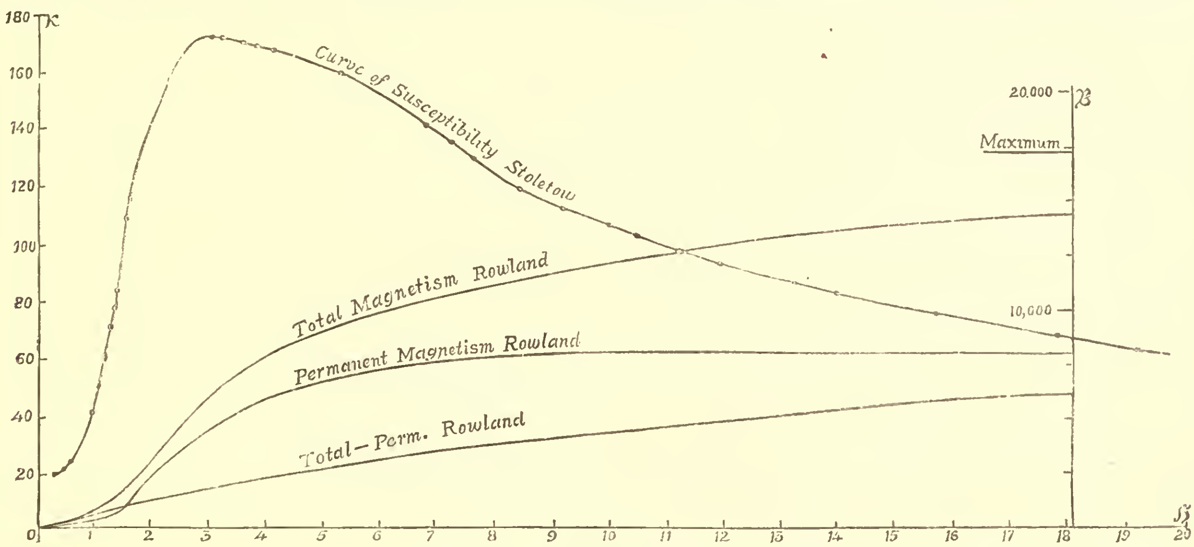

Fig. 34.

Stoletow's experiments; the abscissæ represent the values of $\mathfrak{H}$ in C.G.S. units, and the ordinates the corresponding values of κ.

Rowland's experiments.

About the same time as Stoletow, and independently, Rowland[3] made a much more extensive series of experiments, the results of which form one of the most important contributions yet made to our knowledge of magnetic induction. The experiments were made partly on very long bars; but the published results were mostly obtained from rings, it having been found that the effect of the ends of the bar was sensible even when the length was as much as 144 times the diameter. About a dozen rings of iron, nickel, and cobalt were used; the section was circular in all cases; and a primary and a secondary coil were used as in Stoletow's experiments. The primary current was measured by means of a tangent galvanometer in which 1, 3, 9, 27, or 48 coils could be brought into operation according to the sensibility required. The induction current in the secondary was measured by the swing of a Thomson's galvanometer fitted with a heavier needle than usual. The indications of this last were reduced to absolute measure by taking the swing caused by turning over a horizontal coil of known area, inserted in its circuit, so as to produce the full induction current due to the earth's vertical force. In order to obtain the total induced magnetization the primary current was reversed. To obtain the permanent magnetism it was simply broken; this gives the part of the induced magnetism that disappears with the inducing force (temporary magnetism Rowland calls it); subtracting this from the total magnetization, we get the permanent magnetization. Care was taken in these experiments always to work with magnetizing forces of ascending magnitude, as it was found that the effect of any force is considerably modified if a greater force has previously acted on the body,—in other words, that the magnetic permeability of iron or steel is much affected by pre-existing permanent magnetism. This fact raises an objection to the ring method; for permanent magnetization in a ring is not easily discoverable, and would give it a one-sidedness, so that a magnetizing force would produce much more alteration when exerted in one direction than it would when exerted in the other.[4] Rowland publishes about thirteen different tables, relating to rings of iron and steel in different states, and also to nickel and cobalt, under different conditions as to temper,

[1] *Pogg. Ann.*, cxli., 1870.

magnetization, and so on; the results for cobalt are, however, held to be less satisfactory than those for iron and nickel, for a variety of reasons which he assigns.

In treating his results graphically, two methods are followed. In the first the magnetic induction $\mathfrak{B}$ is plotted against the magnetizing force $\mathfrak{H}$ as abscissa. Figure 34 shows the curve obtained in this way from one of his tables. In the second method (1) the permeability ϖ is plotted against the magnetic induction $\mathfrak{B}$, or (2) the susceptibility κ is plotted against the intensity of magnetization $\mathfrak{I}$. Either variety of the second method leads to a curve having the general form shown in figures 35 and 36.

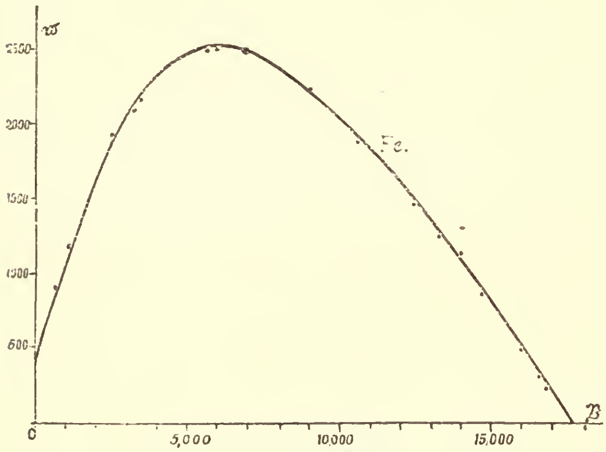

Fig. 35.—Curve $\varpi\mathfrak{B}$ for Iron.

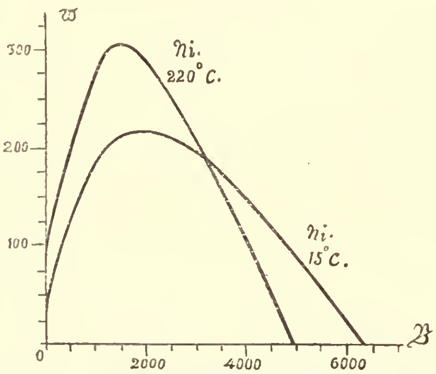

Fig. 36.—Curves $\varpi\mathfrak{B}$ for Nickel at different temperatures.

The curves obtained, whether for ϖ and $\mathfrak{B}$, or for κ and $\mathfrak{I}$, fall very rapidly, and ultimately to all appearance almost straight, towards the axis of $\mathfrak{B}$ or $\mathfrak{I}$. This suggests that $\mathfrak{B}$ or $\mathfrak{I}$ or both reach a maximum when $\mathfrak{H}$ is increased indefinitely. Supposing such an increase of $\mathfrak{H}$ possible, the question arises as to which it is that actually reaches a maximum. Most experimenters seem to assume that $\mathfrak{I}$ does so, but it must be remarked that this is simply an assumption.[1] Several delicate points of great physical interest might be discussed here, but it will be sufficient to refer the reader to the introduction to Rowland's second paper.

General conclusions.

The general conclusions to be drawn from these experiments are as follows:—

1. The magnetic properties of iron, nickel, and cobalt at ordinary temperatures differ in degree but not in quality.

2. As the magnetizing force $\mathfrak{H}$ increases from 0 upwards, the permeability of iron, nickel, and cobalt increases until it reaches a maximum, and after that diminishes down to a very small value. The maximum value[2] is reached when the metal has attained a magnetization of from ·24 to ·38 of the maximum. The following table will give some idea of the order of the magnitudes involved; ϖ_0 denotes the permeability for $\mathfrak{H}=0$, ϖ' the maximum permeability, and $\mathfrak{H}'$ the force for which it occurs. In some cases the actual maximum is given, in other cases simply the greatest recorded in the tables of experimental results, and the values of $\mathfrak{H}$ are stated roughly; strict accuracy is of no consequence, owing to the great variability of all the magnitudes.

The smallest permeabilities (for large forces) observed were—for iron 258, for $\mathfrak{H}=64$; for steel 246, for $\mathfrak{H}=48$; for nickel 41, for $\mathfrak{H}=131$; for cobalt 55, for $\mathfrak{H}=147$.

3. The curve showing the relation between κ and $\mathfrak{I}$, or between ϖ and $\mathfrak{B}$, is of such a form that a diameter can be drawn bisecting chords parallel to the axis of $\mathfrak{I}$ or $\mathfrak{B}$, and its equation is approximately

$$y = \mathrm{B}\sin\left(\frac{x+by+d}{\mathrm{D}}\right),$$

where $y=\kappa$ or ϖ, $x=\mathfrak{I}$ or $\mathfrak{B}$, and b, d, B, D are constants.

4. If a metal is permanently magnetized, its permeability is less for low magnetizing forces, but is unaltered for high magnetizing forces. This applies to the permanent state finally attained after several reversals of the magnetizing force; but if we strongly magnetize a bar in one direction, and apply a weak magnetizing force in the opposite direction, the change of magnetization will be very great.

Maximum intensity of field and of magnetization.

5. Iron, nickel, and cobalt all probably have a maximum of magnetization, although its existence can never be entirely established by experiment, and must always be a matter of inference. If such a maximum exists, then at ordinary temperatures it will be roughly as follows:—

For iron when $\mathfrak{B}=17{,}500$, or when $\mathfrak{I}=1390$;
For nickel when $\mathfrak{B}=6{,}340$, or when $\mathfrak{I}=494$;
For cobalt when $\mathfrak{B}=10{,}000$, or when $\mathfrak{I}=800$.[3]

[1] All the more so that it has been found by some experimenters that the curve ($\kappa\mathfrak{I}$) actually has a point of inflexion and becomes convex to the axis of $\mathfrak{I}$ for very large values of $\mathfrak{H}$.

[2] Baur, *Wied. Ann.*, ii. p. 395, 1880, has remarked that the intensity of magnetization corresponding to the maximum permeability seems to be about the same for different sorts of soft iron; *e.g.*, for two of the ellipsoids of Von Quintus Icilius it is 550 and 540; for Stoletow's ring, 550; for Baur's ring, 540. It would seem that it is much higher for *steel*, judging by Rowland's tables.

[3] The maximum of magnetization for soft iron was calculated from the observations of various experimenters by Von Waltenhofen (*Wien. Ber.*, 1869; or *Pogg. Ann.*, cxxxvi.). He finds 1670, or thereby, for the maximum intensity of magnetization. Stefan, using Rowland's graphical method (*Wien. Ber.*, 1874), had found 1400. Fromme (*Wied. Ann.*, xiii., 1881), who had himself actually observed an intensity of as much as 1531, examined the curve for κ and $\mathfrak{I}$, and found, in agreement with Haubner (*Wied. Beibl.*, v., 1881), that there is a point of inflexion about $\mathfrak{I}=1200$; taking this into account, he finds for the maximum value of $\mathfrak{I}$ 1730, as a mean of results varying between 1720 and 1750. From a result of Weber's (*Elec. Maasbest.*, p. 573) he calculates the value 1737.

For the maximum permanent magnetization of steel, Weber (*Res. d. Mag. Ver.*, 1840) gives 314 (common steel magnet); Von Waltenhofen (*Pogg. Ann.*, 1871) 369 (glass hard wolfram steel); Schneebeli (*Wied. Galv.*, Bd. ii. § 308) 557 to 671 (sewing needles 25 to 66 mm. long and ·6 mm. thick), and 765 to 832 (knitting needles 198 to 210 mm. long and ·83 to 1·75 mm. thick). It must

6. The permeability of any metal depends on the quality of the metal, on the amount of permanent magnetization, on the total magnetization, and on the temperature.

ect of mpera- e.

7. The permeability of nickel and cobalt varies very much with temperature. In nickel for a moderate amount of magnetization the permeability increases with rise of temperature, but for high magnetization it decreases. This is very well shown in fig. 36, where the permeability curves for 15° C. and 220° C. intersect each other. In cobalt, on the other hand, the permeability appears to be always increased. The permeability of iron is not much affected by moderate changes of temperature.

8. The maximum of magnetization of iron and nickel decreases with rise of temperature, at least between 10° C. and 220° C., the first very slowly, the second very rapidly. At 220° C. the maximum for iron is $\mathfrak{B} = 17200$ or $\mathfrak{I} = 1360$, and for nickel $\mathfrak{B} = 4900$ or $\mathfrak{I} = 380$.

The researches of Stoletow and Rowland have undoubtedly made clear the main phenomena of magnetic induction; but in so doing they have raised a host of other questions which have not as yet been settled. There is no lack of recent work bearing on them, but it would be a difficult matter to give succinctly a complete account of the conclusions arrived at. The results of the different experimenters are not seldom contradictory, and the circumstances of experiment are often so complicated that criticism with the view of reconciling them seems hopeless in the meantime. While, therefore, we shall give a fairly complete list of the literature, the reader must not expect in this article an exhaustive analysis of the different memoirs that have recently appeared. Any remarks we shall make have chiefly for their object to call attention to the prominent questions that have been raised by the different workers.

Iperi- nts vh ep- ıls al s eres. ke, mme, Gz.

Riecke[1] made a series of experiments on ellipsoids of soft iron; he expresses his results in terms of p the magnetization function for a sphere, and finds, as he ought to do, that, for a considerable range of values of the magnetizing force, p is approximately constant.[2] In point of fact this method of representation is bad, for the quality of the metal only begins to affect p about the fourth or fifth decimal place. Similar experiments on spheres and ellipsoids of soft iron were made by Fromme;[3] and a very extensive series by A. L. Holz[4] on ellipsoids of iron and steel, in which he gives tables and curves showing the values both of p (to a large number of decimals) and of κ; and the values of the temporary, permanent, and vanishing magnetisms for a considerable range of magnetizing forces. The results, although wanting in regularity and smoothness for the harder kinds of steel, agree in the main with those of Stoletow and Rowland. Holz enters largely in this and in a former paper[5] into speculations concerning the effect of the molecular structure of the metal upon its magnetic properties.

ıty.

Relating more particularly to the phenomena of the permanent and temporary magnetization of steel we have important memoirs of recent date by Bouty, Fromme, and Auerbach. Bouty's papers,[6] besides copious references to the general literature of the subject and interesting critical discussions of magnetic theory, contain the results of careful investigations as to the permanent magnetization attained by repeated applications of magnetic force under various circumstances, and verifications of the formulæ of Green for the magnetic distribution in thin needles and cylindrical bars of steel. Two points as to his methods are worthy of notice. He employs a very simple method of measuring the magnetic moment of small pieces of steel: a small needle of moment m attached to a stiff stem, which carries a mirror, is freely suspended and allowed to come to rest in the magnetic meridian; the needle whose moment x is to be measured is then inserted into a tube fixed to the stem with its axis at right angles to the former needle. The deviation α of the compound system being measured by means of the mirror, we have $x = m \tan\alpha$. He studies the magnetic distribution in very thin hard needles by the method of rupture, finding that, if the needle be carefully broken, so that the distortion or shock caused by the bending does not extend far from the point of rupture, the magnetic moment of the different parts is little, if at all, affected. For thicker magnets he uses the ordinary method of deflexion.

Measurement of small moments.

Rupture of needles.

Bouty found, in agreement with Hermann Scholz and Frankenheim,[7] that, although the *continued* application of a magnetizing force does not increase the resulting permanent magnetization, the *repetition*[8] of its application will. He finds for the magnetic moment y of a thin needle passed x times through a magnetizing spiral the formula $y = A - B/x$, where A and B are constants: *e.g.*, in one case, $A = 57{\cdot}78$, and $B = 6{\cdot}32$. The ratio $A/(A - B)$, that is, the ratio of the moment attained by an infinite number of applications of the magnetizing force to that attained by one, decreases as the force increases; on the other hand, if R′ be the force required to produce by a single application the same effect as R produces by an infinite number, he finds the ratio R′/R fairly constant[9] (viz., from 1·060 to 1·065 in his best experiments) for values of R ranging from 10 to 42. In certain cases where the magnetization was effected by induced currents, he finds the formula $y = A + B\,(1 - e^{-\alpha x})$ to represent the results better.[10]

Effect of repeated application of magnetizing force.

He found that Green's formula,

$$y = A\alpha^2\left(x - \frac{2}{\beta}\,\frac{e^{\frac{1}{2}\beta x} - e^{-\frac{1}{2}\beta x}}{e^{\frac{1}{2}\beta x} + e^{-\frac{1}{2}\beta x}}\right),$$

where $$\beta = \frac{B}{\alpha},$$

giving the moment of a cylinder of length x and diameter α, was sufficiently accurate both for temporary and for permanent magnetism, and for hard or soft tempered steel, whether saturated or not, provided the bars were in a virgin condition before magnetization. For example, in a saturated bar of soft steel ($\alpha = 7$ mm.), for the temporary magnetism $A = 4{\cdot}081$, $B = 1/7{\cdot}142$; for the permanent magnetism $A = 2{\cdot}34$, $B = 1/17{\cdot}857$. In a non-saturated bar of soft steel ($\alpha = 10$ mm.), for temporary magnetism $A = {\cdot}9966$, $B = 1/7{\cdot}142$; for permanent magnetism $A = {\cdot}723$, $B = 1/17{\cdot}857$; so that B is independent of the magnetic force. With hard tempered bars, A was less, both for temporary and permanent magnetism, than with soft bars; B was independent of the magnetizing force for temporary magnetism, but increased for permanent magnetism with large magnetizing forces. He calls the magnetic distribution long or short according as B is small or great, and

be remembered that the maximum of *permanent* magnetization which a body can attain is essentially conditioned by its form; since the more elongated the form the less the demagnetizing force arising from the existing magnetization.

[7] *Pogg. Ann.*, cxxiii., 1864.

[8] In a very interesting paper (*Phil. Mag.*, 1869 and 1870) dealing with certain phenomena of induced currents, Lord Rayleigh incidentally arrives at the conclusion that the magnetizing force of a current depends on its maximum intensity more than on its duration, or on the whole quantity of electricity that passes. This observation has an important bearing on certain experiments of Bouty as to the effect of the "extra current," which it does not seem necessary to mention here.

[9] This conclusion is not in agreement with the results of Fromme.

[10] The formula $y = B(1 - e^{-\alpha x})$ was used by Quetelet for the moment induced in a steel bar by rubbing it x times with a magnet.

explains the phenomena of demagnetized or remagnetized bars by the superposition of long and short distributions. His final conclusion is that there is a greater independence between permanent and temporary magnetism than is usually admitted; and he starts a theory that magnetic bodies are composed of a mixture of two kinds of magnetic molecules, one kind retaining all the induced magnetism, the other wholly devoid of coercive force.

Magnetic after-effect.

It is obvious, from the results of Wiedemann, Frankenheim, and Bouty just alluded to, that the assumption made in the mathematical theory, that the effect of a magnetizing force is independent of the previous magnetic history of the body, is not even a first approximation to the actual truth. It becomes a matter of importance therefore to study the modification in the induced magnetism corresponding to any force produced by the forces that have preceded it. This effect has been called by German experimenters the *magnetic after-effect* (Magnetische Nachwirkung). Fromme and Auerbach have recently occupied themselves with this subject, and it may be of some interest to the reader to indicate a few of their conclusions.

Fromme.

In his first paper[1] Fromme experiments with rotational ellipsoids of soft steel, using partly the method of Weber, Thalén, and Riecke, partly the ordinary method of deflexion. He found, in the first place, that the generalized theory of magnetic induction was applicable for values of $\mathfrak{H}$ varying from ·0061 to ·132, κ decreasing between these limits from 23·5 to 8·68. He attempted to find the maximum force for which permanent magnetism first appears, and fixes it with some reserve at from ·2 to ·3.[2] The curve which he indicates for the temporary magnetization of soft steel has two points of inflexion, being first concave to the axis of $\mathfrak{H}$, then convex, and finally concave again.

He confirms the observation of Frankenheim that repeated applications of the magnetizing force increase the permanent magnetization up to a certain limit, and finds that when that limit is reached the body behaves towards all smaller forces having the same direction as if it were devoid of coercive force. Experimenting on ellipsoids permanently magnetized in this way, he found the mathematical theory of Kirchhoff to be inapplicable, it being impossible to fit the results obtained with the different ellipsoids together; and the discrepancy was greater with the softer than with the harder steel. For forces that are not sufficient to alter the permanent magnetization, κ decreases with decreasing force, as is the case with soft iron, so long at all events as the forces are not very great; and, again, for such forces the variation of κ is more regular the greater the permanent magnetization.

The number of impulses required to saturate with permanent magnetism was greater the greater the ratio of the moment of saturation to the initial moment, *e.g.*, greater for hard than for soft steel. It was found, in extension of a result of Frankenheim's, that, if U be the original moment, R_1 that produced by one and R that produced by an infinite number of impulses of the magnetizing force, then $(U+R_1)\ (U+R)$ is tolerably constant; but R_1/R decreases with increasing magnetizing force.

With reference to the non-permanent magnetism of a bar repeatedly magnetized by the same constant current, he concludes from his researches that it diminishes, but in such a way that the total induced magnetism remains constant,—so that what is lost in non-permanent is gained in permanent magnetism.

In his second paper[3] Fromme experimented both with iron and with steel cylinders, pointed at the end, of lengths varying from 140 to 220 mm., and of thicknesses from 1·5 to 8 mm. The method of deflexion was used, the effect of the magnetizing spiral itself being compensated by an auxiliary spiral suitably placed. The cores were carefully introduced into the spiral after the current was established, removed before it was broken, and then replaced when the permanent magnetism was determined.

In the following extract from his conclusions T_n denotes the total induced magnetization, R_n the whole residual or permanent magnetization, V_n the non-permanent or vanishing magnetization, after n impulses of a given magnetizing force, the suffix being dropped when the number of impulses is not in question, and replaced by ∞ when the number is so great that by further increasing it no alteration in the effect is produced.

Varying effect of successive impulses on temporary magnetism.

A constant force greater than all preceding induces a T which varies with successive impulses, sometimes increasing, sometimes decreasing. If a bar previously heated white hot be subjected to a large force, successive impulses usually give a decrease of T. If, however, the force is preceded by one somewhat smaller, successive impulses usually give an increase. It depends merely on the magnitude and the number of impulses of the preceding force P whether the repeated impulses of a force p will give an increasing or a decreasing T.

Effect on permanent magnetism.

R always increases with successive impulses until the limit is reached, and always faster than T; hence increase of R and decrease of V go hand in hand; the magnitude of this increase depends on P and p, and approaches zero with $P-p$.

In order that the action of a force p may not be influenced by the after-effect of smaller forces preceding it, it must be applied so often that its further application ceases to increase R. When saturation for R is thus reached, then T, R, and V have the values corresponding to frequent impulses of p for a fresh bar.

R_1/R_∞, R_2/R_∞, &c., all starting from unity, decrease as the force p increases from zero, diverging more and more until they all reach minima for the same value of p; they then converge again towards unity, which they all reach at the maximum of permanent magnetization. The values of p corresponding to the maxima of R_∞/p, ... R_2/p, R_1/p are in ascending order of magnitude, and the first of them is the value corresponding to the minima of R_1/R_∞, R_2/R_∞, &c.

What was stated for R_1/R_∞, R_2/R_∞, &c., holds word for word for T_∞/T_1, T_∞/T_2, &c. Hence the decrease of T is conditioned solely by the increase of R; so that it would appear that the after-effect of a preceding force P depends on the R which it produces. It would therefore be more correct to say that the after-effect depends on $r-R$ than to say that it depends on $p-P$.

Laws of after-effect.

When a bar has been magnetized by any force P, all *smaller* succeeding forces leave R unaltered, yet by repeated impulses of p ($<P$) T decreases until it reaches a certain limit. We may repeat the process as often as we please by always beginning with a new application of a larger force P; if we vary P, keeping p constant, T_1, T_2, &c., vary, but the limit T_∞ is always the same. In these experiments it was indifferent whether a few seconds or several hours elapsed between the applications of P and p; time had no influence on the vanishing of this species of magnetic after-effect. On the other hand, several impulses of the greater force gave no more after-effect than a single impulse, of whatever duration. If N denote the after-effect of a greater force P upon the action of a smaller p, the law of the phenomenon is

$$N = cp^a(P-p)^b,$$

where c is a constant and a and b are constant positive

[1] *Pogg. Ann.*, Ergbd. vii., 1875.

[2] So far confirming Maxwell's conclusions from his modification of Weber's theory of molecular magnets, *El. and Mag.*, vol. ii. § 445.

[3] *Wied Ann.*, iv., 1878.

numbers, b being a proper fraction, and a possibly very near unity. This of course gives $N=0$ for $p=0$ and for $p=P$, and gives a maximum value of N for some value of p between 0 and P.

The interposition of a force P′ between P and p increases the after-effect if $P'>P$, diminishes it if $P'<P$; and this holds irrespective of the sign of $P'-p$.

If we denote by k the susceptibility of a body for vanishing magnetism (V) induced by any force p, the question arises how far this is influenced by the permanent magnetism R induced by preceding greater forces. Jamin holds that k is approximately, and Chwolson that it is absolutely, independent of such permanent magnetism. Fromme finds that, when a force p, capable of itself producing a permanent magnetism r, acts on a bar already possessing a permanent magnetism $R>r$, then k is increased (by the presence of R) if $R-r$ is small, but diminished when $R-r$ is great.[1] The after-effect for small forces p may therefore be either increase or decrease of k; but for large forces p it is always increase.

At the conclusion of his paper Fromme points out the contrast between magnetic and elastic after-effect, and dwells upon the analogy between his results and those of Thalén [2] concerning the limits of elasticity in solid bodies.

The experimental method followed by Auerbach [3] was much the same as that of Fromme, except that the core was left in the magnetizing spiral during the make and break of the current. The core was generally a hollow cylinder of soft iron 148·1 mm. long, 17·8 mm. in diameter, 1·6 mm. thick, with end plates 1·5 mm. thick. He distinguishes two kinds of magnetic after-effect. The first kind consists in alteration of the magnetization of the body during the action of a constant force, or after it has ceased to act. The second kind is that already mentioned, in which the action of any force is influenced by preceding forces. It is this second kind of after-effect that is dealt with in the paper from which we are quoting.

The leading peculiarity of his view of the phenomenon is the introduction of the force *zero*, both as a preceding and as a final force. The fundamental principle laid down is the following:—

When the force p, which, following immediately after the force 0, would produce a magnetization T_0, is preceded by a series of forces $P_1, P_2 \ldots P_n$, the magnetization which results is T, differing from T_0 by an amount N called the after-effect. N is wholly determined by the first of the preceding forces P_z, which is such that all the forces that act between P_z and p lie in magnitude between P_z and p.

This general law is, however, subject to exceptions. For example, let the whole series of forces acting be P_{10}, p, P_9, p (evidently an extreme case), then experience shows that neither T_{10} nor T_9 is the resulting magnetization, but something intermediate, much nearer to T_{10}, however, than to T_9. In order to obtain T_9 a force $P_0<p$ must be interposed before P_9; even then the magnetization varies a little with P_0, but, if the stationary condition for P_9, p be established by alternating P_9, p many times after applying P_0, thus $P_{10}, p, P_0, P_9, p, P_9, p, P_9, p, \ldots$ the limit is found to be independent of P_0, and is held to be the true value of T_9.

In this way, for a given p, T can be determined as a function of P. It is necessary, however, to attend to the following principle,—that, of two preceding forces lying in magnitude on different sides of p, the second determines the after-effect exclusively only when it differs more from p than the first; in other cases both contribute to the after-effect; in no case does the first exclusively determine the after-effect. In the case where both preceding forces lie on the same side of p, the exceptions to the general law are far less marked; only where the second force is very nearly equal to p does it exercise a disturbing influence on the after-effect of the first.

The process used for obtaining T as a function of P, for a given p, say 10, is therefore to cause the influencing forces to alternate with the influenced, the succession of the former being such that the one preceding p always differs less from p than the one following. The stationary condition is supposed to be established for each pair as above explained; *e.g.*, starting with $P=11$, the series might be 11, 10, 8, 10, 13, 10, 6, 10, 15, 10, 4, 10, &c. In this way T_{11}, T_8, T_{13}, &c., can be determined.

When the values of T are plotted against the values of P, the curves corresponding to different values of p have all a similar character (see figure 37). They consist of two congruent parts lying on the two sides of a point of inflexion, which is the only point that has any marked character. To the right of the inflexion the concavity is towards the axis of P, to the left in the opposite direction. The infinite branches appear to approach (Curves of temporary magnetism with after-effect.)

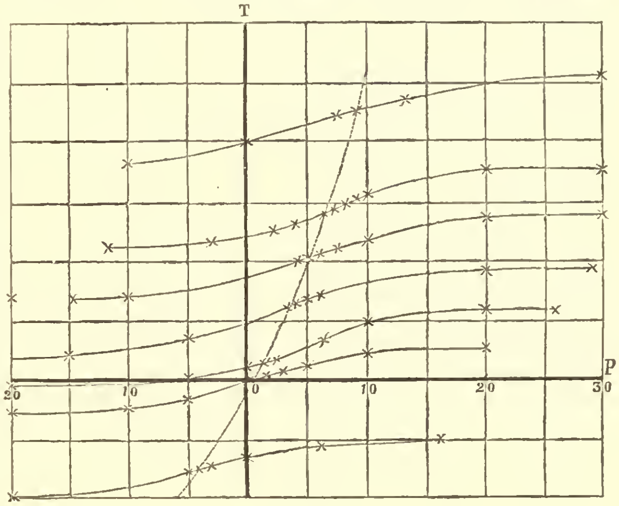

Fig. 37.

asymptotes parallel to the axis of P. The abscissa of the point of inflexion for any particular curve p is $P=p$; the ordinate is T_p, which may be called the normal magnetization corresponding to p when p alone has acted before. This of course is an ideal case; but a process is indicated for determining T_p directly.[4] The dotted curve in the figure is the curve of normal magnetization, whose abscissa and ordinate are p and T_p.

From the symmetry of the curves representing the after-effect Auerbach concludes that the after-effect of forces on opposite sides of p as to magnitude, and equidifferent from it, is equal and opposite, and ascribes the failure to observe the after-effect of forces smaller than p to the interposition of the force zero. He further concludes that the after-effect depends in the same way on $P-p$ as T_p depends on p.

There is one of the curves of after-effect, that, viz., for $p=0$, which has a special meaning. It is clearly the curve

[1] These conclusions are in agreement with the results of Herwig obtained from experiments on the longitudinal and circular magnetization of iron tubes, *Pogg. Ann.*, clvi., 1875.

[2] *Pogg. Ann.*, cxxiv., 1865.

[3] *Wied. Ann.*, xiv., 1881.

[4] A particular case of this process is interesting and practically important; viz., in order to demagnetize a core (*i.e.*, to find T_0) possessing a moment T. Apply in succession the forces $-P$, $+(P-\epsilon)$, $-(P-2\epsilon)$, $+(P-3\epsilon)$, &c., down to 0, P being chosen of sufficient magnitude, rather too great than too small (the smaller ϵ the better).

of permanent or residual magnetism, which is thus in Auerbach's view a particular case of after-effect. To it we can apply the general rule given above, subject of course to like exceptions.

It would be premature to pronounce any opinion as to the ultimate value of Auerbach's results; but the elegance of his representation of the phenomena will scarcely be disputed. In the latter part of his paper he applies his views to explain the peculiarities in the curve of magnetization with forces of ascending magnitude obtained when the after-effect is neglected, and to the cyclical process discussed by Warburg.[1] He also discusses the influence of the duration of the impulse of the magnetizing force and of the sudden closing and opening of the current. His conclusions agree in the main with those of Fromme: in particular he inclines to Fromme's view[2] that there is a specific magnetic effect produced in certain cases by the breaking of the current while the core is in the spiral. This effect in certain cases (with short thick cores) is so great that a permanent magnetization of opposite sign to the total induced magnetism remains.[3] This "anomalous magnetization" was first observed by Von Waltenhofen,[4] who also establishes the more general result, of which this is an extreme case, viz., that the residual magnetism of the core depends upon the rapidity with which the magnetizing force is reduced to zero. Auerbach lays down as a general principle that when the variation of the magnetizing force is slow and continuous the velocity of the transition does not influence the final magnetization; but sudden transition causes the final magnetization to be less or greater than that obtained by gradual transition, according as the passage is from a greater to a less or from a less to a greater force.

Effect of duration and repetition of impulse.

Additional literature.

The reader who wishes to pursue the present subject farther should consult the works of the following experimenters:—

Jamin,[5] who holds what he apparently regards as a new theory of magnetization. It is in point of fact merely a modification of the theory of solenoids, somewhat restricted in its application to the phenomena of magnetic induction. His special point is that the lines of magnetization in a bar magnetized (say) by a magnetizing spiral only penetrate to a limited depth, which is greater the greater the current. The following experiments[6] are adduced in confirmation of his views. The steel tube of a Chassepot rifle was plugged at both ends by screwing into it bolts of the same metal. Inside was placed a cylindrical rod. It was found that, so long as the current in the spiral was not very great, the rod was not sensibly magnetized; but, as the current increased, it became more and more affected, and by and by was as much permanently magnetized as if the enveloping tube had been absent. Again, the rod having been magnetized to saturation and inserted in the tube, a demagnetizing force was applied to the whole, and it was found possible to render the tube and core together seemingly neutral, or even oppositely magnetic, while the rod when taken out proved to be still powerfully magnetized in the original direction. Again, a bar was magnetized by a powerful current, and then magnetized in the opposite direction by another current. The surface of the bar was then eaten away to a certain depth; and it was found that the original magnetization reappeared. These experiments, although most interesting in themselves, do not appear to warrant the interpretation which their author puts upon them. Jamin has made extensive researches on the magnetic distribution in bars and ribbons of steel, partly with a view to obtain empirical rules for the construction of powerful permanent magnets, in which he has been very successful.

Influence of hardness and structure.

Influence of the Hardness and Structure of Iron and Steel on Permanent Magnetism.—Some information has already been given incidentally on this subject, and a lengthy discussion would be out of place here. The statements of the various authorities are very contradictory. This is not to be wondered at; for those best qualified to prepare the materials for experiment are generally deficient in the scientific knowledge requisite to enable them to form a sound judgment as to the result, while thoroughly trained scientific men have not as a rule acquired a command over the delicate manipulation of the forging and tempering of steel, an art which those who possess it usually find difficult to describe in words or reduce to rules. There is the further circumstance that many who have been successful in making good steel for magnetic or other purposes have found it for their interest not to publish the process by which success was attained.

Fineness of grain and uniformity of temper.

Fineness of grain and uniformity of temper are the greatest requisites in steel for permanent magnets. The latter in bars of any size is never attained in perfection, for the surface is always harder than the interior. The mischief which thereby arises may be understood by taking the extreme case of a thin steel tube magnetized to saturation, and then fitted with a perfectly soft iron core. It is clear that the core will act very much like the armature of a horse-shoe magnet; the lines of force will run back through it, and the external action will be in a great measure destroyed.

The different tempers of steel may be roughly classified as glass hard, straw colour, blue, and soft. The current statement is that the harder the steel the more difficult it is to magnetize, but the better it retains its magnetism. If this were so, provided sufficient magnetizing force to produce saturation were at command, the best temper for magnets would be glass hard. Lamont, however, whose experience was great, states that he found the loss after magnetization to be as great, and to continue as long, with glass hard as with blue tempered magnets. The same experimenter gives it as his opinion that great differences in the quality of magnets arise more from defects as to homogeneity, continuity, and uniformity of temper than from the quality of the steel in other respects; he inclines, however, to a preference for English cast steel.

Purity and homogeneity of structure are equally necessary in iron of high magnetic inductive susceptibility and small coercive force. Hammering, rolling, and drawing diminish the susceptibility and increase the coercive force. Rolling does so more in the direction of rolling than transversely, so that the iron becomes æolotropic. It is advisable in all cases where high susceptibility is wished to anneal the

body carefully after manufacture, by heating it in a wood fire and allowing it to cool very gradually; this process is still more effective when the iron is covered all over beforehand with half an inch or so of clay.

The reader who wishes for further details on this subject should consult Lamont's *Handbuch des Magnetismus*, chap. v. The following references to the literature may be useful.

Experiments with Finely Divided Magnetic Metals and with Electrolytic Iron.—These have been made by various physicists, mostly to test the theory of molecular magnets. The earliest of the experiments with finely divided iron was made by Coulomb, who mixed iron filings with wax, and found that the magnetic moment was proportional to the mass of magnetic metal. Similar experiments were made by the elder Becquerel,[1] his result being that the magnetic moment was proportional to the weight of magnetic substance, so long as the filings were not too densely distributed; with increasing density the mixture acquires magnetic properties more like those of a continuous metallic mass. Several modern experimenters have gone into the matter with considerable care; but their results are not sufficiently concordant, or of sufficient general interest, to justify us in dwelling at length upon them here. A few references to recent memoirs will suffice.

Boernstein, *Pogg. Ann.*, 1875; Toepler and Von Ettingshausen, *Ib.*, 1877; Von Waltenhofen, *Wied. Ann.*, 1879; Auerbach, *Ib.*, 1880; Baur, *Ib.*, 1880.

Experiments on electrolytically deposited iron have been made by Beez, *Pogg. Ann.*, 1860; Jacobi, *Ib.*, 1873; Beez, *Ib.*, 1874; Holz, *Ib.*, 1875; Baur, *Wied. Ann.*, 1880.

Using a fine scratch on a varnished silver wire as electrode, Beez deposited a thread of iron between the poles of an electromagnet, and thus obtained a permanent magnet of extreme tenuity. It was found that the inductive susceptibility of this linear magnet was very small, and that considerable magnetizing force produced no increase of its permanent magnetism. Thus in one case the original magnetism was 360, the total magnetism under the inducing force 370, the magnetism remaining after the force ceased to act 360. Broader, but equally thin, magnets deposited in a strong field in the same way gave more temporary magnetism than the linear magnets, but never more permanent magnetism than they possessed originally. Thicker plates exhibited greater temporary magnetism, and also an increase of the permanent magnetism acquired during deposition. With continued reversals of the magnetizing force electrolytic iron gave a continual decrease of the temporary magnetism down to a certain limit (as does steel); but the negative permanent magnetism never approaches so near the positive after many reversals as in the case of steel. On the other hand, Jacobi found that iron reduced electrolytically from ferrous sulphate and sulphate of magnesia, even after tempering, took a considerable temporary moment, but retained very little permanent magnetism. Holz found that the iron reduced from the solution of Jacobi and Klein was not sensibly hardened by heating and suddenly cooling, although its density was increased, and that its coercive force was diminished. On the other hand, it was found that hard tempering decreased the density of steel. He draws the conclusion that the coercive force is greater the farther apart the molecules. Baur's main result is that the maximum of magnetization with electrolytic iron occurs for much larger forces than with ordinary iron. These results are not wholly concordant; but the discrepancies may be reasonably assigned to differences in the preparation of the metal.

Magnetic Properties of Matter in General.

Among the earliest statements of the properties of the loadstone we find accounts of its action on other bodies; but it is clear from their surroundings that these statements are purely fabulous. Many experimenters at a later date found indications of magnetic action in other metals besides iron; but with praiseworthy caution they ascribed them for the most part to the admixture of small quantities of iron.[2] There can be no doubt that the results of Cavallo[3] obtained with brass (especially hammered brass) were due to impurity, for Bennet[4] failed to obtain any indications of magnetism with pieces of brass made from pure zinc and copper, whereas he was immediately successful on adding small traces of iron to the metal.

Early observations.

It very soon appeared, however, that an independent magnetic property must be ascribed to nickel and cobalt, and to these were by and by added with more or less certainty manganese and chromium.[5]

Brugmans[6] seems to have been the first to observe the repulsion by a magnet of a body not permanently magnetized. He found that a piece of bismuth floating upon mercury in a small paper boat was repelled by both poles of a magnet. Lebaillif[7] confirmed the observation of Brugmans, and found that antimony possessed a like property. Saigey,[8] who experimented on the same subject, concluded that all bodies when suspended in air behave like bismuth, unless they contain traces of iron.

Notwithstanding these results and others which we pass over,[9] the whole matter remained in obscurity till the repulsion of neutral bodies was rediscovered by Faraday in 1845. He speedily unravelled the laws of the phenomenon, showing how much depends on the nature of the body, and how much upon the nature of the magnetic field. His observations enabled him in fact to comprehend under a few general principles the action of all magnetic bodies whether of the nature of iron or of the nature of bismuth. The earlier observers had fallen into difficulties by neglecting the effects due to heterogeneity of field; these were pointed out for the first time by Faraday, and since then order reigns where there was formerly confusion.

Faraday's rediscovery and full investigation.

The best arrangement for testing the behaviour of weakly magnetic bodies is to suspend either a small sphere of the substance or else a small cylinder in a heterogeneous magnetic field. This field is usually produced by placing two pointed soft iron poles (fig. 38) on the arms of a powerful electromagnet. The line joining these poles is called the *axial* direction of the field; directions perpendicular to this line are called *equatorial*. The magnetic force varies

Experimental arrangements for testing weakly magnetic bodies.

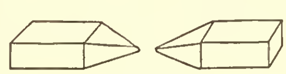

Fig. 38.

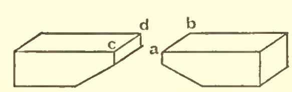

Fig. 39.

along the axial line, being less in the middle than at the poles; and it decreases everywhere from the axial line outwards. For some purposes poles of the shape shown in figure 39 are used; here the line along the upper edges of the poles are lines of greatest force, whereas the line in the plane of the upper faces equidistant from the upper edges is a line of weakest force; the force also decreases to the right of *ab* and to the left of *cd*.

In suspending small spheres the best plan is to hang them from one end of an arm of wood *db* (fig. 40). At the other end of this arm is placed a counterpoise *b*, and the whole is suspended by a fibre of unspun silk *u* from a torsion head *t*, by means of which the arm *db* can be brought into

any required position, and if necessary kept there by the exertion of a known torsional couple. The arm and suspension must be carefully guarded from draughts by enclosing it in a glass case, which fits over the poles of the electromagnet, and is provided with a door and with means for bringing the torsion head *t* over any given part of the magnetic field. When a cylindrical piece is to be tested it is suspended from the fibre *u* so as to hang horizontally. For this purpose Faraday was in the habit of using a stirrup of carefully selected writing paper attached to the lower end of the fibre. It is of the utmost importance to guard against magnetic action on the suspension; the least trace of iron in the arm *db* for instance, or in the paper stirrup, would in many cases be more than sufficient to mask the action proper to a weakly magnetic body.

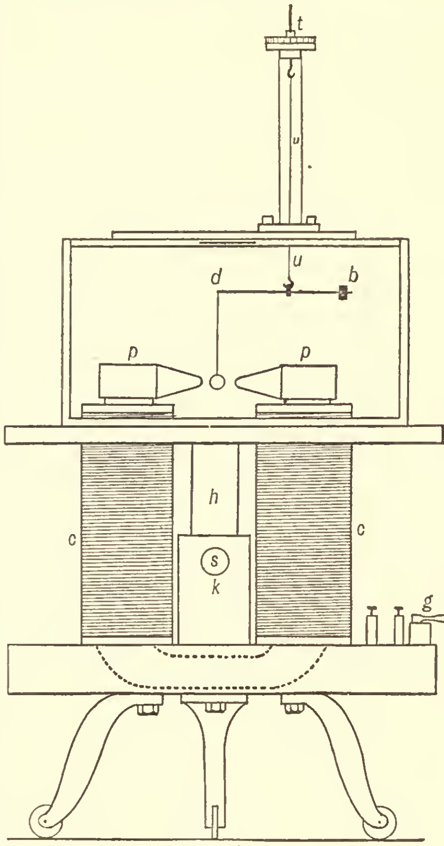

Fig. 40.

In every experiment the magnetic behaviour of the support should be tested by itself beforehand, so that if any residual effect be present it may be allowed for. The greatest caution is also requisite in choosing the material to be experimented upon. There must be no chemical impurity, especially no trace of iron; the spheres and cylinders must not be worked with iron tools or even with dirty hands. A source of error[1] to be specially guarded against in experiments with metals, or other good conductors, is the action arising from induced currents in the mass of the tested body caused by the increase and decrease of the strength of the magnetic field when the circuit of the electromagnet is made and broken. This error is wholly avoided by waiting till the suspended body has come to rest, and attending only to deflexions which are permanent after the intensity of the field has become steady.

Behaviour of heavy glass.

The first substance with which Faraday experimented was a bar of the heavy glass with which he had discovered the rotation of the plane of polarization of light. It took up the equatorial position between the poles of the electromagnet as soon as the current was established. There was no distinction between its ends, or according to the direction of the lines of force; the bar always took the shortest course to the equatorial position, and remained there in stable equilibrium. When placed in the axial position it was in unstable equilibrium, and on the slightest displacement either way it moved off in that direction to the equatorial position. A further action was observed when the bar was placed with its centre of mass out of the centre of the field; it was then repelled as a whole away from the nearest pole (no matter which). On testing a small cube or sphere of the substance, no pointing tendency was observed, but the mass as a whole when it was placed unsymmetrically with respect to the poles tended to pass away from the poles towards the centre of the field, and from the axial line outwards.

Setting of elongated bodies and translation of spheres and cubes.

Experimental law of paramagnetics and diamagnetics.

Faraday sums up the matter by saying that every element of the heavy glass tends to move from places of stronger to places of weaker resultant magnetic force. This is exactly the opposite of the law for bodies like iron (see mathematical theory above, p. 247). All bodies that follow the same law as heavy glass he calls *diamagnetics*, all that follow the opposite law, like iron, *paramagnetics*. For the purposes of experimental demonstration it is better to take some weaker paramagnetic than iron, *e.g.*, a tube filled with a solution of ferric chloride; for the order of magnitude of the effect obtained is then the same as with diamagnetics, and there is no danger of complications arising from the mutual action of the particles of the substance (see above, p. 245).

List of diamagnetics.

Faraday found the following substances to be diamagnetic; *i.e.*, pieces of them tended to set their longest dimension equatorial between pointed poles, and spheres and cubes of them tended to pass from places of stronger to places of weaker force:—rock crystal, sulphate of lime, sulphate of baryta, sulphate of soda, sulphate of potash, sulphate of magnesia, alum, muriate of ammonia, chloride of lead, chloride of sodium, nitrate of potash, nitrate of lead, carbonate of soda, Iceland spar, acetate of lead, tartrate of potash and antimony, tartrate of potash and soda, tartaric acid, citric acid, water, alcohol, ether, nitric acid, sulphuric acid, muriatic acid, solutions of various alkaline and earthy salts, glass, litharge, white arsenic, iodine, phosphorus, sulphur, resin, spermaceti, caffeine, cinchonia, margaric acid, wax from shellac, sealing wax, olive oil, oil of turpentine, jet, caoutchouc, sugar, starch, gum arabic, wood, ivory, mutton (dried), beef (dried), blood (dried or fresh), leather, apple, bread.

Liquids.

In testing liquids Faraday used a very thin glass tube of the form shown in figure 41; the opening being very fine, there was no need for a cork or other stopper which might have caused disturbance; the slight diamagnetic effect arising from the glass was allowed for. Another way of testing a liquid[2] is to place it in the bottom of a watch glass which rests on the edges of the pole of the electromagnet. When the fluid is paramagnetic, it collects in the places of greater force, forming a depression in the centre of the field as in figure 42; when it is diamagnetic, it collects in the places of weaker force in the centre of the field, as in fig. 43. Yet another method[3] is to put a small quantity of the fluid in a narrow tube, and place the tube horizontally in the equatorial line so that the end of the liquid column is just on the axial line. When the electromagnet is excited the liquid will be driven away from the axial line or drawn in according as it is diamagnetic or paramagnetic.

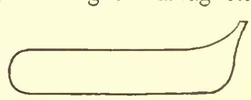

Fig. 41.

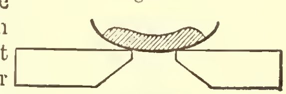

Fig. 42.

Fig. 43.

Powders.

Faraday found that breaking a weakly magnetic body into pieces, or even reducing it to powder, produced no effect upon its magnetic behaviour provided its general form was unaltered. In order to avoid disturbance from

[1] See Faraday, *Exp. Res.*, 2309 *sq.*

[2] Plücker, *Pogg. Ann.*, 1848.

[3] Quet, *Comptes Rendus*, 1854.

the magnecrystallic effect to be described presently, it is often advisable to reduce certain substances to powder before testing them; the powder is filled into a thin glass tube and then tested like a liquid. By means of powdered bismuth the tendency of a diamagnetic to pass from places of stronger to places of weaker force can be very prettily shown. If the powder be strewn upon the circular end of the core of an electromagnet, it will leave the edges and collect in the centre, whereas iron filings will leave the centre and arrange themselves round the edges, the fact being that at the edges the force is much more intense than in the centre.[1]

[...]aday's [...] of [...]gnetic [...]l dia[...]gnetic [...]tals.

Faraday arranges the metals in the following order of descending magnetic susceptibility:—

Paramagnetic.

Iron.	Chromium.	Palladium.
Nickel.	Cerium.	Platinum.
Cobalt.	Titanium.	Osmium.
Manganese.		

Diamagnetic.

Bismuth.	Mercury.	Arsenic.
Antimony.	Lead.	Uranium.
Zinc.	Silver.	Rhodium.
Tin.	Copper.	Iridium.
Cadmium.	Gold.	Tungsten.
Sodium.		

[...]ldi[...]nal [...]t of [...]tals.

Silicium is given as strongly paramagnetic, and beryllium,[2] aluminium, potassium, and sodium[3] as weakly magnetic; the last three were given as diamagnetic by Faraday; the magnetic character appears to depend on the method by which the material is prepared, being doubtless determined by the presence or absence of slight impurities. The copper of commerce is magnetic, owing to traces of iron; but when it is reduced by means of zinc from the chloride or sulphate it is diamagnetic. It would appear that the paramagnetism of titanium, palladium, platinum, and osmium is due to iron impurity.[4] Platinum[5] reduced from very pure chloroplatinate of ammonium by heating in a current of air is diamagnetic. According to Graham the magnetism of palladium when charged with hydrogen is due to the presence of hydrogenium; Blondlot,[6] however, has recently found that palladium is less magnetic when charged with hydrogen than when uncharged, from which he concludes that condensed hydrogen is pretty powerfully diamagnetic. Tellurium, sulphur, selenium, and thallium are strongly, and niobium and tantalum weakly diamagnetic.

[...]arly [...]sults.

Magnetic Properties of Gases.—The earliest results of Faraday were of a negative description, but the discovery by Bancalari[7] of the powerful diamagnetic action of flame again drew the attention of Faraday,[8] Plücker,[9] and Becquerel[10] to the subject. Faraday caused the gas under examination to stream vertically upwards or downwards (according as it was lighter or heavier than the surrounding gas) between the poles of an electromagnet, and observed how the stream was deflected. In the case of colourless gases the deflexion was observed by allowing small traces of hydrochloric acid to mix with the gas, and then placing in different parts of the field small tubes containing pieces of filter paper moistened with ammonia; by noticing in which of these the white fumes of ammonium chloride were formed the course of the gaseous current could be determined. Another method employed was to fix two thin glass tubes containing gases to be tested to the ends of a cross piece on one end of the arm of a torsion balance; the tube containing the most magnetic then moved towards the axial line. Another method, employed both by Plücker and by Faraday, is to blow soap bubbles with the gas to be tested, and observe their behaviour in the magnetic field, allowing of course for the feeble diamagnetism of the water film. Faraday's results are as follows:—

[...]radav's [...]peri[...]nts.

List of gases.

	In Air.	In Carbonic Acid.	In Hydrogen.	In Coal Gas.
Air	0	+	+ weak	+
Nitrogen	−	−	− strong	−
Oxygen	+	+	+ strong	+ strong
Hydrogen	− strong	−	0	
Carbonic acid	−	0	−	− weak
Carbonic oxide	−	−	−	− weak
Nitrous oxide	−	− weak	−	
Nitric oxide	− ? weak	+	+	
Nitrous acid	+ ? weak			
Olefiant gas	−	−	−	− weak
Coal gas	− strong	−		0
Sulphuric acid	−			
Hydrochloric acid	−	−	− ? weak	
Hydriodic acid	−			
Fluosilicic acid	−			
Ammonia	−	−	−	
Chlorine	−		− weak	
Iodine	−			
Bromine	−			
Cyanogen	− strong			

+ means magnetic relatively to the surrounding gas, − diamagnetic; the epithets strong and weak relate of course to the apparent behaviour under the circumstances of the experiment.

Oxygen.

It appears therefore that oxygen is the most paramagnetic of all the gases; on this account Faraday conceived that it probably played an important part as a cause of terrestrial magnetism.[11] Becquerel[12] has concluded from recent experiments of his own that the specific magnetism of ozone is still greater than that of oxygen. Faraday was able by filling thin glass bulbs with oxygen at different densities to show that the magnetic susceptibility decreased with the density, apparently in simple proportion. Some numbers giving an idea of the magnetic susceptibility of the various weakly magnetic bodies are given below.

Faraday's experiments on differential magnetic action.

In all experiments with gases or fluid media, and indeed in every possible magnetic experiment more or less, it is important to notice that the resulting magnetic action is the difference between the action of the movable body and the action on the surrounding medium. This was first pointed out by Faraday.[13] He prepared three solutions of ferrous sulphate. No. 1 contained 74 grains of the hydrated salt for every ounce of water; No. 2 was formed by diluting one volume of No. 1 with two volumes of water, No. 3 by diluting one volume of No. 1 with fifteen volumes of water. Three glasses g_1, g_2, g_3 and three tubes t_1, t_2, t_3 were filled with the respective solutions. The glasses were placed in succession between the pointed poles of the electromagnet, and the tubes tested in them with the following result:—

	In g_1.	In g_2.	In g_3.
t_1	0	+	+ +
t_2	−	0	+
t_3	− −	−	0

+ means pointed axially; + + the same with greater decision; − pointed equatorially; 0 was indifferent.

We have here the experimental confirmation of the important theoretical conclusion (see above, p. 248) that any body will behave paramagnetically or diamagnetically according as it is surrounded by a medium less or more magnetic than itself. In cases where the square of the

[1] This fact explains the astonishing behaviour of a flat disk of thin iron when placed on the centre of the pole.

susceptibility may be neglected, it is clear that the resultant action on any body is the difference between the action upon it and the portion of the medium which it displaces. This principle, which is the analogue of the Archimedean law for floating bodies, is of great use in quantitative magnetic experiments. It was exemplified by Plücker,[1] and extensively applied in magnetic observations by Becquerel.[2] Becquerel found, for instance, that the differences between the couples tending to set a small rod of sulphur in water and in air, in magnesium chloride and in air, and in nickel sulphate and in air were very nearly the same as the corresponding differences for a rod of wax.

Plücker and Becquerel.

Very curious qualitative illustrations of differential magnetic action are obtained by scattering drops of alcoholic solution of chloride of iron in olive oil;[3] the drops of chloride collect and displace the olive oil in the places of stronger force. Another form[4] of the same experiment consists in placing a layer of oil of violets over a layer of solution of chloride of iron. When a narrow cell filled in this way is placed equatorially with the interface of the two liquids in the axial line, on exciting the electromagnet the iron solution rises in the equatorial plane forming a disk-shaped mass around the axial line. Notwithstanding these results the general opinion of experimenters seems to be that no separation of the parts of a solution can be effected magnetically once the constituents have been thoroughly mixed. Thus Faraday[5] could obtain no evidence of the concentration of an iron solution near the pole of a magnet, although it was exposed for days together in the magnetic field, and found no separation of the oxygen and nitrogen of atmospheric air, although they differ greatly in their magnetic character.

Different liquids.

Constituents of a thorough mixture not separated.

Plücker[6] endeavoured to show that the air enclosed in a vessel placed between the poles of an electromagnet was rarefied by the magnetic action. Faraday, however, with almost identical experimental arrangements arrived at a negative result.

Rarefaction of air doubtful.

Elaborate investigations of the magnetism of chemical compounds have been made by G. Wiedemann with a view to connect their magnetic properties with their composition. A full account of these researches will be found in Wiedemann's *Galvanismus*, Bd. ii. § 590 *sq.*[7] The following are some of the more important of his conclusions as to the effect of composition.

Magnetic behaviour of chemical compounds. Wiedemann.

1. The magnetic susceptibility of the dissolved salt by itself is nearly independent of the solvent, being proportional to the concentration.

2. If the magnetic moment m induced by a field of unit intensity in a unit of weight of the salt dissolved in water be called the "specific susceptibility," and the product $\mu = Am$, where A is the molecular weight of the salt, the "molecular susceptibility," then the molecular susceptibility of the dissolved salt of the same metal with different acids is approximately the same. The mean molecular susceptibilities for nickelous, cobaltous, ferrous, and manganous salts are as 142 : 313 : 387 : 468.

3. The molecular susceptibility of cobaltous salts stands about midway between the molecular susceptibilites of nickelous and manganous salts; and the ferrous salts stand midway between cobaltous and manganous.

4. The molecular susceptibility of dry salts (combined with water of crystallization) is for the most part nearly the same as their molecular susceptibility in solution.

A similar law holds to a certain extent for insoluble salts freshly precipitated; and generally, with like chemical properties of the metallic molecule, the molecular susceptibility remains the same.[8]

5. Two diamagnetic elements may give a magnetic compound; *e.g.*, copper and bromine, both diamagnetic, give bromide of copper, which is paramagnetic.

6. When two solutions are mixed and the salts exchange their constituents by double decomposition, the specific magnetism of the solutions taken together is unchanged. Whence the conclusion is drawn that the susceptibility of a binary compound is made up by addition of the susceptibilities of its constituents, and that these constituents preserve their susceptibilities unaltered when their constitution or atomic arrangement in composition is unaltered.

Magnecrystallic Action.—In what precedes we supposed the inductively magnetized body, whether paramagnetic or diamagnetic, to be isotropic, and all experiments on its magnetic properties to be conducted in a heterogeneous magnetic field. In a uniform field such a body would be acted upon neither by force of translation nor by rotational couple. The case is otherwise if the body be magnetically æolotropic. In this case, according to the mathematical theory, (1) the body ought to set in a uniform field so as to place its axis of greatest magnetic permeability (*i.e.*, of greatest paramagnetic and of least diamagnetic susceptibility) parallel to the lines of force, and (2) in a heterogeneous field Faraday's translational force from places of less to places of greater resultant force in the case of paramagnetic, and from places of greater to places of less in the case of diamagnetic bodies, ought to be greatest when the axis of greatest susceptibility is parallel to the lines of force, least when the axis of least susceptibility is in the same position, and intermediate for other positions of the body.

Magne-crystall action.

Two kinds o it.

In observing the first class of phenomena above mentioned, poles with flat faces are placed on the electromagnet. Faraday recommends that the faces should be placed at a distance of about one-third of their breadth. He warns the experimenter, however, that the uniformity with this arrangement is by no means perfect, although in general sufficient. The best arrangement would be to use the magnetic field in the interior of a cylindrical coil of sufficient length were it not for the difficulty of attaining the requisite intensity in this way. In cases where there is any doubt it is well to give the body under examination a spherical or cubical shape, and so eliminate the tendency to set arising from heterogeneity of field.

Approx mately uniforn field betweer flat pol used fo first kin of magne-crystall action.

The first observations of the magnecrystallic couple were made by Plücker,[9] and elaborate investigations of the phenomenon were made by him in conjunction with Beer,[10] in the course of which the magnetic properties of a large number of crystalline bodies were examined. Plücker also detected the magnecrystallic property in a rapidly cooled cylinder of glass. Shortly after Plücker's first results were published, Faraday discovered the magnecrystallic action of crystallized bismuth. At first, misled no doubt by the language in which Plücker stated the newly discovered facts, he did not recognize the identity of the two phenomena; but on further investigation he was able to class all the observations under a few simple laws,[11] which in the mathematical form given to them by Thomson constitute the theory already given. To the observations of Plücker and Faraday Knoblauch and Tyndall added the important discovery that bodies in which the linear density in one direction is greater than in another, whether as a consequence of compression or of stratification artificial or natural, exhibit magnetic æolotropy.

Magnetic classification of crystals.

It is convenient, following the analogy of physical optics, to divide magnetically æolotropic bodies into (*a*) "uniaxal" bodies, *i.e.*, those that are symmetrical about one principal axis of magnetic susceptibility, or, in other words, have two of the principal coefficients of magnetic susceptibility equal ($\kappa_2 = \kappa_3$); and (*b*) "biaxal" bodies, *i.e.*, those that have the three principal susceptibilities unequal.

Uniaxals positive and negative, paramagnetic and diamagnetic.

Class (*a*) naturally divides itself into those in which the susceptibility parallel to the axis of symmetry is greater and those in which it is less than that in the plane perpendicular to it. The former (where $\kappa_1 > \kappa_2$) are said to be positive, the latter ($\kappa_1 < \kappa_2$) negative uniaxals. We have also to attend to the distinction which arises according as the mass of the crystal is paramagnetic or diamagnetic (κ_1 and κ_2 both +, or both −). We have then the following experimental behaviour in uniaxal bodies :—

		Sets the Axis of Symmetry
Positive	Paramagnetic	Parallel to lines of force.
	Diamagnetic	Perpendicular to lines of force.
Negative	Paramagnetic	Perpendicular to lines of force.
	Diamagnetic	Parallel to lines of force.

Faraday found for example that a crystal of bismuth suspended with its plane of smoothest cleavage vertical set with this plane perpendicular to the lines of force, but was indifferent when suspended with this plane horizontal. The axis of magnetic symmetry is therefore perpendicular to the plane of smoothest cleavage, and, since the substance is diamagnetic, it is a negative uniaxal. When suspended in any other way the crystal set so that the magnetic axis rested in a vertical plane through the direction of the lines of force. The difference between the behaviour of magnetic and diamagnetic uniaxals is beautifully illustrated by the behaviour of pure Iceland spar, which is a positive diamagnetic uniaxal, and sets the optic axis, which is the magnetic axis, equatorially; when, however, as sometimes happens, the calcium is partly replaced by iron, its physical properties (optical included) being thereby unchanged, except that the mass of the crystal becomes magnetic, it sets the optic axis axial.[1]

Magnecrystallic couple independent of surrounding medium.

All these cases are of course included in the single rule that the body sets the axis of greatest permeability parallel to the lines of force. Since the setting of weakly magnetic æolotropic bodies depends merely on the differences between the principal magnetic susceptibilities, it follows that it is independent of the medium in which the body is placed. This was established experimentally by Faraday,[2] who found the magnecrystallic couple exerted on a crystal of bismuth to be the same whether it was surrounded by air, by water, or by a saturated solution of protosulphate of iron.

Plücker gives the following list of uniaxal æolotropic bodies :—

MAGNETIC.

Positive.	*Negative.*
Spathic iron ore.	Tourmaline.
Scapolite.	Beryl.
Green uranite.	Dioptase.
Ferruginous sulphate of magnesia.	Vesuvian.
	Sulphate of nickel.
	Ammoniochloride of copper.

DIAMAGNETIC.

Positive.	*Negative.*
Calc-spar.	Bismuth.
Antimony.	Arsenic.
Molybdate of lead.	Ice.
Arsenide of lead.	Zircon.
Sulphate of potash.	Mellite.
Nitrate of potash.	Cyanide of mercury.
	Arseniate of ammonium.

The phenomena in the case of biaxal æolotropies are naturally more complicated; but they are all comprehended in the simple rule given above (page 244) that the axis of greatest paramagnetic or of least diamagnetic resultant susceptibility in the horizontal plane tends to set itself parallel to the lines of force, or, in the words of Faraday, the body tends to set so as to allow the greatest number of lines of magnetic induction to pass through it. In the azimuth just mentioned the body is in stable equilibrium, in the perpendicular azimuth in unstable equilibrium.

Faraday's experimental law.

Plücker's two magnetic axes.

There are two axes of suspension in the plane of the axes of least and greatest susceptibility, viz., the normals to the circular sections of the ellipsoid $\kappa_1 x^2 + \kappa_2 y^2 + \kappa_3 z^2 =$ constant, such that the body behaves indifferently; these axes were called by Plücker the "magnetic axes" of the body. If we observe the times of vibration T_1, T_2, T_3 of a sphere of the substance, when the axes κ_1, κ_2, κ_3 respectively are vertical, then we have at once by the theory already given

$$T_1 : T_2 : T_3 :: 1/\sqrt{\kappa_2 - \kappa_3} : 1/\sqrt{\kappa_1 - \kappa_3} : 1/\sqrt{\kappa_1 - \kappa_2} ;$$

whence $1/T_1^2 + 1/T_3^2 = 1/T_2^2$, and $\tan\omega = T_3/T_1$, ω being the angle between either magnetic axis and the axis of greatest magnetic susceptibility. These results were verified experimentally by Plücker.[3]

Phenomena of second kind.

Magnecrystallic phenomena of the second kind were looked for by Faraday very early in the history of the subject, but at first he was unsuccessful in detecting them.[4] He seems, however, to have understood and clearly represented to himself in his own way their close connexion with the phenomena of the first kind, for he alluded to the subject more than once, and finally in the twenty-sixth series of his experimental researches, where he explained at length his magnetic theory, he showed that such an effect ought to exist, and actually succeeded in observing it in the case of a crystal of bismuth, which he found to be less repelled from places of stronger to places of weaker force when its axis was parallel to the lines of force than when it was perpendicular to them. He concluded that with Iceland spar the translational force ought to be greatest when the axis is parallel to the lines of force, and least when it is perpendicular to them; but his apparatus was not sufficiently delicate to show the effect.

First discovered by Faraday in bismuth.

Phenomena of the second kind depend on the surrounding medium.

Unlike the magnecrystallic phenomena of the first kind, those of the second kind depend on the difference between the susceptibilities of the body and of the surrounding medium. Faraday[5] demonstrated this conclusion experimentally by covering crystals of the red prussiate of potash with a thin layer of wax to prevent dissolution, and immersing them in solution of sulphate of iron of various strengths between the pointed poles of an electromagnet. In water the crystal was attracted to places of stronger force in all positions, in concentrated solution of sulphate of iron repelled in all positions, while in a solution of 14 or 15 volumes of the concentrated solution to 6 volumes of water it was attracted when the axis of symmetry was parallel to the lines of force and repelled about as strongly when the axis was perpendicular to them. Here then the crystal actually behaved paramagnetically in one direction and diamagnetically in the other. Similar results can be obtained with Iceland spar in a mixture of alcohol and water.

Faraday and Thomson.

The prediction of the second class of magnecrystallic phenomena is one of the most extraordinary instances of the theoretic insight which formed so large a part of the genius of Faraday. The laws of the phenomena of the first class might be regarded as merely a skilful classification of observed facts, but the passage therefrom to the second class was a step of the first magnitude; it constitutes in fact the root of the whole matter. To Sir William

[1] Tyndall and Knoblauch, *Phil. Mag.*, 1850.
[2] *Exp. Res.*, 2498 *sq.*, 1848. A later but much more extensive series of experiments led to the same result (*Exp. Res.*, ser. xxx., 1855).

Thomson belongs the credit of throwing the laws of magnecrystallic action into the appropriate mathematical form, and of showing that they range themselves quite naturally under the theory of Poisson.[1]

Tyndall verifies the prediction of Faraday and Thomson for Iceland spar.

Tyndall succeeded, where Faraday had failed, in showing the magnecrystallic phenomenon of the second kind in Iceland spar. It is particularly instructive to compare his results for carbonate of iron and carbonate of lime, both positive uniaxals, but the one magnetic and the other diamagnetic. His results are as follows :—

Substance.	Axis Axial.	Axis Equatorial.	Magnetic Character.
Carbonate of iron	100	71	+
Carbonate of lime	100	90	−
Sulphate of iron..............	100	85	+
Bismuth	71	100	−

Hankel.

Hankel[2] measured the repulsion on a cylinder of bismuth placed with its magnetic axis inclined at angles of 15°, 45°, and 75° with the lines of force, and compared his results with the theoretical formula $90{\cdot}7 + 45{\cdot}3 \sin^2\phi$; the result was as follows :—

	±15°.	±45°.	±75°.
Observed repulsion	94·1	113·3	132·4
Calculated repulsion	93·7	113·3	133·0

Relation of magnetic æolotropy to crystalline form.

Influence of Crystalline Form, Compression, &c., in producing Magnetic Æolotropy.—In general the magnetic æolotropy stands in close relation to the crystalline form, and consequently to a considerable extent also to the optical properties. Thus crystals of the regular system exhibit as a rule no magnecrystallic properties, but there appear to be exceptions in the case of certain pyroelectric crystals such as boracite. Again, crystals that have one crystallographic axis of symmetry are usually magnetically uniaxal, but the optical distinction of positive and negative does not involve the corresponding magnetic distinction, as is shown by the results of Tyndall and Knoblauch with pure Iceland spar and Iceland spar in which part of the calcium is replaced by iron. Crystals that are optically biaxal are as a rule magnetically biaxal, but the magnetic properties cannot be deduced immediately from the optical.

Effect of compression. Tyndall and Knoblauch.

If a small cylinder be made of a paste formed with finely ground bismuth and gum water it will point equatorially in a heterogeneous field, but if the roll be squeezed flat the plate thus formed will point axially, although its length be ten times its breadth. A roll of paste of powdered carbonate of iron, again, will point axially, the plate formed by squeezing it flat equatorially.[3] From these results Tyndall and Knoblauch concluded that, if the arrangement of the particles of any body be such as to present different degrees of proximity in different directions, then the line of closest proximity, other circumstances being equal, will stand axial if the mass be magnetic, equatorial if the mass be diamagnetic.

Effect of laminar structure.

They constructed parallelepipeds (1 in. × ¼ in. × ¼ in.), first, by gumming together rectangular slips of sandpaper (1 in. × ¼ in.), secondly, by gumming together squares of the same (¼ in. × ¼ in.). The paper was comparatively indifferent, while the sand by itself was magnetic ; and it was found that the first model set its longest dimension axially, while the second set its longest dimension equatorially ; *i.e.*, the layers of sand set in both cases axially.

Stratified and fibrous bodies.

Tyndall[4] has observed similar magnecrystallic actions with naturally stratified bodies such as shale, and in fibrous bodies such as wood. He was even able by squeezing plates of bismuth to apparently reverse the magnetic character of the substance ; for the compression rendered the plates æolotropic with an axis perpendicular to their longest dimension, and in consequence they set axially like plates of a paramagnetic substance. A crystal of bismuth compressed in a direction perpendicular to the ordinary magnetic axis, *i.e.*, parallel to the planes of principal cleavage, had its behaviour reversed as to the second class of magnecrystallic effects, the ratio of the repulsions when the crystal was set with its original axis axial and with its original axis equatorial having been changed from 71 : 100 to 112 : 100.

Imitation by compression of a biaxal crystal.

It was also found possible by squeezing a ball of bismuth dough unequally in two perpendicular directions to imitate a biaxal magnetic crystal such as heavy spar. Tyndall and Knoblauch attempt to explain the magnetic phenomena exhibited by crystals proper by means of these results. They assume that the planes of cleavage are directions of closer aggregation, and therefore tend to point axially in magnetic and equatorially in diamagnetic crystals.

Theory of Tyndall and Knoblauch.

For example, the first of the above-mentioned sandpaper models would represent magnetic crystals that cleave parallel to their axis, the second magnetic crystals which cleave perpendicular to their axis. If we regard this theory merely as a way of representing the facts of observation, even if we allow it to be sufficient, it is far inferior in simplicity to the theory of Faraday and Thomson, the sufficiency of which is not disputed. Regarded as an attempt to penetrate a little farther into the relation between molecular structure and magnetic properties, it is of great interest and importance, even if we admit that like most other speculations of the kind it leads us but a little way; for the question arises immediately, How does proximity of the molecules increase specific inductive capacity? This last question is all the more difficult to answer that no experiment has ever yet been adduced wherein the effect of the mutual induction of the parts of a diamagnetic or weak paramagnetic body plays an undoubted part.[5]

Controversy concerning diamagnetic polarity. Faraday.

Discussion as to the Existence of Diamagnetic Polarity.—Soon after Faraday's first discovery of diamagnetism, an animated discussion arose as to the proper way of stating the facts involved in the new phenomenon. Faraday himself inclined in the first instance to put the matter by saying that under the action of an inducing force a diamagnetic body is magnetized in a direction opposite to that of soft iron ; at a later period he abandoned this form of statement in favour of what he called the theory of magnetic conduction, which fitted better with his ideas as to the part played by the surrounding medium by means of which magnetic action is transmitted from one body to another.

Weber and others. Tyndall.

Faraday's first theory under the name of the theory of diamagnetic polarity was immediately adopted by the Continental physicists, such as Weber, Reich, and Poggendorff, who naturally found it consonant with their favourite views as to action at a distance. It was also supported in England by Tyndall and others. Many experiments were advanced on both sides of the question, and the result was much instructive illustration of the laws of magnetic action. But the controversy settled nothing, because in point of fact there was nothing to settle.

The discussion differences as to words merely. Thomson.

Either theory was perfectly sufficient, when properly applied, to represent the phenomena, and each left the question of the ultimate nature of paramagnetic and diamagnetic action where it found it. This ought to have been evident after Thomson had shown that the phenomena were included in a perfectly natural generalizatian of Poisson's theory, indicated in fact by

[5] Faraday, *Exp. Res.*, 2825, &c. There is a further difficulty in the case of diamagnetic bodies. See Thomson's letter to Tyndall, *Reprint of Papers on Elec. and Mag.*, p. 536.

Poisson himself, and demonstrated that Faraday's conception of the phenomena was only another method of viewing the facts leading to identical conclusions. Faraday himself[1] seems in the end to have considered that the difference was a matter of phrases. Since Clerk Maxwell's elaborate mathematical reconstruction of the theories of Faraday this seems to be universally recognized, and the discussion has subsided. For a full account of the various interesting experiments that were made during the controversy the reader may be referred to Wiedemann's *Galvanismus*, § 558 *sq.*, and to the reprint of Tyndall's *Papers on Diamagnetism and Magnecrystallic Action*, pp. 76 *sq.*

Numerical Data respecting the Susceptibility of Weakly Magnetic Bodies.—The earlier experimenters arrived for the most part at the conclusion that the susceptibility κ of weakly magnetic bodies is constant. Among these may be mentioned Weber, who experimented with bismuth, E. Becquerel,[2] Tyndall,[3] Joule,[4] Reich,[5] and Matteucci,[6] who experimented on various substances by means of the torsion balance; Christie,[7] who worked with bismuth, and Arndtsen,[8] who worked with ferric sulphate and ferric chloride, both using Weber's diamagnetometer; and Wiedemann,[9] who experimented with solutions of a variety of salts. E. Becquerel, however, in some of his experiments, *e.g.*, with sulphate of nickel, found that κ showed a tendency to decrease for very large values of the magnetizing force; Plücker,[10] who tested a great variety of substances (powdered or in solution) by measuring with a delicate balance the attraction or repulsion exerted upon them by an electromagnet, arrived at a similar conclusion; but the methods of both these experimenters are open to suspicion.

A large number of relative results were obtained by the earlier experimenters,[11] but in some cases the methods employed were not satisfactory, and in others the results so evidently depend on the state of aggregation of the material that they are of little importance. The following tables will give the reader some idea of the relative magnitudes of the susceptibilities of different substances:—

Plücker's Table for Magnetics.

Iron	100,000	Ferric chloride, conc. soln.	98
Magnetic iron ore	40,227	Ferric sulphate ,,	58
Ferric oxide	286	Ferrous chloride ,,	84
Hematite	134	Ferrous sulphate ,,	126
Specular iron ore	533	Nickelous oxide	35
Hydrated ferric oxide	156	Hydrate of do.	106
Ferric sulphate	111	Hydrated manganic oxide	70
Green vitriol	78	Mangano-manganic oxide	167
Nitrate of iron, conc. soln.	34		

The numbers here denote specific magnetic susceptibility; *i.e.*, equal weights of the substances are compared.

Results of Faraday and Becquerel.

Ferrous chloride, conc. solution	+ 655	Hydrogen	− 0·1
Ammoniacal solution of cuprous oxide	+ 134	Ammonia gas	− 0·5
Do. of cupric oxide	+ 120	Cyanogen	− 0·9
Oxygen	+ 17·5	Glass	− 18·2
Air	+ 3·4	Pure zinc	− 75
Olefiant gas	+ 0·6	Ether	− 75
Nitrogen	+ 0·3	Alcohol absolute	− 79
Vacuum	0·0	Oil of lemons	− 80
Carbonic acid	0·0	Camphor	− 82
		Camphire	− 83
		Linseed oil	− 85
Olive oil	− 86	Chloride of arsenic	− 122
Wax	− 87	Fused borate of lead	− 137
Nitric acid	− 88	Phosphorus*	− 167
Water	− 96·6	Selenium*	− 168
Ammonia solution	− 98	Pure copper*	− 171
Bisulphide of carbon	− 100	Pure silver*	− 235
Sat. solution of nitre	− 100	Pure gold*	− 350
Sulphuric acid	− 104	Bismuth	− 1967
Sulphur	− 118		

The results marked with an asterisk are taken from Becquerel; the rest are from Faraday. The numbers relate to equal volumes of the substances, and the medium is supposed to be vacuum; so that water in air would be represented by 100.

The numbers of Faraday, Becquerel, and Matteucci agree very fairly; *e.g.*, according to Faraday the susceptibilities of water, oxygen, and air are as − 100 : + 1·8 : + ·352, according to Becquerel as − 100 : + 1·82 : + ·382. Plücker's results do not agree so well with those of Faraday and Becquerel; but his method was faulty.

Within the last five years a large number of absolute determinations of κ have been made, chiefly for bismuth and ferric chloride. Toepler and Von Ettingshausen[12] in their experiments on bismuth used with some alteration the method of induced currents employed by Weber[13] in the earliest attempts that were made to determine the susceptibility of bismuth. Like Weber they compare bismuth with iron, an unsatisfactory procedure on account of the great variability of the susceptibility of iron for different magnetizing forces, and for different samples with the same magnetizing force.

Silow worked with ferric chloride. In his first set of experiments[14] he observed the time of vibration of an astatic needle suspended over a cylindrical vessel filled with the solution; in his second investigation[15] the solution was placed in a glass globe, on the outside of which insulated wire was wound so that a given current in it produced a uniform magnetic field whose strength could be calculated;[16] the deflexion of a properly astatized needle suspended inside the globe, was observed when the globe was empty and when it was full, and thence κ was calculated; in his third determination[17] he used the method of Toepler and Von Ettingshausen so improved as to allow an absolute determination of κ to be obtained directly.

Borgmann[18] enclosed one coil within another, and filled the hollow cylindrical space between them with the solution of ferric chloride to be tested; he also used the ring method of Stoletow and Rowland.

Jacques,[19] following a method elaborated by Rowland, measured the repulsion of crystals of bismuth and Iceland spar placed with their magnetic axes axially and equatorially between the poles of a Ruhmkorff's electromagnet, the field of which was carefully explored after the manner of Verdet by means of a small coil moved through a known distance in different parts of it; from these observations the two principal magnetic susceptibilities were calculated.

Schuhmeister[20] experimented with ferric chloride, using the same method as Rowland and Jacques.

In the experiments of Eaton[21] the method formerly employed by Wiedemann was adopted; the data in his paper are, however, insufficient for an absolute determination either of the magnetizing force or of κ; in fact he determines merely the force with which the magnetic body is attracted and the magnetic moment of the electromagnet, assuming that the strength of the magnetic field at a given point is proportional to the latter,—which is not necessarily true, for the magnetic distribution in the core of the electromagnet may alter with increasing current.

Von Ettingshausen. Von Ettingshausen[1] in the most recent research on the subject with which we are acquainted has made determination of the susceptibility of bismuth by four different methods. The first of these was that formerly used by Toepler and himself, with the addition that the action of the bismuth bar was compared with that of a solenoid of as nearly the same dimensions as possible through which flowed a current of given strength (an artifice previously used by Christie). The second method consisted in measuring the force with which a portion of the diamagnetic substance hung in the axis of a coil and near one of its ends was repelled out of the coil when a known current passed through it. The third method was that of Rowland and Jacques. The fourth consisted in measuring the deflexion of a magnetometer needle produced by placing a piece of the diamagnetic substance between the poles of a powerful magnet under whose action the magnetometer needle had come to rest in the first instance.[2] The agreement between the results obtained by all the different methods was very fair considering the smallness of the effects to be measured in some of them. The second method is pronounced to be the best, and by means of it he gives also a determination of κ for ferric chloride.

Results for bismuth. Some of the results of the different experimenters for bismuth are given in the following table :—

Magnetizing Force.	$-10^6\kappa$.	Authority, &c.
63 301	14·6 14·9	Calculated by Stoletow from certain results of Weber's, see Silow, *Wied. Ann.*, 1882.
...	16·4	Calculated by Von Ettingshausen, *l.c.*, from Weber.
...	14·6	Calculated by Von Ettingshausen, *l.c.*, from Christie.
25·8 to 128 71·4 to 110·2 39·2 to 82·2	13·99 14·54 13·48	Three different samples by Von Ettingshausen's second method.

Most of the specimens contained slight traces of iron. Although the range of the magnetizing force in Von Ettingshausen's experiments was considerable, κ was very nearly constant; if there was any tendency to variation, it was decrease with the large magnetizing forces.

Results for ferric chloride. The results for ferric chloride are not so concordant. Silow, after comparing his own earliest result ($10^6\kappa = 81$ for a solution of density 1·475, magnetized by the earth's horizontal force) with those of Borgmann ($10^6\kappa = 48·8$, density 1·87, magnetic force 40 to 59), concluded that the susceptibility of ferric chloride probably follows the same law as that of iron; *i.e.*, it first increases, then reaches a maximum, and afterwards decreases more or less slowly. His later experiments confirm this conjecture, and he finds that κ has a maximum value for a magnetizing force of about ·4 C.G.S. The smallest force used was about ·08 C.G.S. and the corresponding value of $10^6\kappa$ was 34; the largest value of $10^6\kappa$ occurring in his tables is 179. The values obtained in his last investigation are smaller than those given in his first table, but there is the same increase and decrease. The following are his latest results :—

Silow.

$\mathfrak{H}$	$10^6\kappa$.	$\mathfrak{H}$	$10^6\kappa$.
1·15	96	2·45	104
1·35	104	3·73	70
1·60	131	5·33	69
1·70	131	5·35	68
1·81	142	6·54	65
1·90	141	7·00	62
1·96	131	10·00	60
2·13	111	12·60	55
2·40	99		

[1] *Wien. Ber.*, 1882.

[2] This was one of the experiments adduced by Weber in the controversy regarding diamagnetic polarity; see *Pogg. Ann.*, 1848.

The unit of $\mathfrak{H}$ is the earth's horizontal force, presumably at Moscow.

From the observations of Arndtsen on a solution of density 1·495 Silow[3] calculates $10^6\kappa = 57·5$ (magnetic force 20·3). For a solution of density 1·395, with magnetizing forces from 38 to 252, Schuhmeister gets $10^6\kappa = 30$ to 39. Von Ettingshausen, for a solution of density 1·48, with magnetizing force 14 to 20, gets $10^6\kappa = 59$ to 56.

The following are the values of $10^6\kappa$ obtained by Schuhmeister for various substances.

Schuhmeister.

$\mathfrak{H}$	61·5	130·8	252·7
Water	– ·55	– ·45	– ·44

Relation of Magnetism to other Physical Properties.

Shocks, Jarring, or Vibration.—The effect of these in aiding the action of an inductive magnetic force was known to Gilbert; and it was also known to the earlier experimenters that the permanent magnetism of a body not subject to external magnetizing force was destroyed by like causes. The action is precisely similar to that found in the case of bodies temporarily or permanently deformed by mechanical stress, and, again, to the first effects of temperature on bodies temporarily or permanently strained, or temporarily or permanently magnetized.[4] The effect may be conceived as consisting of a loosening of the molecules for the moment, so that they follow more easily any force acting on them whether mechanical or magnetic. The following parallel statements, taken from the results of Wiedemann, who has devoted much careful study to these phenomena, will sufficiently illustrate the matter :—

Wiedemann's parallel statements.

1. Jarring a body under twisting stress causes increase of twist.
2. Permanent twist in a wire is diminished by jarring.
3. A wire permanently twisted and then partly untwisted loses or gains twist when jarred according as the untwisting is small or great.[5]

I. Jarring a bar under magnetizing force causes increase of magnetization.
II. Permanent magnetization in a bar is diminished by jarring.
III. A bar permanently magnetized and then partly demagnetized loses or gains magnetization according as the demagnetization is small or great.[5]

Minuter details regarding the effects of jarring will be found in memoirs by Wiedemann, Fromme, Auerbach, and others already quoted. The reader may also consult Warburg, *Pogg. Ann.*, 1870, and Villari, *Pogg. Ann.*, 1869.

Joule's discovery of the magnet strains. *Mechanical Strain produced by Magnetization.*—The starting point of accurate research on this subject was the discovery made by Joule[6] in 1842 that a bar of soft iron lengthened when it was temporarily magnetized in the longitudinal direction. When the magnetizing force was removed the bar shortened, but in general not quite to its

[3] *Wied. Ann.*, 1882.

[4] Compare also the effect of the same causes on the temporary and residual charge of Leyden jars, art. Electricity, vol. viii. p. 40.

[5] It is possible in this way even to cause a wire to reverse its twist and a bar to reverse its magnetization by jarring.

[6] His attention had been drawn to the subject in 1841 by a Mr Arstall, who had suspected the existence of some such effect. Joule's papers on the subject are in Sturgeon, *Ann. of El.*, 1842, and *Phil. Mag.*, 1847.

original length. This residual extension was due in part to permanent magnetism, but he found that the permanent magnetization due to a current 1088 was reversed from – 1·3 to + ·25 by a current 175, while two-thirds of the permanent extension was still left. The actual elongation of an iron bar magnetized to saturation was found to be from $\frac{1}{720000}$th to $\frac{1}{200000}$th of its whole length. The extension varied approximately as the square of the intensity of magnetization (temporary or permanent). The general character of the phenomena is the same in soft or hard iron, and in soft or hard steel;[1] but the effects are smaller with hard than with soft bars.

ffect of ‹nsion.

It was found that longitudinal compression of the bar influenced the magnetic extension little if at all; on the other hand, longitudinal traction was found to diminish it, and in the case of thin wires under considerable tension the magnetization caused a contraction. Thus in the case of a bar 1 foot long, $\frac{1}{4}$ inch in diameter, with a weight of 600 lb, there was neither extension nor contraction, even with a current of 1600; with weights of 1040 lb and 1680 lb, and a current of 1804, there was a contraction of ·00002 inch and ·000032 inch respectively. The contraction under tension was found to vary approximately as the product of the magnetizing current and the intensity of magnetization. After the magnetizing force was withdrawn the wire regained its original length, permanent magnetization notwithstanding.

ʼo alteration of olume.

Joule made careful experiments to determine whether the magnetization of an iron bar produced any alteration of its volume, but could find none. He therefore concluded that the longitudinal extension of a magnetized bar is accompanied by an equal lateral contraction; and, in accordance with this conclusion, he found that when an iron tube is circularly magnetized, perpendicular to its length, by passing a current along its axis, it contracts longitudinally.

The results of Joule have been verified and to some extent added to by Wertheim,[2] Buff,[3] Beez,[4] Tyndall,[5] Mayer,[6] Righi,[7] and Ader.[8] The three first experimented with magnetizing coils shorter than the bar, and found that the extension was much greater when the coil was near the free end than when it was near the fixed end of the bar. This of course raises the question how far the extension is due to electromagnetic action between the coil and the bar, and how far to internal molecular disturbance.[9] Mayer's results are in agreement with Joule's except in the case of bars of soft steel, which (not under traction) when the magnetizing current was first established, elongated in some cases and retracted in others,—at the first break elongated, and subsequently retracted at make and elongated at break. Righi's results for longitudinal magnetization are in agreement with those of Joule; he also gives a variety of interesting results regarding the effects of circular and longitudinal magnetization on the length of iron wires. Barrett[10] has recently arrived at the interesting result that nickel behaves oppositely to iron,—retracting about $\frac{1}{130000}$th when magnetized to saturation; he gives for the elongation of iron and cobalt under like circumstances $\frac{1}{200000}$th and $\frac{1}{425000}$th respectively.

Effect of traction on magnetization. Matteucci.

Effect upon Magnetization of Traction along the Lines of Magnetization.—Matteucci[11] seems to have been the first to discover that when a bar subject to a magnetizing force in the direction of its length is stretched in the same direction its temporary magnetization increases. When the stretching force is removed the magnetization again diminishes. Wertheim[12] confirmed Matteucci's observation.

Villari.

Villari,[13] however, found that, after the first effect, which is always increase, the application of the traction will cause increase if the intensity of magnetization is not beyond a certain critical value, but decrease if that value is surpassed; the removal of the traction causes in each case the opposite effect to the application.

The effect of the first traction on the permanent magnetization, whether of iron or steel, is a diminution; the effect of subsequent tractions in steel is a diminution on application, with increase on removal; in soft iron an increase on application, a diminution on removal. Partial demagnetization of a steel bar by an opposite magnetic force causes it to behave like soft iron; when the demagnetizing force is sufficient to reverse its polarity, the effect of even the first traction may be to increase the magnetization.

Thomson.

Sir W. Thomson[14] has carefully studied the phenomena in question, as exhibited in a very soft iron wire ·075 cm. in diameter permanently stretched by a weight of 1 lb, and alternately stretched by weights of 7 lb, 14 lb, or 21 lb, and unstretched (so that there was no permanent elongation). As the magnetizing force was increased, the increase of magnetization caused by the application of traction increased to a maximum, then diminished, and became zero for a certain critical value of the magnetizing force; after the critical value was passed, the traction caused a diminution of the magnetization, which increased asymptotically towards a fixed limit as the magnetizing force was increased more and more. The following table will give an idea of the results.

I denotes the maximum increase, and D the limit of the decrease, roughly estimated in the same arbitrary unit; $\mathfrak{H}'$ is the force corresponding to I, and $\mathfrak{H}_0$ the critical force, each expressed in terms of the earth's vertical force at Glasgow as unit; T is the traction, t the temperature.

T	t	I	D	$\mathfrak{H}'$	$\mathfrak{H}_0$
7	Ord.	+31	–6	5·9	34
...	100°	+26	–3	6·4	35
1	Ord.	+35	–14	4·8	25
...	100°	+32	–9	4·5	25
21	Ord.	+54	–21	4·5	26
...	100°	+51	–15	5·0	29

Bars of nickel and cobalt were also examined; and it was found that after the first effect the result of applying traction in the direction of magnetization was in both cases to *diminish* the magnetization. The effect appeared to increase up to a maximum, and then to diminish as the magnetizing force increased; but the critical value was not reached with the largest forces employed.

Traction perpendicular to the lines of magnetization was found by Thomson to diminish the magnetic susceptibility. The experiment was made by means of a gun barrel magnetized longitudinally, and subjected to internal hydrostatic pressure.

The effect of pressure along or perpendicular to the magnetization would in all probability be opposite (and equal?) to that of an equal amount of traction; but no experiments have as yet been made on the subject.[15] The effect of traction is therefore to produce magnetic æolotropy, the susceptibility being increased in the direction of the stress and diminished in the perpendicular direction so long as the intensity of magnetization is not above a certain critical value; above that value the effects are reversed. The effect of pressure would be opposite in every particular. Hence the effect of a shearing stress would be increase of magnetic susceptibility along the principal axis of elongation, and decrease (to an equal extent?) along the principal axis of compression.

[1] In the case of a bar of hard steel he found a considerable increase in length every time the magnetizing current was interrupted. This he attributes to a state of "tension" in the hardened steel.

[15] Pressure applied outside Thomson's gun barrel would enable us to observe the effect of transverse pressure; and by magnetizing the barrel circularly the effect of pressure along the lines of force could be determined.

Wiedemann. Torsion and magnetization.

Relations between Torsion and Magnetization.—These were investigated by Matteucci,[1] and after him by Becquerel and Wertheim.[2] The whole subject was carefully studied by G. W. Wiedemann,[3] who has done more than any living physicist both in discovering new facts in this interesting field and in coordinating those formerly known. We extract from his *Galvanismus* [4] the following series of parallel statements, which will serve the double purpose of making the reader acquainted with the principal facts, and of drawing his attention to the close analogy between the mechanical and magnetic properties of bodies, and to the almost perfect reciprocity of their experimental laws.

Parallel statements for strain and magnetization.

1. The permanent torsion of iron wires is diminished by magnetization in a proportion decreasing with increasing magnetization.	I. The permanent magnetization of steel bars is diminished by torsion in a proportion decreasing with increasing torsion.
2. Repetition of magnetization in the same direction diminishes permanent torsion very little farther; but magnetization in the opposite direction causes a fresh and considerable diminution.	II. Repetition of torsion in the same direction diminishes permanent magnetization very little farther; but torsion in the opposite direction causes a fresh and considerable diminution.
3. When the permanent torsion of a wire has been removed as far as it can be by magnetizations within certain limits repeated alternately in opposite directions, it takes a maximum of torsion when magnetized in one direction, a minimum when magnetized in the other direction.	III. When the permanent magnetization of a bar has been removed as far as it can be by twisting within certain limits repeated alternately in opposite directions, it takes a maximum of magnetization when twisted in one direction, a minimum when twisted in the other direction.
4. A permanently twisted wire partially untwisted loses less of its twist when magnetized than an ordinary permanently twisted wire. If the untwisting has been considerable, feeble magnetization causes an increase of torsion, which rises to a maximum and then decreases as the magnetization is increased. The greater the untwisting the stronger the magnetization corresponding to this maximum, and, when the untwisting is very great, the maximum may not be reached at all.	IV. A permanently magnetized bar partially demagnetized loses less of its magnetization when twisted than an ordinary permanently magnetized bar. If the demagnetization has been considerable, feeble twist causes an increase of magnetization, which rises to a maximum and then decreases as the twist is increased. The greater the demagnetization the greater the twist corresponding to this maximum, and, when the demagnetization is very great, the maximum may not be reached at all.
5. If a wire under the influence of a twisting stress is magnetized, the twist increases with weak but decreases again with strong magnetization. The first effect of magnetization is usually to increase the twist; but, if the wire be jarred beforehand, the magnetization at once causes untwisting, which disappears when the magnetization ceases.	V. If a bar under the influence of a longitudinal magnetizing force is twisted, the magnetization increases with small twists but decreases again with large twists. The first effect of twisting is usually to increase the magnetization; but, if the bar be jarred beforehand, the twist at once causes a decrease, which disappears when the twist ceases.
6. If we magnetize an iron wire so that its free end has north polarity, and then pass a current from the fixed to the free end, or first pass the current and then magnetize, the free end of the wire as seen from the fixed end twists in the direction of the hands of a watch. The reversion of current or of magnetization reverses the twist; reversion of both leaves it unaltered.	VI. If we twist the free end of a wire in the direction of the hands of a watch as seen from the fixed end, while a current from fixed end to free end either is passing through it or has passed through it, the wire becomes longitudinally magnetized so that its free end has north polarity. The reversion of current or of twist reverses the magnetization; reversion of both leaves it unaltered.
[It would appear that when the magnetizing force and the current are both in action the twist tends to a maximum when either is increased, the other remaining constant.]	

The alterations of the longitudinal and circular magnetization of iron wires may be shown by the induced currents thereby caused in a coil surrounding the wire or in the wire itself. For example, if an iron wire be circularly magnetized by passing a current through it, and then twisted in either direction, an induction current flows through the wire in the same direction as the original current; and an opposite current is observed when the wire is untwisted again. This shows that twisting the wire diminishes the permanent circular magnetization, while untwisting partially restores it.[5]

The relation between bending stress and magnetization has been studied by Guillemin,[6] Wertheim,[7] Ader,[8] and Kimball;[9] but the results are not of sufficient interest to be cited here. The question has also been raised whether magnetization affects the elasticity of bodies, and has been answered by Wertheim and Wartmann in the negative. Both Kimball[9] and Piazzoli[10] find that the breaking tension of iron wires is increased by longitudinal magnetization; the former puts the increase at 0·9 per cent. when the wire is saturated.

Magnetic sounds.

This is the place to mention the so-called "magnetic sounds" which accompany the magnetization and demagnetization of the strongly magnetic metals. It is now established beyond all doubt that these sounds have their origin partly at least in the mechanical strains accompanying magnetization. In many cases direct magnetic or electromagnetic action, and even electrostatic and thermal actions, concur in producing them, and it is often difficult to say how much is due to each of these several causes. This is especially to be observed where the sounds are produced by the passage of interrupted or undulatory currents through wires of the strongly magnetic metals. A full discussion of the matter belongs more properly to the subject of electric telephony; but a few notes on the history and literature of the subject may be given here.

Page[11] seems to have been one of the first to notice phenomena of the kind; but Joule[12] appears to have first stated clearly that magnetic-mechanical strain was a specific cause. He says that the magnetic extension in the core of an electromagnet takes place so suddenly that the shock is sensible to the touch, and is accompanied by a musical note arising from vibration in the metal. Marrian,[13] Matteucci,[14] Beatson, and Wertheim[15] all took up the matter; and De la Rive[16] published many investigations concerning it. In 1861 Reiss published the invention of an electric telephone for the transmission of music and speech, which depended essentially on the magnetic sounds produced by a varying current in an iron core. This instrument was the prototype of the telephone of Gray, and of the still more famous instrument of Bell, whose action, although often described as purely electromagnetic, is no doubt in part due to the magnetic strains. Among the more recent investigations on this subject may be mentioned Ferguson, *Proc. Roy. Soc. Edin.*, 1878 and 1880; Ader, *Comptes Rendus*, 1879; Du Moncel, *Ib.*; Chrystal, *Nature*, vol. xxii., 1880; Hughes, *Proc. Roy. Soc. Lond.*, xxxi. and xxxii., 1881.

Effects complex.

General Remarks.—Wiedemann has remarked with justice that most of the effects of strain upon magnetization and *vice versa* are complex. Apart from the possible admixture of direct magnetic action, we must distinguish (1) the mere disturbing effect of jarring: thus the first application of a mechanical stress has the same effect as a shock, *i.e.*, it loosens the molecules of the body, as it were, and renders them more ready to follow any inductive magnetic force, while the first effect of magnetization upon a body under stress is precisely similar, and may in fact be imitated by mechanical jarring pure and simple; (2) after-effect, whether mechanical or magnetic, the consequence of which is that the effect due to any mechanical stress or magnetizing force is affected by pre-existing stress and magnetization; (3) the proper effect of mechanical stress or magnetic force, which appears at once where one or the other is applied, and disappears when it is removed.

heory mole- lar agnets.

In his excellent analysis of the phenomena, Wiedemann coordinates them throughout by means of an extension of Weber's theory of "molecular magnets" (*Drehbare Molecularmagnete*). This of course involves an attempt to pass beyond the mere results of experience; and there can be no question that, on the whole, this theory explains the facts in a highly instructive and suggestive manner. The main defect in it is the multitude of assumptions and the want of clearness and definiteness in its conclusions. Thus it is sometimes not easy to see why exactly the opposite conclusion should not be drawn; and it appears hopeless to bring it to the test of a quantitative comparison with experiment.

ossible on- exion etween ne ifferent he- omena.

Without entering into the ultimate causes of magnetism, we might endeavour to reduce the phenomena to the smallest number of experimental facts. Thus, assuming merely the effects of longitudinal and transverse traction upon magnetization and the magnetic extension and compression along and perpendicular to the lines of magnetization, we might explain many of the results concerning the relation between torsion and magnetization.

Let us take for example No. VI. of Wiedemann's parallel statements. In fig. 44 let the upper end of the wire be the fixed end, and let P be a point in any of the thin coaxal cylindrical shells into which the wire may be supposed divided. First suppose the wire to be circularly magnetized by the action of a downward current, the resultant magnetic force at P being in the horizontal direction PB. If now the wire be twisted in the direction of the arrow T, it acquires two axes of greatest and least magnetic susceptibility P*e* and P*r*. The resultant magnetic force PB being resolved along these axes will induce more magnetism along P*e* than along P*r*; hence the æolotropy will cause the resultant magnetization to take the direction PB′; it will therefore have a positive vertical component downwards, which agrees with statement VI. In fact the twisting converts the circular lines of magnetization into right-handed helices.

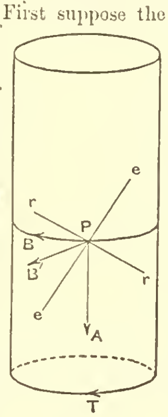

Fig. 44.

Next let us suppose the wire untwisted to begin with, but magnetized both circularly and longitudinally, the components being PB and PA. The resultant magnetization will then have some direction such as P*e*, but, by Joule's principle, this will cause extension along P*e* and compression along the perpendicular direction P*r*; consequently the wire will twist in the direction of the arrow T, which agrees with statement 6. Moreover, since magnetization along PB alone would simply cause the tube to expand along a horizontal section, and magnetization along PA alone would simply cause longitudinal extension, it is clear that when either A or B is given the twisting reaches a maximum and then diminishes when the other is increased.[1]

It does not seem unreasonable to expect that a general mechanical theory of this kind will yet be found to coordinate all the facts; although there are difficulties in its way at present.[2] The phenomena will then be reduced to two or three experimental facts at the utmost, which it will be the business of some ultimate dynamical theory of magnetism to explain.

Effect of Temperature.—Some information on this subject has been given incidentally above, p. 256. We collect here a few additional facts; but a complete account of all that has been done could not be compressed within our available space, owing to the great diversity of opinion upon the subject. That the question is a very difficult one will appear at once, if we reflect that variations of temperature influence the density and molecular structure of magnetic bodies to a remarkable degree, and that thus secondary influences arise in addition to the proper effect of temperature.

That very high temperatures destroy both the magnetic susceptibility and the power of retaining magnetism altogether has been known since the infancy of magnetic science. Thus Gilbert found that a loadstone and a piece of iron equally lost their power of affecting the magnetic needle when heated very hot, and remarks that the magnetic property returns to the iron after it has cooled a little, but that the magnetic virtue of the loadstone is altogether destroyed.[3] Similar results were obtained by Brugmans, Boyle, Cavallo, Barlow and Bonnycastle, Christie, Ritchie, Erman, Scoresby, Seebeck, and others. Faraday[4] found that a steel magnet lost its permanent magnetism rather suddenly at a temperature a little under the boiling point of almond oil; it behaved like soft iron till it was raised to an orange-red heat, and then it lost its magnetic susceptibility and became indifferent. The temperature at which retentive power for permanent magnetism was lost appeared to vary in steel with the hardness and structure; in fragments of loadstone it was very high: they retained their permanent magnetism until just below visible ignition in the dark, but, on the other hand, they lost their susceptibility at dull ignition, *i.e.*, at a much lower temperature than iron. Nickel was found to lose its magnetic susceptibility at a much lower temperature than iron, viz., about 330° to 340° C.[5] Cobalt is much more refractory, for it retains its susceptibility, according to Faraday, nearly up to the melting point of copper, *i.e.*, to a white heat. The writer had occasion to verify these results in the course of some experiments on the magnetic sounds in wires of iron, nickel, and cobalt traversed by an interrupted current of electricity.[6]

Destruction of magnetism by very high temperature.

The effect of extreme cold, produced in the ordinary way by means of solid carbonic acid and ether, was, according to Trowbridge,[7] to diminish the moment of a steel magnet (magnetized at 20° C.) by about 60 per cent.

Effect of extreme cold.

The effect of moderate alteration of temperature varies greatly according to circumstances. We shall consider separately the effect upon the magnetic susceptibility and upon the permanent magnetism; but it must be noticed that no such separation is possible in actual experiment.

Moderate variations of temperature.

The temporary magnetism of bars of cast iron, smithy iron, soft iron, soft steel, and hard steel magnetized by the earth's vertical force was found by Scoresby[8] to be insensible at a white heat, but to be much greater at a dark red heat than at the temperature of the air. The difference was most marked in the case of hard steel, no doubt partly because of the softening of the bar. Similar experiments were made by Barlow, Seebeck, and others. Kupfer[9] experimented on the subject using variations of temperature between 0° and 100° C., and found the susceptibility of soft iron to increase with the temperature. Wiedemann's conclusion is that the first alteration of temperature, whether increase or decrease, increases the temporary magnetism of iron or steel, whatever the temperature at starting. If the temperature be repeatedly altered and brought back to its initial value, the magnetization continues to increase, but after a time becomes more and more nearly constant at the initial temperature. After this state has been reached, an increase of temperature causes increase of magnetization in very hard steel bars, a decrease of temperature a decrease of magnetization; the behaviour of soft steel bars is exactly opposite.

Effect on magnetic susceptibility.

Wiedemann's results.

[1] According to the results of Villari and Thomson, if the magnetization were beyond a certain critical value, P*e* would become an axis of compression and P*r* an axis of extension, in which case the wire would twist in the opposite direction.

[2] See Thomson, *Phil. Trans.*, 1879, p. 73. Not the least of these arise from gaps in our experimental knowledge; *e.g.*, regarding the effects of *permanent set* caused by traction and compression.

Baur's results.

Baur[1] and Wassmuth[2] have recently taken up the matter with all the advantages of modern experience. The former concludes from his experiments on iron by the ring method, at temperatures between 0° and 150° C., that the magnetic susceptibility for a given magnetizing force increases with the temperature if the force be below a certain critical value (3·6 or so), but decreases as the temperature increases if the force be above that value.[3] The smaller the magnetizing force the greater the influence of temperature on the magnetic susceptibility. The result of his experiments at very high temperatures is that, for small magnetizing forces, the susceptibility at first increases rapidly as the temperature increases, reaches a maximum at red heat, and then falls suddenly to zero. For large forces, the susceptibility decreases gradually until red heat, and then falls suddenly to a very small value. According to him, if a bar be cooled from white heat the first traces of susceptibility are observed at a very bright red, the brighter the greater the magnetizing force. He gives a variety of interesting results concerning the phenomenon of Gore,[4] all in accordance with what we have just stated.

Diamagnetism of flame.

In his earlier researches Faraday was unsuccessful in obtaining any evidence of the influence of temperature on the susceptibility of weakly magnetic bodies, such as the chlorides of the magnetic metals or of diamagnetic bodies.[5] His earliest results were obtained with gases, and that too, strange to say, before the magnetic character of gases was fully investigated. It was Bancalari's discovery of the extraordinary behaviour of flame between the poles of an electromagnet that led Faraday to resume his magnetic experiments on gases. Flames of all descriptions are strongly repelled from the axial line of a heterogeneous magnetic field,—so much so that it is impossible to induce the flame of a candle to go between the pointed poles of a powerful electromagnet when they are placed at a short distance apart. The flame is blown aside, or even downwards, as if by a strong current of air issuing from between the poles. If a flat pointed flame is placed with its centre a little below the axial line, when the magnet is excited it drops down and spreads out below and around the axial line, assuming a fish-tail shape. It appears that the effect is not due to the solid matter in the flame but simply to the hot gases in it; for the upper and cooler part of the stream of smoke from a freshly extinguished taper is scarcely affected, while the lower and hotter part is most powerfully acted upon, being blown aside and often split into two independent streams. A careful investigation led Faraday to the conclusion that oxygen, carbonic acid, and coal gas are rendered more diamagnetic, or, what is the same thing so far as the resultant differential action is concerned, less magnetic by heat,[6] and that this effect was much greater than could be accounted for by the mere rarefaction of the gas. He likewise obtained an increase of the susceptibility of oxygen by cooling it with ether and solid carbonic acid. Nitrogen appeared to be altogether indifferent.

Bancalari.

Faraday's experiments on heated gases.

Effect of heat on susceptibility in weak magnetics.

He found in a later series[7] of experiments that the magnecrystallic property of bismuth was destroyed at a temperature a little below its melting point, and that the same thing happened to crystalline antimony a little below red heat. In the thirtieth series of his experimental researches he states that between 35° and 142° C. the susceptibility of a specimen of spathic iron ore perpendicular to its magnetic axis decreased by ·333 per cent. per degree centigrade of rise of temperature; this agrees very closely with the formula which was found by Wiedemann to represent very approximately the temperature effect for salt solutions, viz., $k_t = k_0(1 - \cdot 00325\, t)$. For the decrease in the magnecrystallic couple, or, which is the same thing, in the difference between the susceptibilities along and perpendicular to the magnetic axis, he found for the spathic iron ore ·482 per cent. between 0° and 138° C., and the percentage of decrease was four times as great between −14° and 0° as between 129° and 143°. The corresponding decrease in the case of crystalline bismuth between 36° and 137° C. was ·53 per cent. The experiments of Plücker and Matteucci led them to conclude that the susceptibility of diamagnetics diminishes with increase of temperature; in the case of bismuth the decrease between ordinary temperatures and its melting point is said to be about one-sixth or more.

Effect of heat on permanent magnetism.

Canton seems to have been one of the first to study the effect of moderate variations of temperature on the permanent magnetism of iron and steel. The results of his and Hallström's experiments went to show that permanent magnetization decreases when the temperature rises, and increases again when the temperature falls. In reality, however, as was shown by Kupffer, Riess and Moser, G. Wiedemann, and others, the phenomenon is complicated; for, if we repeatedly heat a magnet and allow it to cool to its initial temperature, the magnetization lost at each heating is only partially recovered on cooling, and thus a progressive loss goes on, until at last a constant state is reached, in which the magnetization lost on heating is completely recovered on cooling. In this respect, as well as in the effect on the magnetic susceptibility already discussed, there is an analogy between the effect of temperature and the effect of strain; *i.e.*, there is a first or permanent effect and a proper or temporary temperature effect. The permanent effect is that any alteration of temperature, be it increase or decrease, diminishes the permanent magnetization just as a shock or a jar would do, and probably for a similar reason. The proper or temporary effect consists in a decrease of magnetization with increase of temperature, which is completely recovered on decrease of temperature and *vice versa*.[8] If this be borne in mind, together with what has already been said above, it will not be difficult for the reader to see that the order and amount of the temperature variations, the hardness and form of the bar, and its magnetic history will all influence the temperature coefficient.

First and permanent effect.

Proper temporary effect.

To take one example, Wiedemann found that a bar magnetized at 0° C. and then partially demagnetized by an opposite force, lost magnetism when heated; if the demagnetization was not carried too far, it did not when cooled again to 0° wholly recover what it had lost. If the demagnetization was carried a certain length, it recovered all that it had lost; if farther still, more than it had lost. It was in fact found possible to demagnetize a bar, so as to render it apparently unmagnetic, and then to restore part of its original magnetism by merely heating and cooling it again. Similar phenomena were observed with a bar magnetized and demagnetized at 100°, and then alternately cooled and heated. Unverdorben,[9] who arrived somewhat later at similar results, represents the matter by saying that the bar in this case has two magnetizations superposed, each having its own temperature coefficient.

The following are a few additional references to sources of information concerning the present subject: Mauritius, *Pogg. Ann.*, 1863, and *Phil. Mag.*, 1864; Jamin and Gaugain, *Comptes Rendus*, *passim*; Favé, *Ib.*, 1876; Poloni, *Wied. Beibl.*, 1878.

om- r's iclu- ns.

Development of Heat during Magnetization.—Reasoning on purely thermodynamic principles from the results of Faraday, as to the influence of temperature on the magnetic properties of bodies, Thomson[1] has concluded—(1) that a piece of soft iron at a moderate or low red heat, when drawn gently away from a magnet, experiences a cooling effect, and, when allowed to approach, a heating effect, and that nickel at ordinary temperatures and cobalt at high temperatures (between the melting point of copper and some lower temperature) experience the same kind of effect; (2) that cobalt at ordinary temperatures and up to the temperature of maximum permeability experiences a cooling effect when allowed to approach a magnet, and heating when drawn away; (3) that a crystal in a magnetic field experiences cooling when the axis of greatest paramagnetic or of least diamagnetic susceptibility is turned from along to across the lines of force, and *vice versa*.

xperi- ental ffi- ılties.

Besides these considerations, the fact that those who adopt the molecular magnet theory are obliged to assume something of the nature of a frictional resistance to the turning of the magnetic molecules, and generally, without reference to any particular theory, many of the phenomena of coercive force,[2] lead us to suppose that some specific development of heat may accompany magnetization and demagnetization. The experimental verification of this suspicion is, however, a matter of great difficulty, owing to the enormous generation of heat arising secondarily from induced currents in the mass of the metal. The development caused by magnetization and demagnetization was taken advantage of by Joule in one of his determinations of the mechanical equivalent of heat, but he makes no attempt to separate the effect of the two causes, indeed it did not concern his purpose to do so.[3] Notwithstanding that several experimenters have attacked the problem, it cannot be said that it is yet completely solved. It will therefore be best simply to call the reader's attention to some of the papers that have been published on the subject, and leave him to form his own judgment.

'hermal onduc- ivity.

Miscellaneous Relations of Magnetism to other Physical Properties.—According to Maggi[4] the thermal conductivity of magnetized iron is less along the lines of force than across them. Naccari and Bellati[5] were unable to verify this result; Tomlinson,[6] however, found that the conductivity of iron and steel bars was diminished by longitudinal and increased by transversal magnetization.

Electric onduc- ivity.

Abraham, Edlund, Mousson, and Wartmann all made experiments in search of a magnetic alteration of the electric conductivity of iron. Thomson seems, however, to have been the first to arrive at any definite result.[7] He found the conductivity to be diminished along the lines of magnetization and increased across them. Beez[8] verified the former result, but doubts the latter, which he is inclined to explain as a secondary effect caused by the compression of the iron arising from the external magnetic action on the plates used in Thomson's experiments.

Thermo-electro-motive force.

Thomson also found[9] that the thermoelectric quality of iron was affected by magnetization; the thermoelectric current flowed from unmagnetized to longitudinally magnetized, and from transversely magnetized to unmagnetized or longitudinally magnetized iron through the hot junction. In the case of nickel, the current flowed from longitudinally magnetized to unmagnetized through the hot junction, *i.e.*, nickel behaved oppositely to iron. Thomson's results have been in part confirmed by a recent investigation of Strouhal and Barus.[10]

Magnetism and light.

A relation between magnetism and light was first established by Faraday's discovery of the magnetic rotation of the plane of polarization of a ray passing along the lines of force. This subject belongs more properly to physical optics, but there is one magnetic phenomenon apparently closely connected with it which falls to be mentioned here. This is Hall's discovery[11] that, if an electric current flow in a thin metallic strip in a direction AB, the effect of placing the strip in a magnetic field with its plane perpendicular to the lines of force is to cause a transverse electromotive force perpendicular to AB, which changes in sign when the direction either of the current or of the magnetic field is changed. This transverse electromotive force is proportional to the product of the current intensity and the strength of the magnetic field; *cæteris paribus*, its direction in the case of iron is opposite to that in other metals, and its magnitude is also greatest with iron. This discovery establishes the existence of the rotatory coefficient of resistance mentioned by Maxwell[12] in his discussion of æolotropic conductivity; and Rowland has shown that the phenomenon is probably due to the same cause as the magnetic rotation of the plane of polarization.[13]

Hall's phenomenon.

Effect of time.

If, as modern physicists suppose, magnetism be a dynamical phenomenon, time must enter as a conditioning element. The question has been raised how long any magnetizing force takes to develop the maximum magnetization that it is capable of producing. There are many facts that go to prove that this time is very small, or, at all events, that any force develops a very large fraction of the total magnetization due to it in a very short period of time. Perhaps the most wonderful evidence on this head is the fact that the telephone, which depends essentially on varying magnetic action, can reproduce the sounds of human speech even to the consonants.[14] Experiments bearing directly on the subject have been made by Villari.[15] A flat circular disk of flint glass was placed between the poles of a Ruhmkorff's apparatus for measuring the magnetic rotation of the plane of polarization. The axis of the disk was perpendicular to the axial line, so that rotation brought the different radii successively into the line of sight. When the disk was at rest the magnetic action in one experiment caused a rotation of 19 divisions; spinning the disk at the rate of 110, 121, 143, and 180 turns per second reduced the magnetic rotation of the plane of polarization by 2, 5, 10, and 17 divisions respectively; the reduction was less the greater the magnetic force. From this Villari concluded that in flint glass not less than 0·001244 second is required to produce such a diamagnetic intensity as can be observed by the rotation of the plane of polarization, and that 0·00241 second at least is required to develop the greatest diamagnetization of which this substance is capable; he also states that the diamagnetism lasts for less than 0·00018 second after the inducing force is withdrawn. A series of interesting experiments on the oscillation of the plane of polarization caused by the oscillatory discharge from a Leyden jar recently made by Bichat and Blondlot[16] led them to a different conclusion, viz., that if any lagging of the induced magnetization behind the magnetizing force

exists it is less than 0·000033 second. No explanation has been given of the discrepancy of these results.

Direct influence of light upon magnetization. In the early part of this century there was an animated controversy as to whether light exerted a direct influence upon magnetization, in which Morichini, Mrs Somerville, Christie, Riess and Moser, and many others took part. Nothing definite, however, was established. A similar fate befell the attempts to trace the influence of magnetic force upon crystallization, and to detect a relation between magnetism and gravity,[1] although both quests at one time or another engaged the skill of Faraday.

Forms, Construction, and Preservation of Magnets.

This subject occupied a large portion of most of the earlier treatises on magnetism. Much of the information given, however, either has now been recognized to be of questionable value or has been superseded by recent progress, and retains a merely antiquarian interest; a few brief remarks, mainly historical, will therefore be sufficient.

Loadstones. The oldest form of magnet was a piece of magnetic iron ore or loadstone. The power of these natural magnets varied exceedingly from one specimen to another. An elaborate discussion of the various kinds of loadstone will be found in Gilbert's *De Magnete.*[2] In order to increase the carrying power, the loadstone was usually fitted with armatures of soft iron upon its polar regions; figure 45, taken from Gilbert, represents one of the oldest arrangements.

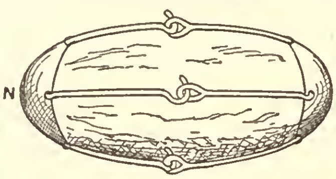

Fig. 45.

Figure 46 is taken from a loadstone in the collection of physical apparatus belonging to the university of Edinburgh, the carrying power of which is 205 ℔. A loadstone in the Teylerian Museum at Haarlem has a carrying power of 230 ℔; and one at Lisbon, presented by the emperor of China to King John V. of Portugal, is said to support as much as 300 ℔. Small loadstones are often very powerful in proportion to their weight; *e.g.*, Newton is said to have worn in a ring one that weighed only 3 grains, and yet was able to carry about 746 grains; and one in the physical collection at Edinburgh, formerly belonging to Sir John Leslie, weighing itself $3\frac{1}{2}$ grains, had at one time a carrying power of 1560 grains.

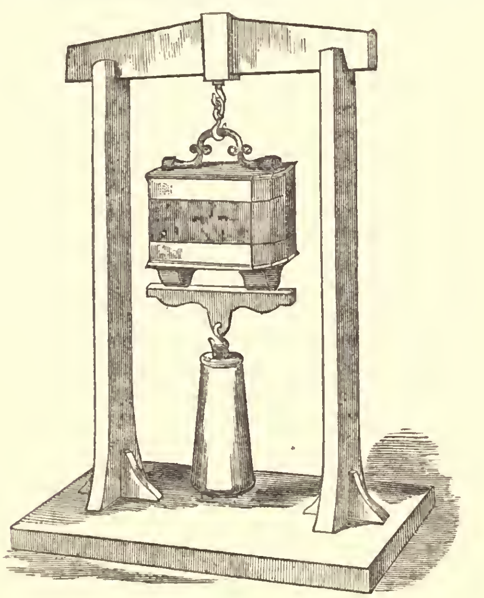

Fig. 46.

Steel magnets. The introduction of steel magnets, and the perfection to which they were gradually brought, caused the loadstone to fall into disuse. It is said that Galileo possessed the art of making steel magnets about the beginning of the 17th century. It was early discovered that the earth's force could be utilized in magnetizing steel. Gilbert was aware that a feeble magnetization could be produced in this way; and Michell, in his treatise on artificial magnets, minutely describes how weak magnets may be made by means of the earth's force, then combined into bundles or "magazines" and used in turn to produce stronger magnets, these used to produce still stronger, and so on.

Single touch. The earliest process of all was no doubt the method of rubbing or touching by another magnet. This method of making magnets was studied with much attention by the natural philosophers of the 18th century, among whom we may mention Savery, Knight, Duhamel, Le Maire, Canton, Michell, Æpinus, Coulomb, and Euler. The method of single touch consists simply in stroking the bar to be magnetized alternately on its two halves with the south and north poles of a loadstone or bar magnet, the stroke beginning always at the middle and ending at the end. According to Lamont, the best plan is to lay the magnet flat, overlapping one half of the bar to be magnetized, and then draw it off; when the magnet is held perpendicular to the bar during the process, the result is apt to give an irregular magnetization: *e.g.*, we may even get a magnet with its two ends north poles and with a south pole in the middle, or one with four poles, a north and south pole at the two ends and a south and north pole in the middle.[3]

Double touch. The first improvement on single touch was double touch with separate magnets. This consists in using two magnets simultaneously on the two halves of the bar undergoing magnetization. The north pole of one and the south pole of the other are placed either close together, or at a small distance apart near the middle of the bar, and then each is drawn towards the end of the half on which it lies; according to Lamont, here, as in single touch, the magnets should be laid flat on the bar.[4] Michell introduced the further improvement of using two bar magnets (or bundles of such) fastened together and kept parallel at a small distance apart by means of small pieces of wood, the north pole of one being conterminous with the south pole of the other. This pair is placed vertical with one end on the middle of the bar, drawn towards one end and slipped off, then replaced on the middle and drawn to the other end, and so on alternately until the moment of the bar ceases to increase any farther. Instead of the pair of bar magnets a horse-shoe magnet might of course be used.

Le Maire[5] introduced the essential improvement of placing the bar to be magnetized upon a larger bar, and then magnetizing the two together. The advantage of this is best seen in the form of the same device adopted by Canton[6] and Duhamel,[5] who magnetized steel bars in pairs, connecting them up parallel to each other by means of two pieces of soft iron, and then magnetizing them in opposite directions. It is easy to see that the magnetization of the one reacts on the magnetization of the other and strengthens it. Michell[7] obtained a similar advantage by magnetizing a number of bars placed end to end in a line; he found, as was to be expected, that the end bars were weaker, but this defect he remedied by repeating the process with the bars arranged in a different order. Coulomb's method was to place the ends of the bar on the north and south poles of two bar magnets arranged in line at the proper distance apart. This process of connecting up the bars to be magnetized in a closed magnetic circuit is sometimes called circular touch; it can be applied to horse-shoe magnets by placing a pair of them with their ends together, and then passing round and round upon them a horse-shoe magnet or a pair of bar magnets arranged as already described.[8]

Electromagnets. Immediately after Œrsted's discovery of the magnetic action of the galvanic current, Arago,[9] Boisgiraud,[10] and Davy almost simultaneously applied this property to the magnetization of iron and steel.[11] Powerful electromagnets, with cores of soft iron, were first constructed a few years later by Sturgeon and Brewster. Pohl, Moll, and Pfaff in Germany, and Henry and Ten Eyck in America, may be mentioned as the most successful of the early constructors. One of the electromagnets of Henry and Ten Eyck reached a carrying

[3] Poles situated abnormally in this way are called "consecutive points."

[4] This method appears to have been invented by Knight (about 1740), and used in producing the powerful magnets for which he was famous. The secret of his process was never divulged by himself, but was published by Wilson after his death. See art. Magnetism, 8th edition of *Encyclopædia Britannica.*

power of 2061 lb; but magnets specially constructed for carrying power have surpassed this limit. As a specimen of scientific toys of this description may be mentioned the electromagnet of Roberts (fig. 47), which consists of a square block of iron deeply slotted with four parallel grooves into which three layers of copper wire cable are wound in zigzag fashion so that the current converts the flanges alternately into north and south poles; the armature is a square block planed to fit the face of the magnet. The carrying power of a machine of this kind was 2949 lb, *i.e.*, more than $1\frac{1}{2}$ tons!

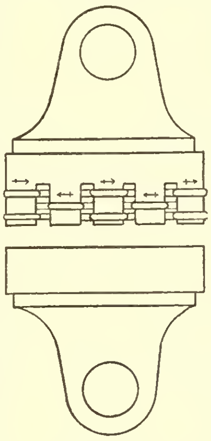

Fig. 47.

The forms of electromagnet used in the arts, *e.g.*, in electric bells, fire alarms, telegraphs, telephones, electric light regulators, dynamo machines, &c., are simply innumerable. It will be sufficient to allude to those constructed for the purpose of producing an intense magnetic field, uniform or non-uniform, over a larger or smaller area; these find their practical application in the construction of dynamo-electric machines, but they are mainly interesting to purely scientific men on account of their use in the investigation of the properties of weakly magnetic bodies. Figure 40 shows the usual arrangement adopted for large laboratory magnets. In considering the greatest available strength of such magnets, it is necessary to bear in mind the fact that magnetic saturation of iron is practically reached with magnetic forces much under the greatest that we can command. The strength of field in a narrow crevasse perpendicular to the lines of magnetization in saturated iron is less than 18,000 C.G.S. units;[1] and this is practically the utmost at present attainable, for any addition to the strength of the field, arising from direct action of the magnetizing helix, would not under ordinary circumstances affect the hundreds in this number. Further increase of magnetizing current after we have reached within a small percentage of the limit of saturation is a waste of power.

[Magnet]ization [by el]ectric [cur]rent. Elias[2] of Haarlem seems to have been the first who applied the electric current directly with success in the manufacture of powerful permanent magnets. He used a short flat magnetizing coil which was pushed backwards and forwards along the bar, the ends of which were caused to abut against two pieces of iron, which becoming inductively magnetized reacted on the bar, and also served to keep the magnetization at the ends more uniform. The famous Logeman magnets were constructed by this process.

[Ma]gnet[iza]tion [by me]ans [of a]n [ele]ctro-[ma]gnet. By far the most convenient way of magnetizing steel is to use an electromagnet.[3] The bar to be magnetized may be laid flat on the pole of the magnet before it is excited, and after excitation drawn slowly off. By repeating this process several times, with the north pole of the electromagnet for one half and the south pole for the other half, saturation can be very quickly obtained. Perhaps a better plan is to lay the bar with its ends on the two poles, and then excite the electromagnet. For reasons already sufficiently explained, it is advisable to hammer the bar with a mallet while the magnetizing force is in action, and to turn the current off and on several times in succession.[4]

[La]mi[nat]ed [ma]gnets. On account of the difficulty of tempering steel to any great depth from the surface, and for specific magnetic reasons as well, it has been customary in constructing powerful permanent magnets to build them up of thin laminæ of steel, each of which is separately magnetized. Figure 48 represents an arrangement of this nature

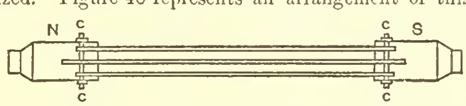

Fig. 48.

adopted by Coulomb, and figure 49 a horse-shoe magnet constructed in the same way. It will be observed that the ends of the laminæ are not exactly conterminous, the middle ones projecting more than the others; this arrangement was adopted with the view of getting rid to some extent of the weakening effect which the induction of one lamina has upon the other. That such an effect exists and is very great was conclusively shown by Coulomb; how far the modification in question cures it is another matter; much no doubt depends on the purpose for which the magnet is required; but it is scarcely worth while to discuss the subject here. We may call attention to a farther point in the construction of Coulomb's magnet, viz., that the ends of the laminæ are embedded in two soft iron terminals N and S; there can be no doubt that, for some purposes at least, this is an advantageous arrangement. Among the famous modern makers of permanent magnets Häcker of Nuremberg, Logeman and Wetteren of Haarlem,[5] Willward, and Jamin deserve to be specially mentioned.[6]

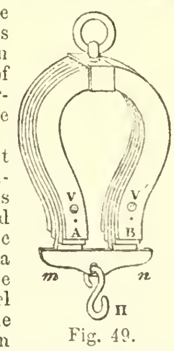

Fig. 49.

Preservation of magnets. In the preservation of permanent magnets it is essential to avoid extreme changes of temperature and shocks. When the magnet is laid aside it should be made part of a closed magnetic circuit; in the case of a horse-shoe magnet this is attained by simply laying a piece of soft iron, called the keeper, across the poles; bar magnets should be kept in parallel pairs, north pole to south pole and south pole to north pole, with two pieces of soft iron between the poles. When this is done the induced magnetism reacts on the magnets and diminishes the demagnetizing force; the action of shocks then ceases to destroy the permanent magnetism, and may even increase it.

Ultimate Theories of Magnetic Phenomena.

Stream theory. If we pass over the stream theory, which, although partially developed by Euler, has never taken root in modern physical science, the first great theory that we find proposed with a view to the explanation of magnetism is the two-fluid theory of Coulomb and Poisson. This is not an ultimate theory in the modern sense, inasmuch as it is not dynamical; but it was, doubtless, looked upon as ultimate in the days when the imponderable fluids had a recognized role in the physical sciences. In the two-fluid theory the imaginary positive and negative attractive agents (called magnetism in the empirical theory developed above) are regarded as imponderable fluids; but the essential point in the definite form of the theory due to Poisson is that he regards a body susceptible to magnetic induction as made up of an infinite number of particles of infinite permeability immersed in an impermeable medium.

Two-fluid theory. Poisson. After pointing out that, if the particles were of elongated form, and arranged so that the axes of elongation had one preponderating direction, or if they were arranged so that the linear density in different directions varied, the result would be æolotropy, he assumes that they are spheres uniformily distributed in the impermeable medium so that the volume of the magnetic particles in unit volume of the substance is the fraction k. The problem of magnetic induction under the influence of a uniform force is then the same as the problem of electric induction for an infinite number of perfectly conducting spheres uniformly distributed in a non-conducting medium. He finds for the permeability $\varpi = (1 + 2k)/(1 - k)$.

Maxwell has pointed out one fundamental objection to this theory, viz., that the value of k calculated from the formula just given by means of observed values of ϖ in the case of iron is greater than it would be even if the magnetic spheres were packed in the closest possible manner. Another objection is that the theory affords no explanation of the variability of k with different forces. We might of course modify the hypothesis, as was done by Plücker, by supposing that a resistance depending on the magnitude of the force opposes the separation of the fluids in the magnetic molecules, and that in certain cases a frictional resistance tends to prevent their reunion. We might in this way explain magnetic saturation and permanent magnetism; but the theory thus burdened has no more scientific value than the purely empiric theory, and, moreover, affords no clue to the phenomena of diamagnetism.

[1] See above, p. 256.

[2] *Pogg. Ann.*, 1844 and 1846.

[3] Frick, *Pogg. Ann.*, 1849, was one of the earliest who practised this method.

[4] It has been several times proposed to magnetize steel bars by heating them red hot, allowing them to cool to the proper temperature under the magnetizing force, and then tempering while the force is still acting. Gilbert, Knight, Robison, Haman, Gaugain, Aimé, and Holz (*Wied. Ann.*, vii., 1879) have all experimented with this method, but it does not appear to possess any advantage over the ordinary modern process, and need not be discussed here.

[5] Advised by Elias and Van der Willigen; see *Nature*, vol. xix. p. 552, 1879.

[6] Further details as to the advantages and disadvantages of various forms of magnets will be found in Wiedemann's *Galvanismus*, and Lamont's *Handbuch des Magnetismus*. See also a recent paper by W. Holz, *Wied. Ann.*, 1880, on hollow cylindrical magnets, and another by Gray on the moments attainable with hard steel bars, *Phil. Mag.*, 1878.

Molecular magnet theory.

In a very important class of modern theories, the fundamental assumption is that the molecules, or at all events a certain proportion of the molecules, of magnetic substances are small permanent magnets. In a body which is to outward appearance unmagnetized, the axes of these molecular magnets are turned indifferently in all directions; in a body which is magnetized in a certain direction a larger proportion than usual of the molecular magnets have their axes more or less in that direction. Magnetic induction is supposed to consist, not in any alteration of the molecular magnets themselves, but in the orientation of their axes under the action of the inducing force. The reader may figure to himself the nature of the action by imagining a line of small magnetic needles with their axes all horizontal, but all pointing in different directions; the whole system thus arranged will have no determinate magnetic moment, and will represent an unmagnetized body. Next, suppose a magnetizing force to act parallel to the line joining the centres of the needles, they will then arrange themselves in that line, and the magnetic moment of the system will be the sum of the moment of the different parts; we have thus an image of a body magnetized by induction.

Weber's form.

The notion of molecular magnets seems to have been suggested by Kirwan; but it was not until a definite form was given to it by Weber that it acquired any importance. The mathematical problem presented is one of great complexity. In the position of equilibrium any molecule is acted on by the magnetizing force, by a magnetic force due to the combined action of the other molecules, and possibly by a force arising from the displacement as well. Weber assumes that the couple tending to restore the molecule to its original position is that due to a constant magnetic force D, parallel to the original direction of its axis. If m be the magnetic moment of a molecule, and there be n molecules in a unit of volume, then the magnetic intensity $\mathfrak{I}$ due to the magnetizing force $\mathfrak{H}$ is given by $\mathfrak{I}=2mn\mathfrak{H}/3\mathrm{D}$, if $\mathfrak{H}<\mathrm{D}$; and by $\mathfrak{I}=mn(1-\mathrm{D}^2/3\mathfrak{H}^2)$, if $\mathfrak{H}>\mathrm{D}$. In other words, the curve ($\mathfrak{I}$, $\mathfrak{H}$) is straight till it reaches the point ($\frac{2}{3}mn$, D), it then becomes concave towards the axis of $\mathfrak{H}$, and rises towards an asymptote parallel to the axis of $\mathfrak{H}$; the maximum value of $\mathfrak{I}$ is mn. The theory does, therefore, give a general explanation of the phenomena of magnetic induction. The reader will be able by comparison with the experimental data given above to see how far it falls short of a complete explanation.

If the magnetic substance be devoid of coercive force, we must suppose that the molecules return to their original positions when the magnetizing force is removed. In substances capable of being permanently magnetized, we must imagine something of the nature of a frictional resistance to the motion of the magnetic molecules; so that, when they are deflected through more than a certain angle, they retain a permanent set after removal of the magnetizing force.

Maxwell's form.

Maxwell has worked out the particular hypothesis that each molecule which is deflected through an angle less than β_0 returns when the magnetizing force ceases to act, but that a molecule deflected through an angle $\beta>\beta_0$ retains the deflexion $\beta-\beta_0$. Denoting $\mathrm{D}\sin\beta_0$ by L, he finds as the result of the above supposition that the curve of temporary magnetization is a straight line from $\mathfrak{H}=0$ to $\mathfrak{H}=\mathrm{L}$; after that it is concave to the axis of $\mathfrak{H}$, and rises to an asymptote, the maximum value of $\mathfrak{I}$ being mn as before. The curve of residual magnetization begins when $\mathfrak{H}=\mathrm{L}$; it is concave to the axis of $\mathfrak{H}$, and rises to an asymptote corresponding to the maximum $\mathfrak{I}'=\frac{1}{4}mn\{1+\sqrt{1-\mathrm{L}^2/\mathrm{D}^2}\}^2$. It results from the hypothesis that, when a bar is permanently magnetized by a positive force $\mathfrak{H}_1$, its magnetism cannot be increased by a positive force $<\mathfrak{H}_1$, but may be diminished by a negative force $<\mathfrak{H}_1$; and, when the bar is exactly demagnetized by a negative force $\mathfrak{H}_2$, it cannot be magnetized in the opposite direction without the application of a force $>\mathfrak{H}_2$; but a positive force $<\mathfrak{H}_2$ is sufficient to begin to remagnetize the bar in the original direction.

Ampère's hypothesis.

Behind the molecular magnet theory there arises the question, What is the nature of the magnetic molecule? One answer to this question is given by the hypothesis of Ampère, that around each such molecule a current circulates in planes perpendicular to the axis of the molecule. That such an arrangement will be equivalent to an infinitely small magnet in the axis of the molecule, so far as external action is concerned, we know from the laws of electrodynamics. It remains only to inquire what the nature and properties of these molecular currents must be, to trace the full logical consequences of the assumption, and to compare them with experience. This was first done by Weber, and afterwards more completely by Clerk Maxwell.

It is obvious in the first place that the circuits in which the molecular currents flow must be perfectly conducting; for otherwise the electrokinetic energy of the molecular currents would be continually transformed into heat, and a constant supply of energy from without would be necessary to support the magnetism of a permanent magnet, which is contrary to experience. Let A be the effective area of a molecular circuit, L its coefficient of self-induction, θ the inclination of its axis to the inducing force $\mathfrak{H}$, γ_0 the primitive current, and γ the current after the inducing force is in action. Then $\gamma=\gamma_0-\mathfrak{H}\mathrm{A}\cos\theta/\mathrm{L}$; and the component of the moment parallel to $\mathfrak{H}$ will be $\mathrm{A}(\gamma_0-\mathfrak{H}\mathrm{A}\cos\theta/\mathrm{L})\cos\theta$. There are three different cases to consider.

1. Let either γ_0 be so great, or $\mathfrak{H}\mathrm{A}/\mathrm{L}$ be so small, that the effect due to the electromagnetic induction may be neglected in comparison with the effect due to the deflexion of the molecule; putting $m=\mathrm{A}\gamma_0$, we have thus merely the theory of molecular magnets already explained.

Weber theory of diamagnetism.

2. Let the force resisting the turning of the molecules be infinitely great, we then find for the magnetic susceptibility the value $\kappa=-\frac{1}{2}n\mathrm{A}^2/\mathrm{L}$. This is the theory originally proposed by Weber to explain diamagnetism.

3. If the effects due to deflexion of the molecules and to electromagnetic induction in the molecular circuits be both considered, we have a theory intermediate to (1) and (2), inclining to the one or the other according to the assumptions made as to the relative values of γ_0, A, and L.

The reader will find a full discussion of the different cases in Maxwell's *Electricity and Magnetism*, vol. ii. chap. xxii.

Maxwell's molecular vortex theory.

The most important attempt that has yet been made to realize a mechanism affording a dynamical explanation of magnetic phenomena is the theory of molecular vortices, published by Clerk Maxwell in the *Philosophical Magazine* for 1861 and 1862 (4th ser., vols. 21 and 23). The general results, stripped of all particular assumptions, will be found embodied in his great treatise on *Electricity and Magnetism*; but the following summary, taken from the original paper, may be of some interest.

1. Magnetoelectric phenomena are due to the existence of matter under certain conditions of motion or of pressure in every part of the magnetic field. The substance producing these effects may be a certain part of ordinary matter, or it may be an æther associated with matter.

2. The condition of any part of the field through which lines of magnetic force pass is one of unequal pressure in different directions, the pressure being least along the lines of force, so that they may be considered as lines of tension.

3. This inequality of pressure is due to vortices coaxial with the lines of force. The density of the revolving matter is proportional to the magnetic permeability of the medium. The direction of rotation is related to the direction of the line of force; and the velocity at the circumference of the vortex is proportional to the resultant magnetic force.

4. The vortices are separated from each other by a single layer of round particles; so that a system of cells is formed, the partitions being layers of these particles, and the substance of each cell being capable of rotating as a vortex.

5. The particles forming the layer are in rolling contact with both the vortices which they separate, but do not rub against each other. They are perfectly free to roll between the vortices and so to change their place, provided they keep within one *complete molecule* of the substance; but in passing from one molecule to another they experience resistance and generate irregular motions which constitute heat. These particles play the part of electricity. Their motion of translation constitutes an electric current; their rotation serves to transmit the motion of the vortices from one part of the field to another; the tangential pressures thus called into play constitute electromotive force; and the elastic yielding of the connecting particles constitutes electric displacement.

Maxwell deduces without difficulty all the principal electrical and magnetic phenomena from this theory; and he points out that its general conclusions have a value which does not depend upon the somewhat intricate kinematical arrangements supposed to exist in the magnetic medium. The theory certainly affords us a most instructive dynamical picture of the phenomena of electricity and magnetism; and it remains, so far as we know, the only successful attempt of its kind. (G. CH.)

MAGNETISM, Animal. The terms *animal magnetism*, *electro-biology*, *mesmerism*, *clairvoyance*, *odylic* or *odic force*, and *hypnotism* have been used to designate peculiar nervous conditions in which the body and mind of an individual were supposed to be influenced by a mysterious force emanating from another person. With the exception of *mesmerism*, a name given to the phenomena in honour of one of their earliest investigators, F. A. Mesmer, each of these terms implies a theory. Thus the phenomena of *animal magnetism* were supposed to be due to some kind of magnetic force or influence peculiar to living beings and analogous to the action of a magnet upon steel or certain metals; *electro-biology*, a more modern term, introduced in 1850 by two American lecturers, referred the phenomena to the action of electrical currents generated in the living body, and capable of influencing electrically the bodies of others; *clairvoyance* implied a power of mental vision or of mental hearing, or of a mental production of other sensations, by which the individual became aware of events happening in another part of the world from where he was, or could tell of the existence of objects which could not affect at the time any of his bodily senses; *odylic force* was a term given to a force of a mysterious character by which all the phenomena of animal magnetism might be accounted for; and *hypnotism*, from ὕπνος, sleep, was a name applied to a condition artificially produced in which the person was apparently asleep and yet acted in obedience to the will of the operator as regards both motion and sensation.

History.—It was natural that the apparent power of influencing the bodies and minds of others should attract much attention and be eagerly sought after for purposes of gain, or from a love of the marvellous, or for the cure of diseases. Hence we find that, whilst not a few have investigated these phenomena in a scientific spirit, more have done so as quacks and charlatans who have thrown discredit on a department of the physiology of man of the deepest interest. Recently, however, as will be shown in this article, physiologists and physicians have set about investigating the subject in such a manner as to bring it into the domain of exact science, and to dispel the idea that the phenomena are due either to any occult force or to supernatural agency. It would appear that in all ages diseases were alleged to be affected by the touch of the hand of certain persons, who were supposed to communicate a healing virtue to the sufferer. It is also known that among the Chaldæans, the Babylonians, the Persians, the Hindus, the Egyptians, the Greeks, and the Romans many of the priests effected cures, or threw people into deep sleeps in the shades of the temples, during which the sleeper sometimes had prophetic dreams, and that they otherwise produced effects like those now referred to animal magnetism. Such influences were held to be supernatural, and no doubt they gave power to the priesthood. In the middle of the 17th century there appeared in England several persons who said they had the power of curing diseases by stroking with the hand. Notable amongst these was Valentine Greatrakes, of Affane, in the county of Waterford, Ireland, who was born in February 1628, and who attracted great attention in England by his supposed power of curing the king's evil, or scrofula. Many of the most distinguished scientific and theological men of the day, such as Robert Boyle and R. Cudworth, witnessed and attested the cures supposed to be effected by Greatrakes, and thousands of sufferers crowded to him from all parts of the kingdom (see Colquhoun's *History of Magic*, &c., vol. ii. p. 146).

Phenomena of a marvellous kind, more especially such as imply a mysterious or supernatural power exercised by one person over another, not only attract attention, but take so firm a hold on the imagination that belief in them breaks out now and again with all the intensity of an epidemic. Thus since the time of Greatrakes, at short intervals, men have arisen who have led the public captive at their will. About the middle of the 18th century John Joseph Gassner, a Roman Catholic priest in Swabia, took up the notion that the majority of diseases arose from demoniacal possession, and could only be cured by exorcism. His method was undoubtedly similar to that followed by Mesmer and others, and he had an extraordinary influence over the nervous systems of his patients. Gassner, however, believed his power to be altogether supernatural and connected with religion.

Friedrich (or Franz) Anton Mesmer was born at Weil, near the point at which the Rhine leaves the Lake of Constance, on May 23, 1733. He studied medicine at Vienna under the eminent masters of that day, Van Swieten and De Haen, took a degree, and commenced practice. Interested in astrology, he imagined that the stars exerted an influence on beings living on the earth. He identified the supposed force first with electricity, and then with magnetism; and it was but a short step to suppose that stroking diseased bodies with magnets might effect a cure. He published his first work (*De Planetarum Influxu*) in 1766. Ten years later, on meeting with Gassner in Switzerland, he observed that the priest effected cures without the use of magnets, by manipulation alone. This led Mesmer to discard the magnets, and to suppose that some kind of occult force resided in himself by which he could influence others. He held that this force permeated the universe, and more especially affected the nervous systems of men. He removed to Paris in 1778, and in a short time the French capital was thrown into a state of great excitement by the marvellous effects of mesmerism. Mesmer soon made many converts; controversies arose; he excited the indignation of the medical faculty of Paris, who stigmatized him as a charlatan; still the people crowded to him. He refused an offer of 20,000 francs from the Government for the disclosure of his secret, but it is asserted that he really told all he knew privately to any one for 100 louis. He received private rewards of large sums of money. Appreciating the effect of mysterious surroundings on the imaginations of his patients, he had his consulting apartments dimly lighted and hung with mirrors; strains of soft music occasionally broke the profound silence; odours were wafted through the room; and the patients sat round a kind of vat in which various chemical ingredients were concocted or simmered over a fire. Holding each others' hands, or joined by cords, the patients sat in expectancy, and then Mesmer, clothed in the dress of a magician, glided amongst them, affecting this one by a touch, another by a look, and making "passes" with his hand towards a third. The effects were various, but all were held to be salutary. Nervous ladies became hysterical or fainted; some men became convulsed, or were seized with palpitations of the heart or other bodily disturbances. The Government appointed a commission of physicians and members of the Academy of Sciences to investigate these phenomena; Franklin and Baillie were members of this commission, and drew up an elaborate report admitting many of the facts, but contesting Mesmer's theory that there was an agent called animal magnetism, and attributing the effects to physiological causes. Mesmer himself was undoubtedly a mystic; and, although the excitement of the time led him to indulge in mummery and sensational effects, he was honest in the belief that the phenomena produced were real, and called for further investigation. For a time, however, animal magnetism fell into disrepute; it became a system of downright jugglery, and Mesmer himself was denounced as a shallow empiric and impostor. He withdrew from Paris, and died at Meersburg in Switzerland on 5th March 1815. He left many disciples, the most distinguished of whom was the Marquis de Puysegur. This nobleman revolutionized the art of mesmerism by showing that many of the phenomena might be produced by gentle manipulation causing sleep, and without the mysterious surroundings and violent means resorted to by Mesmer. The gentler method was followed successfully by Deleuze, Bertrand, Georget, Rostan, and Foissac in France, and by Dr John Elliotson in England up to about 1830.

In 1845 considerable attention was drawn to the announcement by Baron von Reichenbach of a so-called new "imponderable" or "influence" developed by certain crystals, magnets, the human body, associated with heat, chemical action, or electricity, and existing throughout the universe, to which he gave the name of *odyl.* Persons sensitive to odyl saw luminous phenomena near the poles of magnets, or even around the hands or heads of certain persons in whose bodies the force was supposed to be concentrated. In Britain an impetus was given to this view of the subject by the translation in 1850 of Reichenbach's *Researches on Magnetism, &c., in relation to Vital Force*, by Dr Gregory, professor of chemistry in the university of Edinburgh. These *Researches* show many of the phenomena to be of the same nature as those described previously by Mesmer, and even long before Mesmer's time by Swedenborg. The idea that some such force exists has been a favourite speculation of scientific men having a mental bias to mysticism, and it makes its appearance not unfrequently.

The next great step in the investigation of these phenomena was made by James Braid, a surgeon in Manchester, who in 1841 began the study of the pretensions of animal magnetism or mesmerism, in his own words, as a "complete sceptic" regarding all the phenomena. This led him to the discovery that he could artificially produce "a peculiar condition of the nervous system, induced by a fixed and abstracted attention of the mental and visual eye on one object, not of an exciting nature." To this condition he gave the name of *neuro-hypnotism* (from νεῦρον, nerve, ὕπνος, sleep); for the sake of brevity, *neuro* was suppressed, and the term hypnotism came into general use. Braid read a paper at a meeting of the British Association in Manchester on 29th June 1842, entitled *Practical Essay on the Curative Agency of Neuro-Hypnotism*; and his work *Neurypnology, or the Rationale of Nervous Sleep considered in relation with Animal Magnetism, illustrated by numerous cases of its successful application in the relief and cure of disease*, was published in 1843. It is necessary to point this out, as certain recent Continental writers have obtained many of Braid's results by following his methods, and have not adequately recognized the value of the work done by him forty years ago. Braid was undoubtedly the first to investigate the subject in a scientific way, and to attempt to give a physiological explanation. In this he was much aided by the physiologist Herbert Mayo, and also by Dr William B. Carpenter,—the latter being the first to recognize the value of Braid's researches as bearing on the theory of the reflex action of the ganglia at the base of the brain and of the cerebrum itself, with which Carpenter's own name is associated.

Recently the subject has been reinvestigated by Professor Weinhold of Chemnitz, and more particularly by Dr. Rudolf Heidenhain, professor of physiology in the university of Breslau, who has published a small but interesting work on animal magnetism. In this work Heidenhain attempts to explain most of the phenomena by the physiological doctrine of inhibitory nervous action, as will be shown hereafter.

Phenomena and Physiological Explanation.—The usual method of inducing the mesmeric or hypnotic state is to cause the person operated on to stare fixedly at a faceted or glittering piece of glass held at from 8 to 15 inches from the eyes, in such a position above the forehead as will strain the eyes and eyelids. The operator may stand behind the patient, and he will observe that the pupils are at first contracted from the effort of accommodation of each eye for near vision on the object; in a short time the pupils begin to relax, and then the operator makes a few "passes" over the face without touching it. The eyelids then close; or the operator may gently close them with the tips of the fingers, at the same time very gently stroking the cheeks. Often a vibratory motion of the eyelids may be observed when they are closed, or there may be slight spasm of the eyelids. The eyes may afterwards become widely opened. The patient is now in a sleep-like condition, and the limbs often remain in almost any position in which the operator may place them, as in a cataleptic condition. At the same time the patient may now be caused to make movements in obedience to the commands of the operator, and to act according to ideas suggested to him. Thus, he may eat a raw onion with gusto, apparently under the impression that it is an apple; he may make wry faces on drinking a glass of water when told that what he is taking is castor oil; he may ride on a chair or stool as in a horse race; he may fight with imaginary enemies, or show tokens of affection to imaginary friends; in short, all kinds of actions, even of a ridiculous and a degrading nature, may be done by the patient at the command of the operator. Another class of phenomena consists in the production of stiffness or rigidity of certain muscles or groups of muscles, or even of the whole body. For example, on stroking the fore arm it may become rigid in the prone or supine condition; the knee may be strongly bent, with the muscles in a state of spasm; the muscles of the trunk may become so rigid as to allow the body to rest like a log, head and heels on two chairs, so stiff and rigid as to bear the weight of the operator sitting upon it; or various cataleptic conditions may be induced and as readily removed by a few passes of the hand. Many disorders of sensation have been observed, such as defective colour perception, the hearing of special sounds which have no objective existence, or deafness to certain tones, or perverted sensations, such as tingling, prickling, rubbing, &c., referred to the skin. The patient may remain in this condition for an hour or more, and may then be roused by holding him for a few minutes and blowing gently into the eyes. Usually the patient has a vague recollection, like that of a disturbed dream, but sometimes there is an acute remembrance of all that has happened, and even a feeling of pain at having been compelled to do ridiculous actions. Certain persons are more readily hypnotized than others, and it has been observed that, once the condition has been successfully induced, it can be more easily induced a second time, a third time more easily than a second, and so on until the patient may be so pliant to the will of the operator that a fixed look, or a wave of the hand, may throw him at once into the condition. Such are the general facts in artificially induced hypnotism, and they belong to the same class as those referred to animal magnetism, electro-biological effects, odylic influences, &c., according to the whim or theory of the operator.

It is not surprising that such phenomena have been the cause of much wonder and the basis of many superstitions. Some have supposed that they were supernatural, others that they indicated the existence of a specific force exerted by the experimenter upon the passive subject. Many operators have no doubt believed they possessed such a force; such a belief would not affect the success of their experiments except to make them more likely to be successful, as the operator would readily comply with all the conditions; but most of these phenomena can be explained physiologically, and those which cannot be so accounted for will remain hidden until we get further light on the physiology of the nervous system.

The symptoms of the hypnotic state, as shown by Heidenhain, may be grouped under four heads:—(1) those referable to conditions of the sensorium or portion of the brain which receives nervous impulses, resulting in movements of a reflex and imitative character; (2) insensibility to pain, and various forms of perverted sensation; (3) increased irritability of the portion of the nervous system devoted to reflex actions; and (4) states of the nervous centres controlling the movements of the eye, the accommodation of the eye to objects at various distances, and the movements of respiration, &c.

1. *The State of the Sensorium.*—By the sensorium is meant that portion of the nervous system which receives impulses from the nerves coming from the organs of sense, such as those from the eye, ear, nose, tongue, and skin. Each of these nerves brings its message to a portion of the central nervous system in intimate connexion with the rest of the nervous system. This message may possibly arouse nervous actions associated with consciousness, or it may not; or the nervous actions of consciousness may be so transient as to leave a faint impress on the memory, so that it can be revived only if no great interval has elapsed since the impression was made on the sense organ. If, however, the impression be vivid, then it may be revived long afterwards. This impression may be consciously perceived, and then any apparent effect may end; but it may set up a set of actions, resulting in motion, which are apparently of a reflex character. Thus, suppose a person in the dark; light is suddenly brought before the eye; this affects the retina, and through the changes in it the optic nerve and central organ; there may be consciousness or there may not; if the person be wide awake he will see the light; if he be asleep he will not see it, at all events he will give no indication of seeing it; on awaking, he may have a recollection of a dream in which light has a place, or his memory may be blank; but nevertheless the light will cause the pupil of the eye to contract by reflex action without his consciousness; and perhaps, also, without consciousness, the sleeping person may make an effort to avoid the light, as has been noticed in the case of somnambulists.

Now, when a patient has been thrown into a weak hypnotic state, there may be a vivid recollection on awaking of all that happened during the apparent sleep. This implies, of course, that conscious sensory perceptions took place during the condition. Memory depends on the direction of the attention to sensations. If the effort of attention be strong, the recollection will probably be vivid, and the converse is true. But this does not preclude the supposition that sensory perceptions may come and go, like the shadows of clouds on a landscape, without any attempts at fixing them, and consequently with no recollection following their occurrence. The sensory perceptions may have existed for so short a time as to leave no impress behind. This may explain how it is that in the deeper forms of hypnotism there is either no recollection of what occurred or the recollection can only be aroused by hints and leading questions. Attention is necessary, therefore, to form a conscious idea arising out of a sensation.

It is generally admitted by physiologists that the cerebral hemispheres are the seat of the higher mental operations, such as attention, &c., although the interdependence of these hemispheres with the lower sensory ganglia, which receive all sensory impressions in the first instance, and with motor ganglia, which are, in like manner, the starting-points of motor impulses, is not understood. The one portion of the nervous system may work without the other. Thus, during free cerebral activity we pay little attention to what we see or hear, and consequently we remember nothing. A man in a reverie may have many impressions of sight or of hearing of which he has been really unconscious. On the other hand, the cerebral apparatus may be so attuned with the recipient portion that if the latter receives a message the former sympathetically responds. For example, a mother sound asleep is disturbed by the slightest cry of her child, although loud sounds of other kinds may not awake her.

It would appear then that impressions on the senses and the consciousness of impressions are two separate states which may occur in a manner independently; that is to say, there may be purely sensory operations, in which consciousness is not involved, or there may be the conscious repetition of old impressions, or what is called memory. Now it is a law of nervous action that processes which at first are always of a conscious kind may by repetition become so habitual as to be performed without consciousness. Thus a child learns to perform a piece of music on the pianoforte by conscious efforts, often of a painful kind; each note has to be recognized, and the appropriate muscular movements required for its production on the instrument executed with precision and delicacy; but by and by the music may be performed accurately even while the attention is directed to something else. In like manner, all movements which are the results of sensory impressions may become unconscious movements; the sensory impressions are at first paid attention to; but as they become habitual the mind becomes less and less engaged in the process, until the movements resulting from them are practically unconscious. A familiar illustration is that of a man in deep reverie walking along a street. Immersed in thought, he pays little or no attention to passers by; as his eyes are open, their images, or those of adjacent objects, must affect his visual apparatus, but they arouse no conscious impression, and still those impressions, evanescent as they are, are sufficient to excite the appropriate movements of locomotion. These movements are in all respects like voluntary movements, but they are not really voluntary, showing that, by the machinery of the nervous system, movements like voluntary movements may be executed without volition. It is important to observe, however, that these movements are the result of sensory impressions. A man in the deepest reverie, with his eyes blindfolded, could not execute the requisite movements; and when we see the blind walking in the streets, they afford no contradiction to this view, as their minds are busily engaged in noticing another set of sensory impressions derived from the sense of touch, muscular movement, and hearing, a set of impressions of the greatest importance to them, although of little importance comparatively to ordinary people, who are guided chiefly by visual impressions.

A person in a state of hypnotism may be regarded as in a condition in which the part of the nervous apparatus associated with conscious perception is thrown out of gear, without preventing the kind of movements which would result were it really in action. Impressions are made on the sensory organs; the sensory nerves convey the impression to a part of the brain; in the deepest condition of hypnotism these impressions may not arouse any consciousness, but the result may be the kind of movement which would naturally follow supposing the person had been conscious. The movements made by the hypnotic are chiefly those of an imitative kind. It has often been noticed that the mere suggestion of the movement may not be enough to excite it; to secure success, the movement must be made before the eyes of the person. For example, it is a common part of the exhibition of such persons for the operator to clench his fist; the patient at once clenches his; the operator blows his nose; the patient does likewise; but if the operator performs these actions behind the back of his patient the chances are that the patient will not repeat the movements.

The condition seems to be one in which the sensory impression leads to no conscious perception and to no voluntary movement, but is quite sufficient to arouse those nervous and muscular mechanisms which lead to unconscious imitation. The patient is in a sense an automaton played upon by the operator through the medium of the patient's sensory organs. It is important to observe that in deep hypnotism the patient has no idea corresponding to the movements he makes in obedience to the example of the operator. For example, suppose he is swallowing a glass of water and the operator tells him it is castor oil, at the same time making the requisite grimaces, the patient will imitate these grimaces without having any idea either of water or of castor oil. The grimaces are purely imitative, without any connexion with the idea which would naturally excite them. This is the case only with those deeply hypnotized. In some cases, however, the hypnotism is so deep as to resemble coma, and in these there is no trace of any sensory impressions or of movements. In cases where the hypnotism is slight, there may be a curious mixture of effects. Here the patient may be partially conscious of the requests made to him, and of the imitative movements executed before his eyes; to some extent he may resist the commands of the operator, he may feel he is being fooled, and yet he may perform many ridiculous actions; and when he awakes he may have a vivid recollection of the events in which he participated. A hypnotized person, in fact, is in a state similar to that of the somnambulist, who acts the movements of a disturbed dream. There are many degrees of the sleeping state, from the profound condition resembling coma to that of the light sleeper who starts with every sound. In some sleeps there are dreams in which the sleeper is so occupied with the phantoms of thought as to pay no attention to external impressions, unless these be sufficiently powerful to awake him, whilst there are other sleeps in which the boundary between the conscious reception of new impressions and the reproduction of old ones is so thin as to permit of a blending of the two. In this kind of sleep, a spoken word, a familiar touch, the suggestion of something in keeping with the thoughts of the dreamer, are sufficient to change the current of the dream, and even to excite movements. When the ideas of the dreamer cause movements corresponding to these ideas, then the dreamer becomes a somnambulist. He acts the dream; according to the depth of the semi-conscious state will be his capacity for responding to external impressions. Some somnambulists respond to external suggestions readily, others do not; and in all there is almost invariably no recollection of the state. Artificial hypnotism is a condition of the same kind, though usually not so profound.

The question now arises as to how this artificial state may be induced. In one awake and active, all sensory impressions as a rule are quick, evanescent, and constantly renewed. New successions of images and thoughts pass rapidly before the mind during walking, working, eating, or in the leisure hours of social life; but none last so long as to cause fatigue of any particular part of the body. By and by there is a general feeling of fatigue, and then sleep is needed to restore exhausted nature. But if the attention be fixed on one set of sensory impressions, fatigue is much sooner experienced than if the impressions are various in kind and degree. Thus one or two hours spent at a picture gallery or at a concert, if the attention be devoted to the impressions on the eye or ear, usually cause fatigue. It would appear that the method of exciting hypnotism by causing the patient to gaze at a bit of glass or a bright button depends in the first place on the feeling of fatigue induced. At first there is a dazzling feeling; then the eyes become moist; images become blurred and indistinct, and seem to swim in the field of vision; the field of vision becomes unsteady, and just about this period ideas do not pass in the mind in orderly sequence, but irregularly, as in the few minutes immediately before passing into sleep. At this stage also the pupils become widely dilated, and the eyeballs become more prominent than usual. The innervation of the iris must be understood, so as to appreciate the physiological meaning of these changes. The muscular structure of the iris is supplied by two nerves, the third cranial nerve and the sympathetic nerve. If the third nerve be cut the pupil dilates; if the distal end of the nerve be irritated the pupil contracts. On the other hand, if the sympathetic nerve be cut the pupil contracts, whilst if the distal end be irritated the pupil dilates. These experimental facts show that the radiating fibres of the iris which dilate the pupil are under the control of the sympathetic nerve, whilst the circular fibres which contract the pupil are supplied by the third. Further it can be shown that the corpora quadrigemina, two ganglionic masses in the brain, are the reflex centres for the regulation of these movements. The optic nerve from the retina supplies the sensory stimulus which causes the pupil to contract. Thus, suppose light to be brought before the eye while the pupil is dilated; the retina is affected, a stimulus is sent to the corpora quadrigemina along the fibres of the optic nerve, and from the corpora quadrigemina a nervous influence passes along the fibres of the third nerve to the circular fibres of the iris, causing the pupil to contract. It is also very probable that the corpora quadrigemina act as reflex centres for nervous impulses regulating the calibre of the blood-vessels of the eye, the vaso-motor nerves. If we apply these facts to the case of a hypnotized person, we find that (1) the pupil of a hypnotized person contracts energetically when light falls upon the eye, showing that the reflex mechanism is still intact; (2) just before the hypnotic state is induced the pupil dilates, indicating feeble nervous impulses passing along the third from the corpora quadrigemina; (3) at first, the eyeballs seem to sink in, but when hypnotism is complete they project in a manner similar to what has been observed in an animal when the arteries supplying the head have been compressed so as to make the brain anæmic or bloodless; and (4) the ophthalmoscope has not shown any change in the calibre of the blood-vessels of the retina in the hypnotic state. From a consideration of these facts and inferences Heidenhain was at first inclined to believe that hypnotism might be due to a reflex influence on the vessels of the brain, causing them to contract so as to permit the passage of only a small quantity of blood, and make the brain anæmic. This view, however, had to be abandoned, as the faces of hypnotized persons are usually red, and not pale, as they would be were the arterioles contracted. Further, Heidenhain performed a crucial experiment by giving to his brother nitrite of amyl, which causes dilatation of the vessels by vaso-motor paralysis, when he still found hypnotism could be readily induced, showing that the state was not caused by deficient blood supply.

Heidenhain has advanced another and more probable hypothesis. During the past twenty years a new mode of nervous action, known as inhibitory action, has been discovered by physiologists. A good example is supplied by the innervation of the heart. This organ has nervous ganglia in its substance by which its rhythmic contractions are maintained. Further it is supplied by the vagus or pneumogastric nerve and by the sympathetic. Section of the vagus is followed by quickening of the heart's action, and stimulation of the lower end causes slowing and, if the stimulation be strong enough, stoppage of the heart, not, however, in a tetanic state (which would be the case if the fibres of the vagus acted directly on the muscular structure of the heart, as a motor nerve), but in a state of complete relaxation or diastole. Opposite results follow section and stimulation of the sympathetic fibres. It has been clearly made out that the terminal fibres of both nerves do not act on muscular fibres but on ganglion cells, those of the vagus "inhibiting" or restraining, whilst those of the sympathetic "accelerate" the action of the cells. Inhibition is now known to play an important part in all nervous actions, and it would seem that any powerful impression in a sensory nerve may inhibit or restrain motion. This is strikingly seen in some of the lower animals. A ligature applied loosely round the thigh of a frog whilst it lies on its back apparently deprives it of all power of motion. The weak sensory stimulation in this case seems to stop voluntary motion. Pressure on the internal organs of such animals as the rabbit, although gentle, sometimes causes paralysis of the lower or hinder limbs. Again, it has been ascertained that, whilst the spinal cord is the chief reflex centre, the reflex activity can be inhibited by impulses transmitted to it from portions of the cerebral hemispheres which are in a state of high activity. It would appear then that, if we suppose one set of sensory or recipient cells in the brain to be brought into a state of exalted irritability by the preliminary operations of hypnotism, the result might be inhibition of the parts devoted to voluntary movement. In like manner, the activity of sensory nerve cells may become inhibited. Thus stimulation of a certain cutaneous area, say the arm, by a mustard plaster, has been found to lower the sensibility of the corresponding portion of skin on the opposite arm. The theory then offered is that "the cause of the phenomena of hypnotism lies in the inhibition of the activity of the ganglion-cells of the cerebral cortex, . . . the inhibition being brought about by gentle prolonged stimulation of the sensory nerves of the face, or of the auditory or optic nerve."

According to this view, the portion of the brain devoted to voluntary movements is as it were thrown out of gear, and the movements that follow, in the hypnotic state, are involuntary, and depend on impressions made on the senses of the patient. To understand how this is possible, we must now consider shortly some of the views presently held as to the action of the brain. The researches of Hitzig, Fritsch, Ferrier, Hughlings Jackson, and many others indicate that certain movements initiated as a consequence of perception, and of the ideas thereby called forth, are due to nervous actions in the grey matter in certain areas on the surface of the cerebral hemispheres, and that there is another class of movements which do not require the agency of the cortex of the brain, but depend on the activity of deeper centres. These deeper centres are the optic thalami, which receive sensory impressions from all parts of the skin; the corpora quadrigemina, which receive luminous impressions from the retina; and the corpora striata, which are the motor centres whence emanate influences passing to the various groups of muscles. No doubt other sensory centres exist for hearing, taste, and smell, but these have not been clearly ascertained. In the case of conscious and voluntary movements carried out as the result of external impressions, the excitation would pass first to the thalami optici (tactile) or corpora quadrigemina (visual), thence to the cerebral hemispheres, where ideas would be called forth and volitional impulses generated; these would then be transmitted downwards through the corpora striata (motor) to the crura cerebri and spinal cord, and from thence to special groups of muscles, thus causing specific movements. Suppose now that the portions of cerebral hemispheres connected with ideation and volition were thrown out of gear, and that a similar sensory impression was made on the person; again the path of nervous impulses would be to the thalami optici (tactile) or corpora quadrigemina (visual), and from thence directly through corpora striata (motor) to crura cerebri and spinal cord, then passing out to muscles, and causing movements as precise as those in the first instance, and apparently of the same character. The difference between the two operations, however, would be this:—in the first there would be movements following perception, ideation, and volition; in the second the same class of movements would be effected by an automatic mechanism without any of the psychical operations above alluded to. This theory has the merit of simplicity, and is in accordance with most of the facts. The chief difficulty in the way of accepting it is to understand why, if hypnotism be so induced, it is not induced much oftener. One would suppose that, if gazing at a coin and having a few passes made with the hand were sufficient to bring about physiological changes of such importance, men would be oftener hypnotized in daily life than they are. But it is to be remembered that attention is seldom fixed on one object so long as in the experiment of producing hypnotism. The first occasion the experiment is made, even with so-called susceptible persons, the time occupied may be from 10 to 20 minutes, and during all that time the attention is on the strain, and feelings of fatigue are excited in the way above described. Again it is well known that sudden and strong sensory impressions often paralyse voluntary action for a time, even in ordinary life, and what is called "presence of mind" really means that power of self-control which prevents the bodily energies being paralysed by strong sensory impressions. A carriage bearing down on a nervous lady in a crowded street may deprive her of all power of movement, or she may automatically run here or there in obedience to the shouts of the bystanders; but one with coolness can thread her way among the vehicles without fear or trouble.

A hypnotized person is therefore to be regarded as an automaton. "To cause him to move his arm, the image of a moving arm must pass over his retina, or an unconscious sensation of motion must be induced through passive movement of his arm."

2. *Insensibility to Pain.*—It has often been noticed that in the mesmerized or hypnotized person there may be complete insensibility to pain, so that deep pricks with a needle are not felt. During deep hypnotism a pin may be run into the hand without pain, but pain will be felt on awaking, and pulling out the pin in the waking state will cause acute pain. It would appear that certain nerves may convey tactile sensibility whilst others convey only painful impressions, and in certain forms of paralysis the patient may have tactile sensibility without pain, or the reverse. In hysterical women, as has been shown by Charcot and others, disorders of sensibility of this kind are not uncommon, indicating changes in the nervous centres.

3. *Increased Reflex Spasm of Muscles.*—One of the most striking phenomena of the hypnotic state is the ease with which certain voluntary muscles may be rendered stiff. For example, if the operator stroke the skin over the biceps muscle in the upper arm, the limb will be at once powerfully flexed, and the biceps can be felt stiff and rigid. To understand the physiological explanation offered of this

phenomenon it will be necessary shortly to describe the mechanism of reflex acts. If a sensory nerve be irritated at its periphery, say in the skin, a nervous impulse is transmitted to a central nervous organ, such as the spinal cord, and through the agency of nerve cells in this organ impulses are then transmitted by motor nerves to muscles, causing movements, without any operation of the will. Thus a particle of food getting into the larynx irritates sensory nerves of the vagus, and there is a reflex spasm of various muscles of expiration, causing a violent cough. That such reflex acts not only can occur without the will, but in spite of it, is shown by the want of control over a sneeze when the nostril is irritated by snuff. Now these reflex centres in the cord are partially under the control of higher centres in the brain. If the agency of the latter be removed, the activity of the cord-centres is increased, and reflex actions are more easily induced. This we have assumed to be the state of the hypnotic. If a portion of his skin be stroked, first one muscle, say the one immediately under the skin stroked, will become stiff, then in obedience to a law regulating reflex actions,—namely, that they tend to become diffused according to the strength and duration of the stimulus,—other muscles become rigid, and so on until the whole trunk becomes cataleptic. This phenomenon is so well described by Heidenhain that we quote as follows (pp. 23, 24):—

"With slight increase of reflex irritability, those muscles alone contract which lie immediately under the area of skin which has been stroked. In this condition it is easy to bring single muscles and groups of muscles into isolated action, and thus demonstrate their special motor function. Stroking the ball of the thumb causes adduction of the thumb (towards the palm). Stimulating the skin over the sterno-mastoid causes the head to assume the well-known oblique position which it has when one has got a "stiff neck"; stroking the skin at one corner of the mouth leads to distortion of the mouth on that side, owing to the contraction of the muscles inserted there. When the irritability is somewhat more increased, we are able, by continuous irritation of a defined group of skin, to set in activity neighbouring and distant groups of muscle, according to the degree of irritation. Thus, when I gently stroke the ball of the thumb, only the flexors and the adductors of this member are set in activity. If I stroke somewhat harder, the forearm muscles, especially the flexors of the fingers, contract. Our patient can, however, still bend and stretch his arm at the elbow, the upper arm muscles being still unaffected. Through further increase of the irritation, the latter too and the shoulder muscles are thrown into spasm, so that the whole limb appears immovably fixed. But the highest degree of reflex irritability is not yet attained. Mr A. Heidenhain sits quietly here on a chair. I now once stroke the ball of his left thumb. Please observe the exact succession in which the spasm slowly spreads from one part of the body to the other. You will see the following muscle groups successively affected, some seconds intervening in the passage from one group to another:—left thumb, left hand, left forearm, left upper arm and shoulder, right shoulder and arm, right forearm, right hand, left leg, left thigh, right thigh, right leg, muscles of mastication, muscles of the neck. But now I must put an end to it. I strike forcibly the left arm, and the rigor at once disappears. Instant relaxation of the whole body occurs also when I forcibly extend a finger of the clenched fist. Probably the reflex excitement would extend still farther, but I naturally consider it out of the question to try whether the muscles of respiration would become affected. It is easily understood that such experiments require the greatest caution, and may be very seldom carried out."

This condition of the muscles is exactly like that in catalepsy, a peculiar nervous disease; and hypnotism may be regarded as an artificial catalepsy.

4. *Other Peculiar Nervous Phenomena of the Hypnotic State.*—The changes in the eyes have been already alluded to. The pupils dilate, the eyelids open widely, and the eyeballs protrude. Occasionally the upper eyelid droops, so that the eyelids seem closed. It has often been asserted that clairvoyants see with the eyelids closed, but they are really partially open. The movements of respiration are often quickened from 16 to 30 or 35 per minute, indicating stimulation of the respiratory centres in the medulla oblongata. Sometimes the flow of saliva is increased. Hallucinations of sense may occur, though they are rare. One man in the hypnotic state experienced a strong odour of violets.

There is a class of phenomena referred to the hypnotic state of a very doubtful character, inasmuch as we have to depend entirely on the statements of the person operated on, and no objective tests can be employed. Such, for example, are various disturbances of sensation, hearing with the pit of the stomach more acutely than when the sound is made in the usual ways towards the ear, and the application of the hand of the operator to the body giving rise to profound sleep or dreams, induced dreaming, &c. Again it is asserted by Heidenhain and Grützner (*Breslauer Aerztl. Zeitsch.*, No. 4, 28th February 1880) that unilateral hypnosis is possible. Thus stroking the left forehead and temple caused immobility of the right arm and leg.

"Stroking on both sides causes catalepsy of all four limbs; no facial paralysis or aphasia. Unilateral stroking causes crossed catalepsy and facial paralysis, accompanied when on the left by aphasia. If in addition to unilateral stroking, and this being still maintained, the other side be stroked, then the same result is brought about as if both sides had been stroked from the beginning. . . . Measurement of the volume of the arm by means of Mosso's volumeter [an instrument for estimating the bulk of the limb by displacement of water and movements of a recording lever] proves that in the cataleptic arm the quantity of blood (in consequence of the vascular contraction) sinks enormously, whilst it simultaneously rises in the other arm. When the catalepsy is gone by, the quantity of blood in the cataleptic arm increases, whilst in the other arm it sinks" (Heidenhain, p. 91).

Charcot has pointed out that in certain kinds of hysteria in women there are remarkable unilateral disturbances or perversions of sensory impressions of colour. Phenomena of the same kind have been observed by Cohn, Heidenhain, and others in hypnotized persons. Thus A. Heidenhain became completely colour blind in the eye of the cataleptic side. All colours appeared grey in different degrees of brightness, from a dirty dark grey to a clear silver grey.

"If one eye be treated with atropin, whilst the effect of the latter is making its appearance, the phenomena of colour blindness are changed as follows:—red and green still appear as different shades of grey; blue and yellow, on the other hand, do not appear grey. They appear differently in the different stages of atropin action:—*first stage*, yellow appears grey, with a glimmer of blue; *second stage*, yellow appears pure blue; *third stage*, yellow appears blue with a slight tinge of yellow, somewhat as in the so-called struggle of the fields of vision,—yellow is seen, as it were, through a blue mist; *fourth stage*, yellow appears mostly yellow, with a tinge of blue. When blue is tried, the corresponding result is obtained; that is, at last blue with a slight yellow tinge is seen. During the action of atropin the sensation of yellow or blue passes from grey through the contrast colour to the right colour, whilst red and green only appear as different shades of grey" (Heidenhain, p. 95).

These facts are interesting as showing perverted sensation in the particular individual affected, but they throw no light on the condition of hypnotism.

It is evident then that animal magnetism or hypnotism is a peculiar physiological condition excited by perverted action of certain parts of the cerebral nervous organs, and that it is not caused by any occult force emanating from the operator. Whilst all the phenomena cannot be accounted for, owing to the imperfect knowledge we possess of the functions of the brain and cord, enough has been stated to show that just in proportion as our knowledge has increased has it been possible to give a rational explanation of some of the phenomena. It is also clear that the perverted condition of the nervous apparatus in hypnotism is of a serious character, and therefore that these experiments should not be performed by ignorant empirics for the sake of gain, or with the view of causing amusement. Nervous persons may be seriously injured by being subjected to such experiments, more especially if they undergo them repeatedly; and it should be illegal to have public exhibitions of the kind alluded to. The medical profession has always been rightly jealous of the employment of hypnotism in the treatment of disease, both from fear of the effects of such operations on the nervous systems of excitable people, and because such practice is in the border land of quackery and of imposture. Still in the hands of skilful men there is no reason why the proper employment of a method influencing the nervous system so powerfully as hypnotism should not be the means of relieving pain or of remedying disease.

Literature.—A very complete bibliography will be found appended to the article "Mesmérisme," *Dictionnaire Encyclopédique des Sciences Médicales* (deuxième série, 1873). In addition, see Braid, *Neurypnology*, London, 1843; Elliotson, *Human Physiology*, London, 1840; Colquhoun, *History of Magic, Witchcraft, and Animal Magnetism*, London, 1851; Mayo, *Letters on the Truths contained in Popular Superstitions, with an Account of Mesmerism*, Edinburgh, 1851; Scoresby, *Zoistic Magnetism*, London, 1849; Hughes Bennett, *Lecture on the Mesmeric Mania of* 1851, Edinburgh, 1851; Reichenbach, *Researches in Magnetism, Electricity, Heat, Light, Crystallization, and Chemical Attraction, in their relation to Vital Force* (translated by Dr Gregory, London, 1850; in this volume the doctrine of odylic force is set forth); Andrew Buchanan, *Darlingism, misnamed Electro-Biology*, London, 1851; Alexander Wood, *What is Mesmerism?* Edinburgh, 1851; Weinhold, *Seven Lectures on Somnambulism*, translated by J. C. Colquhoun, Edinburgh, 1845; John Forbes, *Illustrations of Modern Mesmerism*, London, 1845. See also Maudsley, *Physiology of Mind*, London, 1876; and especially Carpenter, *Mental Physiology*, p. 547 *sq.* (where the author attempts to account for many of the phenomena by the theory of a dominant idea influencing and governing all other mental operations), London, 1874. The most recent account of these phenomena will be found in Heidenhain's *Animal Magnetism*, translated by Wooldridge, with a preface by G. J. Romanes, London, 1880. For a short and clear account of hysteria as bearing on the phenomena of hypnotism, see Rosenthal, *Clinical Treatise on the Diseases of the Nervous System*, vol. ii. p. 29 *sq.*, London, 1881. (J. G. M.)

MAGNOLIA, L., the typical genus of the order *Magnoliaceæ*, named from Pierre Magnol, professor of medicine and botany at Montpellier. It contains about fourteen species, distributed in Japan, China, and the Himalayas, as well as in North America and Mexico (De Candolle, *Prod.*, i. 79; Bentham and Hooker, *Gen. Pl.*, i. 18; A. Gray, *Gen. Ill.*, xxiii., xxiv.).

Magnolias are trees or shrubs with evergreen or deciduous foliage. They bear conspicuous, and often large, fragrant, white, rose, or purple flowers. The sepals are three in number, the petals six to twelve, in two to four series of three in each, the stamens and carpels being numerous. The fruit consists of a number of follicles which dehisce (contrary to the rule) along the outer edge to allow the scarlet or brown seeds to escape, but which are suspended by a long slender thread. Of the Old-World species, the earliest in cultivation appears to have been *M. Yulan*, Desf. (*conspicua*, Salisb.), of China, of which the buds were preserved, as well as used medicinally and to season rice (Pickering, *Chron. Hist. of Pl.*, p. 600). It, together with *M. fuscata*, Andr., was transported to Europe in 1789 (Paxton's *Bot. Dic.*) and thence to North America, and is now cultivated in the middle States. Of the Japanese magnolias, *M. Kobus*, DC., and the purple-flowered *M. obovata*, Thim., were met with by Kaempfer in 1690. They were introduced into England in 1709 and 1804 respectively. The species *M. pumila*, Andr., the dwarf magnolia, from the mountains of Amboyna, is nearly evergreen, and bears deliciously scented flowers. It was introduced in 1786. The Indian species are three in number, *M. globosa*, H. f. et T., allied to *M. conspicua* of Japan; *M. sphenocarpa*, Roxb., and the most magnificent of all magnolias, *M. Campbellii*, H. f. et T., which forms a conspicuous feature in the scenery and vegetation of Darjiling. It was discovered by Dr Griffith in Bhutan. It is a large forest tree, abounding on the outer ranges of Sikkim, 80 feet high, and from 6 to 12 feet in girth. The flowers are 6 to 10 inches across, appearing before the leaves. They vary from white to a deep rose colour (Hook. fil., *Ill. Him. Pl.*, pls. iv. and v.).

The first of the American species brought to Europe (in 1688, by Banister) was *M. glauca*, L. It is found in low situations near the sea from Massachusetts to Louisiana, —more especially in New Jersey and Carolina. In 1712 Catesby visited Virginia and found *M. acuminata*, L., the so-called cucumber tree, from the resemblance of the young fruits to small cucumbers. It ranges from Pennsylvania to Carolina. The wood is yellow, and used for bowls; the flowers are rather small. It was introduced into England in 1736. He also found *M. umbrella*, Lam. (*tripetala*, L.), called the umbrella tree. The flowers are very large, white, and highly scented. It was brought to England in 1752. *M. pyramidata*, Bart., discovered by Bartram in 1773, is a native of the western parts of Carolina and Georgia. The most beautiful species of North America is *M. grandiflora*, L., discovered by Catesby in 1719 in South Carolina and Florida, and introduced into England in 1734. It grows a straight trunk 2 feet in diameter, and upwards of 70 feet high, bearing a profusion of large powerfully lemon-scented creamy-white flowers. In England it is customary to train it against a wall; and the original species is surpassed by the Exmouth varieties, which originated as seedlings at Exeter from the tree first raised in England by Sir John Colliton, and which flower much more freely than the parent plant. The remaining North-American species are *M. auriculata*, Lam., *M. macrophylla*, Michx., and *M. cordata*, Michx. The Mexican species is *M. mexicana*, DC. The tulip tree, *Liriodendron tulipifera*, L., frequently cultivated in England, is also a member of the same family. It is the sole species, and is a native of North America.

For a description of the principal species of magnolia under cultivation see Hemsley's *Handbook of Hardy Trees, &c.*, p. 24; Loudon's *Arboretum*, vol. i. p. 260.

MAGNUS, Heinrich Gustav (1802–1870), an eminent German chemist and physicist, was born at Berlin May 2, 1802. He early showed a strong scientific bias, which was well fostered and strengthened by his education. Six years of thorough study at Berlin university were supplemented by a year's course at Stockholm in Berzelius's laboratory (1828). After some time spent in Paris under Gay-Lussac and Thénard, Magnus settled at Berlin in 1831 as lecturer on technology and physics in the university. In 1834 he was elected extraordinary and in 1845 ordinary professor of these subjects. He died April 4, 1870. His numerous papers, which appeared chiefly in *Poggendorff's Annalen* and in the publications of the Berlin Academy of Sciences, cover a wide range of chemical and physical subjects. His first memoir, published in 1825, while he was yet a student, was a discussion of the spontaneous inflammability of finely divided iron, nickel, and cobalt. From 1827 to 1833 he was occupied mainly with chemical researches, which resulted in the discovery of sulphovinic, ethionic, and isethionic acids and their salts, and, in conjunction with Ammermüller, of periodic acid. The absorption of gases in blood (1837–45), the expansion of gases by heat (1841–44), the vapour pressures of water and various solutions (1844–54), thermo-electricity (1851), electrolysis (1856), induction of currents (1858–61), conduction of heat in gases (1860), and polarization of heat (1866–68) are some of the many subjects of which he treated. From 1861 onwards he devoted much attention to the still vexed question of diathermancy in gases and vapours, especially to the behaviour in this respect of dry and moist air, and to the thermal effects produced by the condensation of moisture on solid surfaces. Many of his papers were translated and published in the *Philosophical Magazine*.

MAGNUSSON, Arni (1663-1730), a scholar to whom we are largely indebted for the preservation of the old Icelandic literature, was born in the west of Iceland in 1663. In his youth he resided for a time at Hvamm, then the residence of his mother's father, Ketil the priest, who was a well-known copyist of manuscripts. In 1683 he came to Copenhagen, and was employed by Bartholinus at first as a copyist, and afterwards to investigate the monuments and ancient customs of Norway. In 1697 he was appointed secretary of the archives of the kingdom. Before this he had begun to collect Icelandic manuscripts, his earliest acquisition (*Hulda*) being in 1687. From that time he steadily persevered, but his great acquisitions were chiefly made in Iceland, whither he went in connexion with the royal survey in 1702-12. The old and important manuscripts were by that time falling into neglect, and it is more than probable that without Arni's intervention the greater part would have been lost to us. On his return from Iceland he was appointed professor of history and Danish antiquities in the university of Copenhagen. He is said never to have recovered the shock caused by the mischief done to his library by the great fire of Copenhagen in 1728. He himself had never the courage to ascertain exactly what he had lost; but it appeared afterwards that scarcely any MS. of real importance had perished. On his death on 6th January 1730, he bequeathed his property to the university of Copenhagen for the purpose chiefly of publishing Icelandic manuscripts (Arna-Magnæan Bequest). The first volume published under the bequest was *Njala*, which appeared in 1772, and was succeeded by a number of valuable publications of the same class. Arni left behind him no literary work of any consequence, and his notes and historical material were mostly destroyed in the conflagration. The signal service which he rendered to Icelandic literature lay in his judicious and extensive collection of the old manuscripts, and investigation of their history so far as attainable, at a time when they were rapidly being superseded and disappearing through neglect.

MAGO was one of the most common Carthaginian names, borne among others by the reputed founder of the military power of Carthage, and the Punic admiral in the war with the elder Dionysius (see Carthage). The most famous of the name was the youngest of the three sons of Hamilcar Barca. He accompanied his brother Hannibal on his expedition into Italy, and held important commands in the great victories of the first three years. After the battle of Cannæ he marched through southern Italy and sailed to Carthage to report the successes gained. He was about to return to Italy with strong reinforcements for Hannibal, when the Government ordered him to go to help his other brother, Hasdrubal, who was hard pressed in Spain. He maintained war there with varying success in concert with the two generals Hasdrubal, until, in 209 B.C., his brother marched into Italy to help Hannibal. Mago remained in Spain with the other Hasdrubal. In 207 he was defeated by M. Silanus, and in 206 the combined forces of Mago and Hasdrubal were scattered by Scipio in the decisive battle of Silpia. Mago maintained himself for a long time in Gades, but afterwards received orders to carry the war into Liguria. He wintered in the Balearic Isles, where the fine harbour Portus Magonis, Port Mahon, still bears his name. Early in 204 he landed in Liguria, where he maintained a desultory warfare till in 203 he was defeated in Cisalpine Gaul by the Roman forces. He received orders soon after to return to Carthage, but on the voyage home he died of wounds received in the battle.

The name of Mago—but which Mago is uncertain—is attached to a great work on agriculture which was brought to Rome and translated by order of the senate after the destruction of Carthage. The book was regarded as a standard authority, and is often referred to by later writers.

MAGPIE, or simply Pie (French, *Pie*), the prefix being the abbreviated form of a human name (Margaret[1]) applied as in so many other instances to familiar animals, as this bird once was throughout Great Britain, though of late years almost exterminated in many parts, and now nearly everywhere scarce. Its pilfering habits have led to this result, yet the injuries it causes are unquestionably exaggerated by common report; and in many countries of Europe it is still the tolerated or even the cherished neighbour of every farmer, as it formerly was in England if not in Scotland also. There is ample evidence[2] to prove that it did not exist in Ireland in 1617, when Fynes Morison[3] wrote his *Itinerary*, and that it had appeared there within a hundred years later, when Swift mentions its occurrences in his *Journal* to Stella, under date of 9th July 1711. It is now common enough in that country, and there is a widespread but of course unfounded belief that it was introduced by the English out of spite. It is a species that when not molested is extending its range, as Wolley ascertained in Lapland, where within the last century it has been gradually pushing its way along the coast and into the interior from one fishing-station or settler's house to the next, as the country has been peopled.

Since the persecution to which the Pie has been subjected in Great Britain, its habits have undoubtedly altered greatly in character. It is no longer the merry, saucy hanger-on of the homestead, as it was to writers of former days, who were constantly alluding to its disposition, but is become the suspicious thief, shunning the gaze of man, and knowing that danger may lurk in every bush. Hence opportunities of observing it fall to the lot of few, and most persons know it only as a curtailed captive in a wicker cage, where its vivacity and natural beauty are lessened or wholly lost. At large few European birds possess greater beauty, the pure white of its scapulars and inner web of the flight-feathers contrasting vividly with the deep glossy black on the rest of its body and wings, while its long tail is lustrous with green, bronze, and purple reflexions. The Pie's nest is a wonderfully ingenious structure, placed either in high trees or low bushes, and so massively built that it will stand for years. Its foundation consists of stout sticks, turf, and clay, wrought into a deep, hollow cup, plastered with earth, and lined with fibres; but around this is erected a firmly-interwoven, basket-like outwork of thorny sticks, forming a dome over the nest, and leaving but a single hole in the side for entrance and exit, so that the whole structure is rendered almost impregnable. Herein are laid from six to nine eggs, of a pale bluish-green freckled with brown and blotched with ash-colour. Superstition as to the appearance of the Pie still survives even among many educated persons, and there are several versions of a rhyming adage as to the various turns of luck which its presenting itself, either alone or in company with others, is supposed to betoken, for some of these versions contradict one another in details, though all agree in this that the sight of a single Pie unquestionably presages sorrow.

The Pie belongs to the same Family of birds as the Crow (vol. vi. p. 617), and is the *Corvus pica* of Linnæus, the *Pica caudata*, *P. melanoleuca*, or *P. rustica* of modern

[1] "Magot" and "Madge," with the same origin, are names frequently given in England to the Pie; while in France it is commonly known as *Margot*, if not termed, as it is in some districts, *Jaquette*.

[2] A compendious summary of this will be found in Yarrell's *British Birds*, ed. 4, ii. pp. 318-320.

[3] His predecessor Derricke, in 1578, said:—

"No Pies to plucke the Thatch from house,
are breed in Irishe grounde:
But worse then Pies, the same to burne,
a thousande maie be founde."

—*The Image of Irelande*, London, 1581.

ornithologists, who have recognized it as forming a distinct genus, but the number of species thereto belonging has been a fruitful source of discussion. Examples from the south of Spain differ slightly from those inhabiting the rest of Europe, and in some points more resemble the *P. mauritanica* of north-western Africa; but that species has a patch of bare skin of a fine blue colour behind the eye, and much shorter wings. No fewer than five species have been discriminated from various parts of Asia, extending to Japan; but only one of them, the *P. leucoptera* of Turkestan and Tibet, has of late been admitted as valid. In the west of North America, and in some of its islands, a Pie is found which extends to the upper valleys of the Missouri and the Yellowstone, and has long been thought entitled to specific distinction as *P. hudsonia*; but its claim thereto is now disallowed by some of the best ornithologists of the United States, and it can hardly be deemed even a geographical variety of the Old-World form. In California, however, there is a permanent race if not a good species, *P. nuttalli*, easily distinguishable by its yellow bill and the bare yellow skin round its eyes; and it is a curious fact that on two occasions in the year 1867 a bird apparently similar was observed in Great Britain (*Zoologist*, ser. 2, pp. 706, 1016). (A. N.)

MAHÁBALESHWAR, a hill station in Satára district, and the principal sanatarium in the Bombay presidency, India (17° 58′ N. lat., 73° 42′ E. long.), occupies the summit of a range of the Western Gháts, with a general elevation of 4500 feet above sea-level. It was established by Sir John Malcolm, the governor in Bombay in 1828, who obtained the site from the rájá of Satára in exchange for another patch of territory. The superior elevation of Mahábaleshwar renders it much cooler than Mátherán (2460 feet), but its heavy rainfall (about 240 inches) makes it almost uninhabitable during the rainy season. It forms the retreat usually during spring, and occasionally in autumn, of the governor of Bombay, the commander-in-chief of the Bombay army, and the chief officers of their establishments, and has the usual public buildings of a first-class sanatarium. The population was returned in 1872 at 2759.

MAHABHARATA. See SANSKRIT LITERATURE.

MAHÁNADI, or MAHANUDDY ("The Great River"), a river of India, rising in 20° 10′ N. lat., 82° E. long., 25 miles south of Ráipur town, in a wild mountainous region of the Central Provinces. At first an insignificant stream, it flows in a tortuous easterly course through the hills in a rocky bed until it reaches Dholpur in Orissa. From this point it rolls its unrestrained waters straight for the outermost line of the Eastern Gháts. This mountain line it pierces by a gorge about 40 miles in length, overlooked by hills, shaded by forests, deep and tranquil, and navigable at all seasons. It pours down upon the Orissa delta at Naráj, about 7 miles west of Cuttack town; and after traversing Cuttack district from west to east, and throwing off numerous branches (the Kátjuri, Paika, Birúpá, Chitartalá, &c.), it falls into the Bay of Bengal at False Point by several channels.

The Mahánadi has an estimated basin of 43,800 miles, and its rapid flow renders its maximum discharge in time of flood second to that of no other river in India. During unusually high floods 1,800,000 cubic feet of water pour every second through the Naráj gorge, one-half of which, uncontrolled by the elaborate embankments, pours over the delta, filling the swamps, inundating the rice-fields, and converting the plains into a boundless sea. In the dry weather the discharge of the Mahánadi dwindles to 1125 feet per second. Efforts have been made to husband and utilize the vast water supply thrown upon the Orissa delta during seasons of flood. Each of the three branches into which the parent stream splits at the delta head is regulated by a weir. Of the four canals which form the Orissa irrigation system, two take off from the Birúpá weir, and one, with its branch, from the Mahánadi weir. On the 31st December 1868 the Government took over the whole canal works from the East Indian Irrigation Company, at a cost of £941,368, since which time the gradual prosecution of the Orissa scheme to completion has been sanctioned. The canals thus taken over and since completed, or carried to an advanced stage of construction, are the High-Level Canal, the Kendrápárá Canal, the Táldandá Canal, and the Máchhgáon Canal, with their distributaries, designed to irrigate a total of 1,600,000 acres.

MAHANOY CITY, a post borough of the United States, in Mahanoy township, Schuylkill county, Pennsylvania, lies at a height of 1211 feet above the sea, 56 miles north-east of Harrisburg, with a station both on the Lehigh Valley and on the Philadelphia and Reading Railway. It was founded in 1859, and owes its existence to the great anthracite mines in the neighbourhood. Two public halls, a public library, two weekly newspapers, and the increase of its population from 5533 in 1870 to 7181 in 1880, betoken its prosperity.

MAHASEER, or MAHSEER (*Barbus mosal*), a kind of barbel, abundant in the rivers of India, especially in pools of the upper and more rapid streams where they issue from the mountainous part of the country. It is one of the largest species of the family of carps, attaining to a length of from 3 to 5 feet, and exceeding sometimes a weight of 70 lb. Its body is well-proportioned, rather elongate, and somewhat like that of the European barbel, but covered with very large scales, of which there are only twenty-five or twenty-seven placed along the lateral line; the dorsal fin is armed with a long and strong spine, and the mouth provided with four slender and short barbels. The lips are sometimes produced into fleshy lobes. To the fisherman in India the mahaseer affords the same kind of sport as the salmon in the British Isles, and it rivals that fish as regards size, strength, and activity. Its flesh is likewise much esteemed.

MAHDÍ, *i.e.*, "he who is guided aright," the third caliph of the house of 'Abbás (see MOHAMMEDAN EMPIRE). The name of Mahdí is also that which the Shí'ite Mohammedans give to their Messiah, the last of the Imáms of the house of 'Ali. It was under the name of al-Mahdí that Mokhtár proclaimed 'Ali's son Mohammed as the opponent of the caliph 'Abd al-Malik, and, according to Shahrastani, p. 111, the doctrine of the Mahdí, the hidden deliverer who is one day to appear and fill the oppressed world with righteousness, first arose in connexion with a wild notion that this Mohammed had not died but lived concealed at Mount Radwá, near Mecca, guarded by a lion and a panther. The hidden Imám of the common Shí'ites is, however, the twelfth Imám, Mohammed Abu'l-Kásim, who disappeared mysteriously 879 A.D. The belief in the appearance of the Mahdí readily lent itself to imposture. Of the many pretendants to this dignity known in all periods of Moslem history down to the present day[1] the most famous was the first caliph of the Fatimite dynasty in North Africa, 'Obaid-alláh al-Mahdí, who reigned 909–934 A.D. From him was named the capital of the dynasty, the once mighty city of Mahdíya, the port and entrepôt of Kairawán (see MOHAMMEDAN EMPIRE under the reign of Moktadir). Another great historical movement, headed by a leader who proclaimed himself the Mahdí (Mohammed ibn Abdallah ibn Túmrut), was that of the ALMOHADES (*q.v.*).

MAHÉ, a French settlement and town, in the Malabar district, Madras, India, is situated in 11° 41′ 50″ N. lat. and 75° 34′ 25″ E. long., to the south of the river Mahé, with an area of 1445 acres. It is the only French possession on the west coast of India, and is in charge of a *chef-de-service*, subordinate to the governor-general at Pondicherri. It is now a decaying place, with most of its chief buildings

[1] Thus there are at the present date (1882) three actual pretendants to the dignity of Mahdí, Sheikh Mohammed of Dongola in the Egyptian Súdán, the Sheikh El-Senúsí in Tripoli, and a third in the vilayet of Aídín.

picturesquely situated close to the river mouth. The population in 1871 was 8492. It contains a Román Catholic chapel, a school, and a British post-office; and a long wooden bridge maintained by the British Government gives access to the British territory beyond the river.

MAHI KANTHÁ, THE, a group of native states forming a political agency under the Government of Bombay, India, lying between 23° 14′ and 24° 28′ N. lat. and 72° 40′ and 74° 5′ E. long., with an area of about 4000 square miles, and an estimated population of 447,056. It is bounded on the N.E. by the Rájput states of Udáipur and Dunyarpur, on the S.E. by Rewa Kanthá, on the S. by Kaira district, and on the W. by the native states of Baroda and the Pálanpur agency. The Mahi Kanthá territory is divided among a number of chiefs, of whom the rájá of Edar is by far the most important. In May 1877 these chiefs were classified in seven divisions, according to their importance and the extent of their jurisdiction. There are two states of the second class, three of the third, nine of the fourth, nine of the fifth, fourteen of the sixth, and fourteen of the seventh class. The entire revenues amount to about £110,000.

MAHMÚD OF GHAZNI (971-1030), known also as Mahmúd, son of Subuktigín, was born October 2, 971. His fame rests chiefly on his successful wars, in particular his numerous invasions of India. His military capacity, inherited from his father, Nasír-ud-din Subuktigín, was strengthened by youthful experience in the field. Subuktigín, a Turki slave of Alptigín, governor of Khorásán under Abd' ul Malik Núh, king of the Sámáni dynasty of Bokhára, early brought himself to notice. He was raised to high office in the state by Alptigín's successor, Abú Isḥák, and in 366 A.H. (977 A.D.), by the choice of the nobles of Ghazni, he became their ruler. He soon began to make conquests in the neighbouring countries, and in these wars he was accompanied by his young son Mahmúd. On one occasion, when Mahmúd was fourteen years of age, his advice with respect to a military operation in the hills was approved and adopted by the generals. Before he had reached even this age he encountered in two expeditions under his father the Indian forces of Jaipál, raja of Lahore, whom Subuktigín defeated on the Punjab frontier.

In 994 Mahmúd was made governor of Khorásán, with the title of *Saif-ed-daulah* ("Sword of the State"), by the Sámáni emir, Abd' ul Malik Núh. Two years later, his father Subuktigín died in the neighbourhood of Balkh, having declared his second son, Ismáil, who was then with him, to be his successor. As soon as Ismáil had assumed the sovereignty at Balkh, Mahmúd, who was at Nishápúr, addressed him in friendly terms, proposing a division of the territories held by their father at his death. Ismáil rejected the proposal, and was immediately attacked by Mahmúd and defeated. Retreating to Ghazni, he there yielded, and was imprisoned, and Mahmúd obtained undisputed power as sovereign of Khorásán and Ghazni (997).

The Ghaznavi dynasty is sometimes reckoned by native historians to commence with Subuktigín's conquest of Búst and Kusdár (978). But Subuktigín, throughout his reign at Ghazni, continued to acknowledge the Sámáni suzerainty, as did Mahmúd also, until the time, soon after succeeding to his father's dominions, when he received from the caliph of Baghdad, Al Kádir Billah, a *khilat* or robe of honour, with a letter recognizing his sovereignty, and conferring on him the titles *Yamín-ed-daulah* ("Right Hand of the State"), and *Amín-ul-Millat* ("Guardian of the Faith"). From this time it is the name of the caliph that is inscribed on Mahmúd's coins, together with his own new titles.[1] Previously the name of the Sámáni sovereign, Mansúr bin Núh (successor of Abd' ul Malik) is given along with his own former title, Saif-ed-daulah Mahmúd. The earliest of those of the new form gives his name Mahmúd bin Subuktigín. Thereafter his father's name does not appear on his coins, but it is inscribed again on his tomb.

The new honours received from the caliph gave fresh impulse to Mahmúd's zeal on behalf of Islam, and he resolved on an annual expedition against the idolaters of India. He could not quite carry out this intention, but a great part of his reign was occupied with his Indian campaigns. In 1000 A.D. he started on the first of these expeditions, but it does not appear that on this occasion he went farther than the hill country near Peshawar. The hostile attitude of Khalaf ibn Ahmad, governor of Sístán, called Mahmúd to that province for a short time. He was appeased by Khalaf's speedy submission, together with the gift of a large sum of money, and further, it is said, by his subdued opponent addressing him as *sultán*, a title new at that time, and by which Mahmúd continued to be called, though he did not formally adopt it, or stamp it on his coins. Four years later Khalaf, incurring Mahmúd's displeasure again, was imprisoned, and his property confiscated.

Mahmúd's army first crossed the Indus in 1001, opposed by Jaipál, raja of Lahore. Jaipál was defeated, and Mahmúd, after his return from this expedition, is said to have taken the distinctive appellation of *Ghází* ("Valiant for the Faith"), but he is rarely so called.[2] On the next occasion (1005) Mahmúd advanced as far as Bhera on the Jhelum, when his adversary Anang-pál, son and successor of Jaipál, fled to Kashmir. The following year saw Mahmúd at Multan. When he was in the Punjab at this time, he heard of the invasion of Khorásán by Ilak Khan, ruler of Transoxiana (whose daughter Mahmúd had married). After a rapid march back from India, Mahmúd repelled the invaders. Ilak Khan, having retreated across the Oxus, returned with reinforcements, and took up a position a few miles from Balkh, where he was signally defeated by Mahmúd.

Two years had elapsed since his last visit to India when Mahmúd again entered the Punjab (1008), this time for the express purpose of chastising Séwah Pál, who, having become a Mussulman, and been left by Mahmúd in charge of Multan, had relapsed to Hinduism. The Indian campaign of the following year (1009) was a notable one. Near the Indus Mahmúd was opposed again by Anang-pál, supported by powerful rajas from other parts of India. After a severe fight, Anang-pál's elephants were so terror-struck by the fire-missiles flung amongst them by the invaders that they turned and fled, the whole army retreating in confusion and leaving Mahmúd master of the field.[3] Mahmúd, after this victory, pushed on through the Punjab to Nagar-kót (Kangra), and carried off much spoil from the Hindu temples to enrich his treasury at Ghazni. In 1011 Mahmúd, after a short campaign against the Afghans under Mohammed ibn Súr in the hill country of Ghor, marched again into the Punjab. The next time (1014) he advanced to Thanésar, another noted stronghold

[1] Even before succeeding his father he struck coins in his own name at Nisábúr (Nishápúr), when he was governor of Khorásán.

[2] The emperor Bábar gives him this title (1526). He himself was the second Mohammedan king who had conquered India, the first being Sultan Mahmúd Ghází.

[3] The terms in which native historians have described the effects of these missiles—not unlike the account given by De Joinville of the Greek fire which caused such consternation to the army of St Louis something more than two centuries later—gave rise at one time to the idea that something like modern artillery was meant. The fact that naphtha is distinctly mentioned as having been used by Mahmúd on a later occasion, and the knowledge that petroleum is found at several places on both sides of the Indus near the scene of the fight with Anang-pál, furnish the most probable explanation.

of Hinduism, between the Sutlej and the Jumna. Having now found his way across all the Punjab rivers, he was induced on two subsequent occasions to go still farther. But first he designed an invasion of Kashmir (1015), which was not carried out, as his progress was checked at Lóh-kót, a strong hill-fort in the north-west of the Punjab. And then before undertaking his longer inroad into Hindustan he had to march north into Khwárizm (Khiva) against his brother-in-law Mamún, who had refused to acknowledge Mahmúd's supremacy. The result was as usual, and Mahmúd, having committed Khwárizm to a new ruler, one of Mamún's chief officers, returned to his capital. Then in 1018, with a very large force, he proceeded to India again, extending his inroad this time to the great Hindu cities of Mathra on the Jumna and Kanauj on the Ganges. To the glory of reducing the one and receiving the submission of the other he added, as was his custom, the further satisfaction of carrying back great stores of plunder from both to his own country. Three years later he went into India again, marching over nearly the same ground, to the support, this time, of the raja of Kanauj, who, having made friendship with the Mohammedan invader on his last visit, had been attacked by the raja of Kalinjar. But Mahmúd found he had not yet sufficiently subdued the idolaters nearer his own border, between Cabul and the Indus, and the campaign of the year 413 (1022 A.D.) was directed against them, and reached no farther than Peshawar. Another march into India the following year was made direct to Gwalior.

The next expedition (1025) is the most famous of all. The point to which it was directed was the temple of Somnath on the coast of the Gujerát peninsula. After an arduous journey by Multan, and through part of Rajputana, he reached Somnath, and met with a very vigorous but fruitless resistance on the part of the Hindus of Gujerát. Moslem feet soon trod the courts of the great temple. The chief object of worship it contained was broken up, and the fragments kept to be carried off to Ghazni. The story is often told of the hollow figure, cleft by Mahmúd's battle-axe, pouring out great store of costly jewels and gold. But the idol in this Sivite temple was only a tall block or pillar of hewn stone, of a familiar kind. The popular legend is a very natural one. Mahmúd, it was well known, made Hindu temples yield up their most precious things. He was a determined idol-breaker. And the stone block in this temple was enriched with a crown of jewels, the gifts of wealthy worshippers. These data readily give the Somnath exploit its more dramatic form. For the more recent story of the Somnath gates see GHAZNI, vol. x. p. 560.

After the successes at Somnath, Mahmúd remained some months in India before returning to Ghazni. Then in 1026 he crossed the Indus once more into the Punjab. His brilliant military career closed with an expedition to Persia, in the third year after this, his last visit to India. The Indian campaigns of Mahmúd and his father were almost, but not altogether, unvarying successes. The Moslem historians touch lightly on reverses. And, although the annals of Rajputana tell how Subuktigín was defeated by one raja of Ajmír and Mahmúd by his successor, the course of events which followed shows how little these and other reverses affected the invader's progress. Mahmúd's failure at Ajmír, when the brave raja Bisal-deo obliged him to raise the siege but was himself slain, was when the Moslem army was on its way to Somnath. Yet Mahmúd's Indian conquests, striking and important in themselves, were, after all, in great measure barren, except to the Ghazni treasury. Mahmúd retained no possessions in India under his own direct rule. But after the repeated defeats, by his father and himself, of two successive rajas of Lahore, the conqueror assumed the right of nominating the governors of the Punjab as a dependency of Ghazni, a right which continued to be exercised by seven of his successors. And for a time, in the reign of Masáúd II. (1098–1114), Lahore was the place of residence of the Ghaznavi sovereign. Certain silver coins of Mahmúd's reign bear inscriptions in Sanskrit characters as well as Arabic, betokening sovereignty in India. They are dated 418 and 419 A.H., the two years immediately following his last visit to the Punjab, and are struck at a place called by his name, Mahmúdpúr, supposed to be Lahore. There are also copper coins struck at Lahore (now retaining legible dates) bearing Mahmúd's name and the caliph's, in Arabic characters only. Mahmúd's coins are numerous and historically important. They were issued from mints at Nisábúr, Hirát, Ghaznah (a common alternative form of the name), Farwán, and Balkh, besides Mahmúdpúr and Lahore, just mentioned. Mahmúd died at Ghazni in 1030, the year following his expedition to Persia, in the sixty-first year of his age and thirty-third of his reign.

Mahmúd stands conspicuous for his military ardour, his ambition, strong will, perseverance, watchfulness, and energy, combined with great courage and unbounded self-reliance. But his tastes were not exclusively military. His love of literature brought men of learning to Ghazni. His acquaintance with Moslem theology was recognized by the learned doctors. Mahmúd is accused of avarice. It has been said that the prospect of booty was as strong a motive power in these repeated invasions of India as his love of military glory and desire to shine as a champion of the faith. An illustration commonly given of his want of liberality is his treatment of the poet Firdousi. Delighted with a portion which was read to him of the poet's metrical romance narrating the deeds of the early kings of Persia, Mahmúd presented him with a thousand *dínárs*, one for each couplet, with an implied promise, or at least expectation on the part of the author, of payment on the same scale for the rest. The completed *Sháh Námah*, presented in due course, contained no less than sixty thousand couplets, and the reward this time was given in *dirhems* instead of *dínárs*. Firdousi retired in disgust to his native place, Tús, and satirized the sultan. At a later time, it is said, Mahmúd sent him the larger sum; but the poet died just before it arrived. Mahmúd had the general reputation of giving liberal and discerning encouragement to learned and literary men. Among those who took up their abode at Ghazni in his time, the most noted, after Firdousi, were the poet Unsuri of Balkh, whose compositions were largely devoted to the praise of the sultan Mahmúd; another poet, Asjudi of Merv, who wrote a grand ode on the Somnath expedition; El Utbi of Khorásán, author of the *Kitáb-i-Yamíni*, a history of Subuktigín and of Mahmúd (to about the middle of his reign); and the accomplished historian, Abú Rihán, called Al Biríni, author of the *Taríkh ul Hind*, as well as of a number of scientific works. The sultan established large educational institutions at Ghazni.

Mahmúd also found time to bestow attention on other arts of peace, and did not neglect his capital and the country around. Large sums were devoted to important public works. The building of the great Jama Masjid of Ghazni is described by El Utbi in admiring terms. A splendid palace which Mahmúd built induced wealthy nobles at Ghazni to erect great mansions for themselves. Two fine towers or minarets at Ghazni, 140 feet in height, bearing Mahmúd's name (though one is said to have been built by his successor) have attracted the attention of travellers. They are of a remarkable construction, the lower part with a zigzag or star-shaped outline, the upper part round, like the third and fourth stories of the Kutb Minar at Delhi, built two centuries later. Like the Kutb pillar too, they are isolated, and may, like it, have served as the minarets for a separate mosque or mosques. The dam called the *Band-i-Sultán*, which Mahmúd constructed to form an artificial lake for irrigation, appears to have been a really great and substantial work.

Mahmúd, besides being marked by small-pox, had an ill-favoured countenance, and knew it. Courtiers met his allusions to his personal appearance by the familiar complimentary remarks about inward graces more than counterbalancing outward defects. He himself is said to have observed, after looking in the glass, that he saw so many faults in himself he was ready to excuse those of others.

Mahmúd's tomb stands in a garden a short distance from Ghazni, called *Rauzat-i-Sultán* ("the sultan's tomb," or "garden"—the word means both). On one of the minarets is an inscription which gives all his titles. On the massive tombstone within the building he is named more briefly Nizám-ed-din Abu'l Kásim Mahmúd, son of Subuktigín. He was succeeded by his son Muhammad, who was soon displaced by his more vigorous brother Musáúd.

The principal histories of Mahmúd's reign are—*Kitáb-i-Yamíní* (Utbi); *Taríkh-us-Subuktigín* (Baihaki); *Tabakát i Násiri* (Minháj el-Siráj); *Rauzat-us-Safa* (Mir Khond); *Habib-us-Siyar* (Khondamir). See Elliot, *History of India*; Elphinstone, *History of India*; *Jour. Roy. As. Soc.*, vols. ix., xvii.; *Jour. As. Soc. Bengal*, vol. xii.; *As. Res.*, vols. xvi., xvii. (R. M'L*.)

MAHOGANY, a familiar dark-coloured wood largely used for household furniture, and supplied by a large tree indigenous to Central America and the Antilles. It was originally received from Jamaica; 521,300 feet were exported from that island in 1753. *Swietenia Mahogani*, L., is the sole species of the genus of the order *Meliaceæ* (Benth. and Hook., *Gen. Pl.*, i. 338). It bears imparipinnate leaves, like those of the ash, and panicles of small pentamerous flowers with 10 monadelphous stamens. The fruit is a pear-shaped woody capsule, with many winged seeds. The dark-coloured bark has been considered a febrifuge, and the seeds were used by the ancient Aztecs with oil for a cosmetic, but the most valuable product is the timber, first noticed by the carpenter on board Sir Walter Raleigh's ship in 1595, for its great beauty, hardness, and durability. Dr Gibbons brought it into notice as well adapted for furniture in the early part of the 18th century, and its use as a cabinet wood was first practically established by a cabinetmaker named Wollaston, who was employed by Gibbons to work up some mahogany brought to England by his brother. Since its introduction no wood has been more generally used for cabinet-making purposes, and none possesses like advantages of combined soundness, large size, uniform grain, durability, beauty of colour, and richness of figure.

In the trade the wood is generally classified under the two heads of Spanish Mahogany and Honduras Mahogany or Baywood. The former comprises the rich, solid, and heavy varieties, susceptible of a high degree of polish, and frequently showing rich wavy figuring, in which case the wood is enormously enhanced in value, and used only in the form of veneers. Under the name of Honduras mahogany or baywood is embraced the light open-grained and plain classes of mahogany, uniform in colour, and valuable for the ease with which they can be worked for an endless variety of uses where sound straight timber, free from all tendency to warp, is required. By importers, however, several classes of mahogany are recognized. The original Spanish mahogany is the produce of the island of San Domingo, whence only small supplies now come, and these mostly in logs of not more than 8 to 10 feet in length by 12 or 13 inches in thickness. Cuba mahogany is in richness of figure and other properties little inferior for ornamental purposes to San Domingo wood, while it possesses the advantage of being obtained in logs up to 35 feet long and 2 feet square in cross section. Squared Honduras logs are sometimes obtained 40 feet long and 2 feet thick, and, although the wood is generally plain in character, richly figured logs are occasionally got. It appears that the Honduras wood obtained in the north, near the Mexican boundary, is much more rich, dense, and solid than the soft swamp-grown timber, which commonly goes by the name of Honduras or baywood. In Mexico the mahogany tree attains its greatest dimensions, and thence logs squared to 40 and even 48 inches are sometimes obtained, whilst the common size of logs varies between 15 inches and 3 feet. The Mexican wood is cut into lengths of from 18 to 30 feet, for convenience of shipment, and, while in general the wood is plain and somewhat soft in the core, the produce of some provinces, Tabasco especially, is firm, solid, and not unfrequently richly figured. Occasionally the wood which has been floated in tropical seas is found to be badly "wormed" or attacked by marine borers. The cutting, squaring, and shipment of the wood in the tropical regions which are its home are conducted under circumstances of great difficulty. The tree has recently been introduced into the north-west provinces of India under very favourable conditions, and its successful cultivation there is likely to prove a matter of considerable economic importance. Mahogany is included among the second-class woods in Lloyd's list for ship-building purposes; it is a good deal employed in internal joiner work both in ships and houses; it is a favourite turnery wood, and is equally preferred by wood-carvers. The imports of mahogany into the United Kingdom during 1881 were 42,412 tons, of an estimated value of £390,418, fully one-half of which came from Mexico.

MAHOMET. See MOHAMMED.

MAHONY, FRANCIS (1804-1866), "Father Prout," Roman Catholic priest, scholar, journalist, song-writer, and humorist, was born at Cork of a respectable middle-class family in 1804. His classical education was chiefly obtained at a Jesuit college at Amiens, and after studying theology at Paris he received clerical ordination, and served in Switzerland and Ireland. He then came to London, and officiated for some time in the chapel of the Bavarian Legation. While there he fell in with the coterie of wits and men of letters who were then engaged on *Fraser's Magazine*, and, soon finding their society and pursuits more congenial to him than those of the Romish priesthood, he, about 1834, began to contribute his celebrated Prout papers to *Fraser*. These consist principally of translations of well-known English songs into Latin, Greek, French, and Italian verse, which he humorously represents as being the true originals from which the English authors had merely plagiarized them. The songs of France, and those of modern and ancient Italy (including among the latter many most felicitous renderings of Horace's odes), were then given in English versions, accompanied by a running commentary full of queer humour and often acute criticism. Prout's translations have been universally admired for the extraordinary command which they display of the various languages into which his renderings are made, and for their spirit and freedom both of thought and expression. Perhaps, however, the wonder at his polyglott learning has led to less attention than is deserved being paid to the remarkable excellence of many of his English versions of French and Latin odes. In happy abandon they are often almost unequalled, and most of them have all the unfettered character of original compositions. It might have been expected that with his great gift of poetical expression he would have left behind him more of what was exclusively his own. What he has given us in this line tends chiefly to show that with all his sarcastic and cynical wit his genius had also its tender, serious, and sentimental side. His "Bells of Shandon" have always been greatly admired; and "The Mistletoe," "The Redbreast of Aquitaine," "The Lady of Lee," and the "Legend of Arethusa" are not without a certain sweetness and beauty. In 1846 Mahony became "own correspondent" at Rome to the *Daily News*, and his letters from that capital gave very vivid pictures, and contain much valuable and interesting information, of the first years, so full of liberal promise, of the reign of Pius IX. The last twelve or fifteen years of his life were spent at Paris, from which he supplied the *Globe* with a series of piquant letters on the incidents of the day. His death took place in May 1866. Mahony was not less distinguished as a conversationalist than as a writer. He had great stores of very various knowledge, had seen much of the world, and had a quick power of repartee and no end of sharp cynical wit. It is difficult to suppose that he could ever have been in his true place as a priest of the Roman Catholic Church. Bohemian as he was, however, he never separated himself from it, or seems to have lost his attachment to it; and it is creditable to his character that, though living much among scorners and indifferentists, he would never suffer injurious reflexions either upon his church or upon Christianity to pass without sharp rebuke.

The *Reliques of Father Prout* were collected from *Fraser's Magazine* and published in two handsome volumes in 1836, a considerably enlarged edition appearing in 1860. A biographical notice of him by his friend Mr Sheehan was prefixed to the *Bentley Ballads*; and many additional details were given, with a considerable amount of his fugitive work contributed to the *Daily News* and the *Globe*, edited by Mr Blanchard Jerrold, in the *Final Reliques of Father Prout*, published in 1876.

MAHRATTAS. The Mahrattas inhabit that portion of India which is known by the ancient name of Mahârâshtra (Sanskrit for the great kingdom or region). This large tract, extending from the Arabian Sea on the west to the

Sâtpura mountains in the north, comprises a good part of western and central India, including the modern provinces of the Concan, Khandesh, Berar, the British Deccan, part of Nagpur, and about half the Nizam's Deccan. Its area amounts to about 120,000 square miles, and its population to about 12 millions of souls, or 100 to the square mile. The population has increased greatly in the 19th century under British rule; but there had been much decrease during the 17th and 18th centuries owing to war and devastation. Frightful depopulation occurred from the famine which was at its height in 1400 A.D., and was called the Dûrga Dévi or the goddess of destruction. Much mortality was also caused by famine between 1801 and 1803. There was probably a period of high prosperity during the first centuries of the Christian era, under a number of petty indigenous sovereigns, among whom these wide territories had become parcelled out before the first invasion of the Deccan by the Moslems about 1100.

The etymology of the word Mahratta (or Marhatta, as it is written in the vernacular) is uncertain. The name does not indicate a social caste, or a religious sect; it is not even tribal. It embraces the people of all races who dwell in the region of Mahàrâshtra, both high-caste and low-caste Hindus; it is applied, of course, to Hindus only. Thus there are Mahratta Brahmans, next Mahratta Kumbis or cultivators, and Mahratta Rajputs or warriors, though the latter have but a small infusion of real Rajput blood. The Mahrattas, then, are essentially Hindus in religion and in caste ordinances, not differing in these respects from the Hindus in other parts of India. They have a language of their own, called the Mahratti, a dialect of the Sanskrit, —a copious, flexible, and sonorous tongue.

But the Mahrattas have always been a separate nation or people, and still regard themselves as such, though nowadays they are almost all under British or Mohammedan jurisdiction; that is, they belong either to British India or to the Nizam's Dominions. A few states or principalities purely Mahratta,—such as Kolhapur and some lesser states clustering round it in the southern Deccan,—still survive, but they are under close supervision on the part of the British Government. There are indeed still three large native states nominally Mahratta, namely, that of Sindhia near the borders of Hindustan in the north, that of Holkar in Malwa in the heart of the Indian continent, and that of the gaekwar in Gujerat on the western coast. But in these states the prince, his relatives, and some of his ministers or employés only are Mahrattas; the nobility and the mass of the people are not Mahrattas at all, but belong to other sections of the Hindu race. These states then are not to be included in the Mahratta nation, though they have a share in the Mahratta history, and are concerned in the extraneous achievements of that people.

In general terms the Mahrattas, as above defined, may be described under two main heads, first the Brahmans, and secondly the humble or low-caste men. The Mahratta Brahmans possess, in an intense degree, the qualities of that famous caste, physical, intellectual, and moral. They have generally the lofty brow, the regular features, the spare upright figure, the calm aspect, the commanding gait, which might be expected in a race maintained in great purity yet upon a broad basis. In modern times they have proved themselves the most able and ambitious of all the Brahmans in the Indian empire. They are notably divided into two sections—the Concanast, coming from the Concan or littoral tract on the west coast below the Western Ghât mountains, and the Dèshast, coming from the uplands or Deccan, on the east of the mountains. Though there have been many distinguished Dèshasts, yet the most remarkable of all have been Concanasts. For instance, the pèshwas, or heads of the Mahratta confederation which at one time dominated nearly all India, were Concanast Brahmans. The birthplaces of these persons are still known, and to this day there are sequestered villages, nestling near the western base of the Ghâts, which are pointed to as being the ancestral homes of men who two centuries ago had political control over the Indian empire.

Apart from the Brahmans, the Mahrattas may be generally designated as Sùdras, or men of the humblest of the four great castes into which the Hindu race is divided. But, as indicated above, the upper classes among the Mahrattas claim to be Kshattriyas or Rajputs. They probably are aborigines fundamentally, with a mixture of what are now called the Scythian tribes, which at a very early time overran India. They have but a slight admixture of the Aryans, who victoriously immigrated from Central Asia and established the Hindu system.

These ordinary Mahrattas, who form the backbone of the nation, have plain features, an uncouth manner, a clownish aspect, short stature, a small but wiry frame. Their eyes, however, are bright and piercing, and under excitement will gleam with passion. Though not powerful physically as compared with the northern races of the Punjab and Oudh, they have much activity and an unsurpassed endurance. Born and bred in or near the Western Ghât mountains and the numerous tributary ranges, they have all the qualities of mountaineers. Among their native hills they have at all times evinced desperate courage. Away from the hills they do not display remarkable valour, except under the discipline which may be supplied by other races. For such organization they have never, of themselves, shown any aptitude. Under civilized authority, however, they are to be reckoned among the good soldiers of the empire. In recent times they enter military service less and less, betaking themselves mainly to cultivation and to the carrying business connected with agriculture. As husbandmen they are not remarkable; but as graziers, as cartmen, as labourers, they are excellent. As artisans they have seldom signalized themselves, save as armourers and clothweavers.

Those Mahrattas who dwell in the extreme west of Mahàrâshtra, within the main range of the Western Ghâts, and in the extreme north of Mahàrâshtra near the Sâtpura mountains, are blessed with unfailing rainfall and regular seasons. But those who dwell at a distance from these main ranges, or among the lower or subsidiary ranges, are troubled with variable moisture and uncertain seasons, frequently, too, with alternations of drought and of flood. Periodically they are afflicted by scarcity, and sometimes by severe famine. They have within the last half century largely extended their area of cultivation. Their industry, which is chiefly agricultural, has grown apace. Their tendency is undoubtedly to increase in numbers; and, despite occasional depopulation from disasters of season, they have increased considerably on the whole. But in some districts, owing to the famine of 1877, and the sickness which ensued when excessive rainfall followed the drought, the population has been stationary, while in others it has actually retrograded because epidemics and plagues of vermin were added to the misfortunes of season.

Among all the Mahrattas the land is usually held on the tenure technically known as "ryotwari." This tenure is now established under the British Government by surveying and assessing operations comprehended under the official term "settlement." It practically means peasant proprietorship. The proprietor, or ryot, is a cultivator also. His holding may be on the average 20 or 30 acres, divided into small fields. Of these fields he cultivates some, himself working at the plough, and his family weeding and cleaning the soil. He will also hire labour, and thus the farm-labourers become a considerable class. He pays to the Government direct the land tax, which is assessed on his holding for the long term of thirty years, so that he may have the benefit of his improvements. His property in the land is absolute; it descends according to the Hindu law of inheritance; it can be sold or otherwise transferred by private arrangement; it is pledged or mortgaged for debt, and money is largely borrowed on its security. It is liable to sale for default in regard to land revenue; and Government as a creditor has the first claim. Thus, as a peasant proprietary, the Mahrattas are in the best possible position, and have been so for many years since the completion of the British settlement. Their only fault is a disposition to live beyond their humble means. They have thus been of late years led into debt, which has produced disputes between them and the money-lenders, ending sometimes in agrarian disturbance.

In the Concan there are some superior proprietors termed Khotes. With this and perhaps some other exceptions, notably that of Nagpur, there are not in the Mahratta country many large landlords, nor many of the superior tenure-holders whose position relatively to that of the peasantry has caused much discussion in other parts of India. There are indeed many Mahratta chiefs still resident in the country, members of the aristocracy which formerly enjoyed much more wealth and power than at present. They are sometimes in the position of landlords, but often they are the assignees of the land revenue, which they are entitled under special grants to collect for themselves instead of for Government, paying merely a small sum to Government by way of quit-rent. Under them the cultivators are by British arrangements placed in the position of peasant proprietors. The village community has always existed as the social unit in the Mahratta territories, though with less cohesion among its members than in the village communities of Hindustan and the Punjab. The ancient offices pertaining to the village, as those of the headman (*patēl*), the village accountant, &c., are in working order throughout the Mahratta country.

The Mahratta peasantry possess manly fortitude under suffering and misfortune. Though patient and good-tempered in the main, they have a latent warmth of temper, and if oppressed beyond a certain endurable limit they would fiercely turn and rend their tormentors. Cruelty also is an element in their character. As a rule they are orderly and law-abiding, but traditions of plunder have been handed down to them from early times, and many of them retain the predatory instincts of their forefathers. The neighbourhood of dense forests, steep hill-sides, and fastnesses hard of access offers extraordinary facilities to plunderers for screening themselves and their booty. Thus gang robbery is apt to break out, gains head with rapidity, and is suppressed with difficulty. In time of peace it is kept under, but during war, or whenever the bands of civil order are loosened, it becomes a cause of anxiety and a source of danger. The women have frankness and strength of character; they work hard in the fields, and as a rule evince domestic virtue. Conjugal infidelity, however, is not unknown among them, and here, as elsewhere in India, leads to bloodshed.

The peasantry preserve a grave and quiet demeanour, but they have their humble ideas of gaiety, and hold their gatherings on occasions of births or marriages. They frequently beguile their toil with carols. They like the gossiping and bartering at the rural markets and in the larger fairs, which are sometimes held in strikingly picturesque localities. They are utterly superstitious, and will worship with hearty veneration any being or thing whose destructive agency they fear. They will even speak of the tiger with honorific titles. They are Hindus, but their Hinduism is held to be of a non-Aryan type. They are sincerely devout in religion, and feel an awe regarding "the holy Brahmans," holding the life and the person of a Brahman sacred, even though he be a criminal of the deepest dye. They of course regard the cow as equally sacred. There are two principal sects among the modern Hindus—those who follow Vishnu, and those who follow Siva. The Mahrattas generally follow Siva and his wife, a dread goddess known under many names. The Mahratta war-cry, "Hur Hur Mahadeo," which used to be heard above the din of battle urging the soldiers to onset with victorious *ēlan*, referred to Siva. All classes high and low are fond of the religious festivals, the principal of which, "the Dasserah," occurs in October, when the first harvest of the year has been secured and the second crops sown. This has always been held with the utmost pomp and magnificence at every centre of Mahratta wealth and power. The people frequently assemble in bowers and arbours constructed of leafy boughs to hear "kathas" recited. These recitations are partly religious, partly also romantic and quasi-historical. After them national resolves of just resistance or of aggressive ambition have often been formed.

Apart from the Mahratta Brahmans, as already mentioned, the Mahratta nobles and princes are not generally fine-looking men. Their appearance, notwithstanding jewellery and rich apparel, is still that of peasants. There certainly are some exceptions, but there is general truth in what was once said by a high authority to the effect that, while there will be something dignified in the humblest Râjpût, there will be something mean in the highest Mahratta. Bluff good-nature, a certain jocoseness, a humour pungent and ready, though somewhat coarse, a hot or even violent disposition, are characteristics of Mahratta chieftains. They usually show little aptitude for business or for sedentary pursuits; but, on the other hand, they are born equestrians and sportsmen. As a rule they are not moderate in living, and are not unfrequently addicted to intemperance. Instances of licentiousness and debauchery have always been found among them. They have generally sprung from a lowly origin, and they have been proud of this fact even after attaining greatness. For instance, three Mahratta chiefs, each of whom established a large kingdom—Sindhia, Holkar, and the gaekwar—declared the lowliness of their birth. Holkar was the descendant of a shepherd; Sindhia boasted of having begun life by keeping his master's slippers; and by his very title the gaekwar perpetuates the memory of his progenitor having tended the cow (gâe). Mahratta ladies and princesses have often taken a prominent part in public affairs and in dynastic intrigues; in some instances their conduct has been of the highest type, in others their influence has been exerted for evil.

Though they have produced some poetry, the Mahrattas have never done much for Oriental literature. Nor have they been distinguished in industrial art. Their architecture in wood, however, was excellent; and the teak forests of their country afforded the finest timber for building and for carving. They had also much skill in the construction of works for the supply of drinking water on a large scale, and for irrigation.

On the whole the Mahrattas will hardly be regarded by Europeans as being among the most interesting of the Indian races. The admirable *History of the Mahrattas*, by Captain Grant Duff (1826), may possibly awaken enthusiasm, as written under personal advantages and with a living knowledge which will never again be possessed by a historian of the later Mahratta times. At all events, a strange interest gathers itself around the Mahratta history.

In the first place the Mahratta country is for the most part strategically important as well as highly picturesque. Some parts of the Deccan are indeed almost irretrievably ugly. The stretches of low hill have long been disforested, and even laid bare of lesser vegetation, and the champaign tracts are treeless as far as the eye can reach. Still much of the Mahratta country lies in the bosom or near the skirts of mountains. The geological formations may be popularly described as consisting of trap, basalt, and indurated lava in magnificent layers. The black precipices, scarped for thousands of feet, and striped with marks of the layers, are superb. The summits, though generally flat with horizontal outlines, are often broken into towers and cones. The vapours from the Arabian Sea are propelled by the south-west monsoon against these mountain tops, and produce an excessive rainfall. Hence arise a luxuriant vegetation and the surprising spectacle (at certain seasons) of cascades tumbling down the perpendicular flanks of the mountains. The forests have suffered during ages from wasteful cutting; but of late years a system of conservancy has been established, and many great forests remain.

The mountains stand in the midst of a fertile and populous country; on both sides of them are rich valleys, cultivated plains, numerous villages, and large towns. Thus insurgents or warriors had here a complete military base, with sources whence supplies could be drawn, and strongholds for organizing power or for securing refuge. This hill country has been regarded by strategists as one of the strongest, in a military sense, to be found in India. It extends over nearly 500 miles from north to south, and has at least twenty fortresses which in uncivilized warfare were virtually impregnable if resolutely defended, and which, though of course unable to resist a scientific attack in these times, would yet prove difficult of approach. Several of these are surrounded with historic traditions. In former times there was no road worthy of the name across these mountains. No means of passage existed save steep rugged pathways for footmen and pack animals. Within the last generation the British Government has, in Oriental phrase, lifted up the veil of these mountains, piercing them with well-made roads and with railways. There are now seven of such roads, and two lines of railway open, a third being projected. Guns and troops as well as goods and produce can now be moved up and down these once impassable mountains.

It is the range of the Western Ghâts which enabled the Mahrattas to rise against their Mohammedan conquerors, to reassert their Hindu nationality against the whole power of the Mogul empire, and to establish in its place an empire of their own. It is often held that in India British conquest or annexation succeeded Mohammedan rule; and to a considerable extent this was the case. But, on the other hand, the principal power, the widest sovereignty, which the British overthrew in India was that of the Mahrattas.

During the earlier Moslem invasions in 1100 and in subsequent years, the Mahrattas do not seem to have made much resistance. They submitted to several Mohammedan kings under the changing circumstances of those times. They were despised by their conquerors, and were called "mountain rats" in derision. It was against the Mohammedan king of Bijapur in the Deccan that Sivaji, the hero of Mahratta history, first rebelled in 1657. Sivaji and his fighting officers were Mahrattas of humble caste, but his ministers were Mahratta Brahmans. When the Mogul empire absorbed that kingdom he defied the emperor. He imparted a self-reliant enthusiasm to his countrymen, formed them into an army, and organized them as a political community; his mountaineer infantry, though limited in numbers, proved desperately courageous; his cavalry was daring and ubiquitous. Having once overcome the Hindus in almost all parts of India, often after heroic resistance, the Moslems had not for centuries met with any noteworthy uprising. Sivaji, however, planned their expulsion, and before the end of his restless life made much progress in the execution of that design. The new Mahratta state which he founded was maintained under various vicissitudes after his death. Still Mahratta resistance, once aroused by him, was never extinguished, and the imperial resources were worn out by ceaseless though vain efforts to quell it. The great Mogul emperor's impoverished and enfeebled successor was fain to recognize the Mahratta state by a formal instrument. The Mahratta king, a descendant of Sivaji, was a *roi fainéant*, and the arrangement was negotiated by his Brahman minister, whose official designation was the pêshwa. The office of pêshwa then became hereditary in the minister's family, and grew in importance as the Mahratta kingdom rose, while the king sunk into the condition of a puppet. Thus the Mahratta power was consolidated throughout nearly the whole of Mahârâshtra under the Brahman pêshwa as virtual sovereign, with his capital at Poona, while the titular Mahratta raja or king had his court at the neighbouring city of Sattara. Despite his political importance, however, the raja was still venerated as the descendant of Sivaji.

Then several chiefs carved out principalities of their own from among the ruins of the Mogul empire. Thus Raghoji Bhônsla established himself in the tracts lying underneath the southern base of the Satpura range (namely, Nagpur and Berar), overran Orissa, and entered Bengal. Dammaji Gaekwar descended from the Western Ghâts upon the alluvial plains of Gujerat around Baroda; Takaji Holkar subdued the uplands of Malwa beyond the Vindhya range on the north bank of the Nerbudda; and Madhaji Sindhia obtained possession of large tracts immediately south of Agra and Delhi, marched into Hindustan, and became virtually the master of the Mogul emperor himself. Princes of Sivaji's own family founded a dominion at Tanjore, in the rich delta of the Kaveri south of Madras.

But these principalities, though really independent respecting internal administration, and making war or peace with their neighbours according to opportunity, yet owned allegiance to the pêshwa at Poona as the head of the Mahratta body. On state occasions heads of principalities would visit Poona by way of acknowledging the superior position of the pêshwa. On the other hand the pêshwa was careful to obtain the sanction of his nominal sovereign at Sattara to every important act of state. Thus a confederation was formed of which the Brahman pêshwa or head was at Poona, governing the adjacent territories, while the members, belonging to the lower castes of Mahrattas, were scattered throughout the continent of India. Such was the Mahratta empire which supplanted the Mogul empire. The Mahratta power grew and prospered till it embraced all India with certain exceptions. Its culminating point was reached about 1750, or about a century after Sivaji first rebelled against his Mohammedan sovereign.

Its armies drew soldiers from all parts of India. The infantry was not of good quality; but its cavalry was really an enormous force, numbering fully a hundred thousand in all. The horsemen were splendidly audacious in riding for long distances into the heart of a hostile country, without support, striking some terrific blows, and then returning rapidly beyond reach of pursuit. They could truly boast of having watered their horses in every Indian river from the Kaveri to the Indus. If attacked, however, in a competent manner they would not stand; and afterwards, in conflict with the British, whole masses of them behaved in a dastardly manner. As their ambition grew, the chiefs began to organize their troops after the system learnt from the English and French. In this way several Frenchmen—De Boigne, Perron, and others—rose in the Mahratta service to a position dangerous to the British. But the new system was unsuited to the Mahratta genius; it hampered the meteoric movements of the cavalry, which was obliged to manœuvre in combination with the new artillery and the disciplined battalions. Mahratta elders hence uttered predictions of military disaster which were in the end more than fulfilled.

While the Mahrattas collected vast quantities of treasure and valuables, the ordinary revenue of the confederation hardly exceeded ten millions sterling annually. Large amounts, however, were drawn by feudal tenure-holders, which never appeared in the public accounts. The area and population under the dominion or the control of the confederation could hardly have been less than 700,000 square miles and 90 millions of souls.

The rapid and amazing success of the Mahratta confederation rendered it the largest Hindu sovereignty that ever existed in India. But it lacked the elements of true greatness. It was founded by plundering expeditions, and its subsequent existence was tainted by the baseness of this predatory origin. With the exception of the pêshwas, its chiefs were little more than freebooting warriors, for the most part rude, violent, and unlettered. Their custom was to offer their neighbours or victims the alternative of paying "chouth," that is, one-fourth of the revenue, or being plundered and ravaged. Thus the Mahratta chouth came to have an ominous significance in Indian history. Desultory efforts were made to establish a civil government, but in the main there was no administration formed on statesmanlike principles. The pêshwas, on the other hand, as Brahmans, were men of the highest education then possible in India. But they were absorbed by the direction of military and political combinations, and by intrigues for the preservation of their own power; and, even allowing for all this, they failed to evince the civil capacity which might have been anticipated. While several displayed commanding abilities, and some possessed many virtues, one only attempted to conduct an administration in an enlightened manner, and he died prematurely.

There were at the same time powers existing in India to keep the Mahrattas in check, and it has just been mentioned that some parts of India were excepted from their depredations. The English power was rising at Calcutta, Madras, and Bombay. The nascent Sikh power prevented Mahratta incursions from being permanently successful in the Punjab. As the Mogul empire broke up, some separate Mohammedan powers rose upon its ruins. The nizam of the Deccan established himself at Hyderabad, comparatively near the headquarters of the pêshwa. Hyder Ali was proclaimed sultan of Mysore in the south. Ahmed Shah Abdali burst upon India from Afghanistan. The Mahrattas bravely encountered him at Panipat near Delhi in 1761, and were decisively defeated. The defeat, however, did not essentially shake the Mahratta empire. It was collision with the English that broke that wonderful fabric to pieces.

The first collision with the English occurred in 1780; it arose from a disputed succession to the pêshwaship. The English Government at Bombay supported one of the claimants, and the affair became critical for the English as well as for the Mahrattas. It was at this conjuncture that Warren Hastings displayed his political genius and rendered signal service to his country.

The next collision happened in 1803. The pèshwa had fallen into grave difficulties with some of the principal members of the Mahratta confederation, namely Sindhia, Holkar, and the Bhonsla raja of Nagpur. He therefore placed himself under British protection, and this led to the great Mahratta war, in which the Marquis Wellesley displayed those talents for military and political combination which have rendered him illustrious. It was during the campaigns which ensued that General Arthur Wellesley defeated Holkar and the Bhonsla raja at Assaye, and General Lake won the victories of Farrukhabad, Dig, and Laswari over Sindhia and Holkar. The three confederates, Sindhia, Holkar, and the Bhonsla, concluded peace with the British Government, after making large sacrifices of territory in favour of the victor, and submitting to British control politically. Thus the Mahratta empire was broken up. It was during these events that the British won the province of Orissa, the old Hindustan now known as the North-Western Provinces, and a part of the western coast comprising Gujerat.

The third collision came to pass between 1816 and 1818, through the conduct, not only of the confederates, but also of the pèshwa himself. During the previous war the pèshwa had been the protégé and ally of the British; and since the war he had fallen more completely than before under British protection and guidance, British political officers and British troops being stationed at his capital. He apparently felt encouraged by circumstances to rebel. Holkar and the Bhonslas committed hostile acts. The predatory Pindaris offered a formidable resistance to the British troops. So the pèshwa ventured to take part in the combination against the British power, which even yet the Mahrattas did not despair of overthrowing. After long-protracted menaces, he attacked the British at Kirki, but failed utterly, and fled a ruined man. Ultimately he surrendered to Sir John Malcolm, and was sent as a state pensioner to Bithûr, near Cawnpur. Thus the last vestige of the Mahratta empire disappeared. The British, however, released the raja of Sattara from the captivity in which he had been kept during the pèshwa's time, and reinstated him on the throne. Owing to these events the British Government became possessed of the Concan and of the greater part of the Deccan.

It remains to mention briefly the fortunes of each remaining member of the once imperial confederation. The principality of Sattara was held to have lapsed in 1849 by the death of the raja without lineal heirs, and was annexed by the British Government. The Bhonsla raja of Nagpur and Berar was obliged to surrender Berar to the nizam, as the ally of the British, in 1803. Berar then remained under the nizam till 1854, when it came under British administration, though it is still included in the nizam's dominions. The raja of Nagpur died without lineal heirs in 1853, and his territory, being held to have lapsed, was annexed to the British territories. The house of Holkar has, during the last sixty years, remained faithful to its engagements with the British Government, and its position as a feudatory of the empire is well maintained. In Sindhia's territory, by reason of internal feuds, the British had to undertake measures which were successfully terminated after the battles of Maharajpur and Panniar in 1843. But on the whole the house of Sindhia has remained faithful. Sindhia himself was actively loyal during the war of the mutinies. The gaekwar gradually fell under British control towards the close of last century, and his house has never engaged in hostilities with the British Government. The gaekwar Khande Rao signalized himself by loyalty during the war of the mutinies. His successor, Malhàr Rao, has recently been deposed by the British Government on account of gross maladministration. The ex-pèshwa lived to old age at Bithûr, and died in 1851. His adopted son grew up to be the Nana Sahib, of infamous memory, who took a leading part in the war of the mutinies. (R. T.)

MAḤZOR (מַחְזוֹר), or MAḤAZOR,[1] as some write the word (from the root חָזַר, to go round, to return), signifies a cycle. The term is used by the Jews in a threefold sense:—(1) astronomically, as *Maḥzor Ḳatan* for the cycle of nineteen years, *Maḥzor Gadol* for that of twenty-eight years, *Maḥzor Gadol lallebanah*[2] for the Metonic cycle; (2) liturgically, for the "Larger Prayer-Book," whether in its narrower or its wider meaning (see below); and (3) ritually, for a book containing religious laws and directions, as, for example, *Maḥzor Vitri* by R. Simḥah b. Shemuel of Vitri-le-Français, *Maḥzor Rabbenu Tam* by R. Ya'aḳob b. Meir of Rameru, &c. In the first sense the plural is either *Maḥazoroth*,[3] or *Maḥzorim*,[4] or *Maḥazorin*;[5] in the second and third it is exclusively *Maḥzorim*. As most ancient prayer-books contain more or less fully elaborate "tables," exhibiting calendar matter, in connexion with the fixing of feasts and fasts and of the lessons from the Pentateuch and the Prophets, we cannot be in doubt as to the true cause of the application of the word *Maḥzor* to the "Larger Prayer-Book." It is not applied because it is the equivalent of the Syriac *ḥudrâ*, as some think, but simply because *Maḥzor* is the equivalent of the Greek *cyclos* (κύκλος).[6]

The *Maḥzor*, meaning prayer-book, is capable of division from different points of view. According to its contents we may divide it into two parts,—the Smaller and the Larger. The Smaller Maḥzor contains the ordinary prayers, together with the poetical insertions and the lessons from the Pentateuch and the Prophets used on the *Yamim Noraim*, or "Awe-inspiring Days" (*i.e.*, New Year and the Day of Atonement), and those used on the *Yamim Tobim*, the three principal festivals (Passover, Pentecost, and Tabernacles). The Larger Maḥzor is, indeed, the only one which really deserves this name, since it embodies the ordinary prayers, together with the poetical insertions for the whole year, and the lessons from the Pentateuch and the Prophets for all feasts and fasts and the other extraordinary occasions. According to its various "uses" the Maḥzor may be divided into the Rabbanite and the Anti-Rabbanite. The Anti-Rabbanite Maḥzor comprises the Karaite,[7] used by the so-called Ḳaraites, or Scripturalists, inhabiting Russia (especially the Crimea), Galizia (Austrian Poland), Egypt, Palestine, &c., and the Semi-Karaite, adopted by the so-called "Reformed Jews" of England, in reality the "Congregations of British Jews" of London, Manchester, and Bradford.[8] The Rabbanite Maḥzor may be divided into that of the Ashkenazim, the Sepharadim, and the Italiani. The Italian Maḥzor, though embodying large Ashkenazic and Sepharadic elements, is yet a distinct "use." It branches out at home into three subdivisions—(1) the Roman,[9] (2) the Neapolitan[10] (now extinct), and (3) the Italian proper;[11] and abroad into (4) the Greek Rites of Kaffa,[12] Crete, &c. (Crete having very early received a large influx of immigrants from France and Germany, but chiefly from Italy), and (5) the Romanian,[13] *i.e.*, the "use" obtaining, among others, at Constantinople and other Byzantine cities. The Italians who, long before the year 1000, had given Jewish learning and poetry, not merely to

[1] Targum Yonathan on Genesis i. 14 (וּמַחֲזוֹרִין), which is the plural of *Maḥazoro*, and mediately of *Maḥazor*.

[2] This must not be mistaken for *Maḥzor Gadol shel Lebanah*, which consists of twenty-one years. See *Pireḳe R. Eli'ezer*, cap. vii.

[3] See *Pireḳe R. Eli'ezer*, cap. vi.

[4] See *Pireḳe R. Eli'ezer*, cap. vi.

[5] See note [1] above.

[6] For the sake of completeness we may mention the term "Mahazorto," which occurs in the Massoreth. It is not so called, as some have thought, because the *Maḥzor Vitri* (or, indeed, any other Maḥzor), ever gave the text of the whole Bible. The *Maḥazorto* was a pattern *codex* of the Bible, and got its name simply from its containing the *cycle* of the sacred Scriptures,—the Law, the Prophets, and the Hagiographa. It (or a similar codex) is also sometimes called *Maḥazoro Rubbo*, in contradistinction to smaller codices, which contained only some part of the Bible. It should be also borne in mind that the Babylonian Jews (as we are distinctly told of those of Nehardea) used in olden times to read on Sabbaths in the synagogue not merely, as nowadays, the Pentateuch and portions of the Prophets, but, in the afternoon service, portions of the Hagiographa also (T. B., *Shabbath*, 116*b*).

Germany, but to the whole Roman empire, received in the 14th century numerous immigrants from northern France,[1] in the 15th century from Spain and Portugal, and at all times from Germany. The "uses" of these immigrants are practically preserved side by side with the native Italian to this day. The pure Sepharadic Ritual[2] represents, in the first instance, of course, the "use" of the Jews formerly inhabiting Spain and Portugal, who now form the minority in Hamburg, Amsterdam, Manchester, London, Paris, Vienna, Budapest, Temesvár, Semlin, Bucharest, Venice, Rome, and some other Italian and Greek cities, as also in Canada and the United States, and the majority in India, Persia, Morocco, Leghorn, Corfu, Belgrade, all Bulgaria, Constantinople, Palestine, Egypt, South Arabia, and other parts of the Turkish empire, in the French possessions in Africa, and in the south of France. Some of these, although characteristically Sepharadic, are distinct enough to claim a ritual of their own, as those of "Catalonia,"[3] Algiers,[4] Tunis,[5] Tripoli,[6] Tlemcen,[7] Ceylon and Cochin in India,[8] the Comtat in France,[9] and Provence, as a whole, in bygone days.[10] The "use" of the Ashkenazim,[11] *i.e.*, of the majority of the Jews inhabiting Germany, the Austrian states, Hungary, Russia, Denmark, Sweden, France, Belgium, Holland, the British empire (India excepted), the United States, &c., branches out into two rituals, the German proper[12] and the Polish. This latter has some differences of use between Great Poland and Little Poland.[13] The German proper had in times past the separate rituals of Worms and other cities in the empire, which are all now extinct. Those of Frankfort-on-the-Main and of other towns are not sufficiently marked to deserve separate notice. It should, however, be mentioned that there are scattered everywhere, both at home and abroad, "Reformed congregations," whose separate uses and practices are more or less an imitation of the "Temple" (Reformed congregation) of Hamburg.[14] Some of these have only introduced choirs, others have introduced instrumental music, and others again have considerably curtailed not merely the poetical insertions, but the ordinary prayers themselves, and have introduced hymns and prayers in the vernacular. (S. M. S.-S.)

MAI, ANGELO (1782–1854), cardinal, well known as the discoverer and editor of numerous ancient texts, was born of humble peasant parentage at Schilpario, a mountain village in the province of Bergamo, Lombardy, on March 7, 1782. For the excellence of his early education, received at Bergamo, he was indebted to a Jesuit priest named Mozzi, whom the suppression of the order had caused to settle in the neighbourhood. He afterwards accompanied Mozzi to a college at Colorno, in the duchy of Parma, where the Jesuits had been permitted to re-establish themselves; and there he entered the noviciate of the society in 1799. In 1804, after the brief which restored the Jesuits to the Two Sicilies had been granted, he was removed to Naples as teacher of classics in the college there. Next, after completing his theological studies at the Collegium Romanum, he lived for some time at Orvieto, where he was admitted to priestly orders, and was engaged partly in teaching and partly in the palæographical studies for which he had already manifested a strong partiality. The political events of 1808 necessitated his withdrawal from Rome (to which he had meanwhile returned) to Milan, where he assumed the functions of a secular priest, and in 1813, through the influence of Mozzi, was made custodian of the Ambrosian library. He now threw himself with characteristic energy and zeal into the business of carefully exploring the numerous and valuable MSS. committed to his charge, and in the course of the next six years was able to restore to the world a considerable number of long-lost works. With the full approval of all concerned he now withdrew from his connexion with the Society of Jesus, and in 1819 he was invited to Rome as chief keeper of the library of the Vatican. Soon after his installation there he found the palimpsest from which he edited the *De Republica* of Cicero; this, probably the most important work of his life, was followed by the publication of a vast number of fragments of Greek and Latin fathers and historians. In 1833 Mai was transferred from the office of Vatican librarian to that of secretary of the congregation of the Propaganda; on February 12, 1838, he was raised to the dignity of cardinal. In this rank he successively discharged the functions of prefect of the congregation for the supervision of the Oriental press, prefect of the congregation of the council of Trent, and cardinal librarian of the Roman Church. He died at Castelgandolfo, near Albano, on September 9, 1854, bequeathing his valuable private library at half its estimated value to the Vatican, the proceeds to be applied to the relief of the poor of his native village.

To the period of his Milanese activity belong *M. T. Ciceronis trium orationum, pro Scauro, pro Tullio, pro Flacco, partes ineditæ* (1814, from a palimpsest containing the poems of Sedulius); *M. T. Ciceronis trium orationum, in Clodium et Curionem, de ære alieno Milonis, de rege Alexandrino, fragmenta inedita* (1814, from a MS. containing a Latin translation of the *Acta* of the council of Chalcedon); *M. Corn. Frontonis opera inedita, cum epistolis, item ineditis, Antonini Pii, Marci Aurelii, Lucii Veri et Appiani, necnon aliorum veterum fragmentis* (1815); portions of eight speeches of Quintus Aurelius Symmachus, fragments of Plautus, the oration of Isæus *De hereditate Cleonymi*, the last nine books of the *Antiquities* of Dionysius of Halicarnassus, and a number of other editorial labours. *M. Tullii Ciceronis de Republica quæ supersunt* appeared at Rome in 1822; *Scriptorum Veterum nova collectio, e Vaticanis codicibus edita* (10 vols. 4to), in 1825–38; *Classicorum Auctorum Collectio e Vaticanis codicibus edita* (10 vols. 8vo) in 1828–38; *Spicilegium Romanum* (10 vols. 8vo) in 1839–44; and *Patrum nova Bibliotheca* (6 vols. 4to) in 1845–53. His edition of the celebrated *Codex Vaticanus*, completed in 1838, but not published (ostensibly on the ground of inaccuracies) till four years after his death (1858, 5 vols. 4to), is unsatisfactory and has been superseded

[1] There are to this day three congregations in Italy (Asti, Fossano, Moncalvo), which use the ancient ritual of northern France (see MS. Add. 667, in the Cambridge University Library).

[2] *Seder Tephilloth*, &c., Amsterdam, 1642, 16mo; in 4 vols., 1644; in 6 vols., London, 1789–93; *Maḥzor*, &c., Vienna, 1820, 8vo.

[3] *Maḥzor*, &c., Salonika, 1863, 8vo.

[4] *Ḥokhmath Hammisken*, &c., 1793; קרובין, 1823; *Maḥzor Ḳatan*, &c., 1861, all at Leghorn, in 8vo.

[5] *Maḥzor*, &c., Pisa, 1794; *Seliḥoth*, 1845; *Pene Haragel*, 1856, all at Leghorn, and in 8vo.

[6] *Siphethe Renanoth*, &c., 2 vols., Venice, 1648, 1711, 4to, Leghorn, 1837; *Ḳisshurin Leya'aḳob*, Leghorn, 1858; *Readings*, Venice, 1736, all three in 8vo.

[7] *Maḥzor*, &c., 1842 and 1861, both at Leghorn, and in 8vo.

[8] *Order of Prayers*, &c., Amsterdam, 1757 and 1769, Leghorn, 1849, all in 8vo.

[9] Or Venaissin, *i.e.*, the four congregations of Carpentras, Avignon, Lisle, and Cavaillon. See *Seder Hattamid*, &c., Avignon, 1767, Aix, 1855, 8vo; *Seder leyamim Noraim*, &c., 1739; *Seder leshalosh Regalim*, 1759–1762, both at Amsterdam, and in 8vo; *Seder Hakunteris*, &c., Avignon, 1765; *Seder shel yom Kippur*, 1766, and *Seder Haashmuroth*, 1763, both at Amsterdam, and all three in 4to.

[10] It ought not to be omitted that in the old Provençal ritual and the South Arabian there are several points of contact existing. A teacher or teachers must have come from the one country and settled in the other. We will give but one example. The phrase, בבניניה דמקדשא ובשכלוליה דהיכלא, which occurs in the *Path-shegen* (on Genesis ii. 1), by an anonymous author, and published by Dr Nathan Adler, and which the editor modestly says he has not succeeded in finding, is in reality to be found in the service of the *Hosha'noth*, both in the old Provençal *Maḥzor* (Camb. MS. Add. 752, leaf 205*b*; only that, instead of דמקדשא, it reads דבית מקדשא) and in that of Yemen (Camb. MS. Add. 1200, leaf 62*b*), though in no other so far as we know.

[11] *Maḥzor*, Pesaro, 1520, Augsburg, 1536, Venice, 1567, all in folio; 6 vols., London, 1807, 1824, 1826, &c., 8vo.

[12] *Maḥzor*, 2 vols., Sulzbach, 1794, folio.

[13] These differences show themselves first in the prayer "El erekh appayim" in the service for Monday and Thursday.

[14] *Ordnung der öffentlichen Andacht*, &c., 1819; *Seder Ha'abodah*, &c., both at Hamburg, and in 8vo.

by the subsequent magnificent edition of Vercellone and Cozza (Rome, 1868), which in turn leaves much to be desired. Generally speaking, it may be said that the services rendered to scholarship by Mai (great though they were) were merely those of a laborious and persevering pioneer; as a textual critic he does not rank high, either for sagacity or for accuracy.

MAIA was the eldest and fairest of the Pleiades, the seven daughters of Atlas and the Oceanid Pleione. Her name marks her as the "fruitful mother"; and the seven sisters have no individuality except as the mothers of famous families. They were all born on Mount Cyllene in Arcadia, and are sometimes called mountain goddesses. In a cave of Cyllene, in the darkness of night, Maia became by Zeus the mother of the god Hermes. Maia bears one of the most characteristic names of the Phrygian mother, Cybele or Ma, the goddess whose home is on mountains and in caves; and in a common class of votive reliefs Hermes-Cadmilus is represented as a youth bearing a vase standing beside the throne on which Cybele sits. Maia was also an epithet of the Bona Dea, who is a form of Cybele, in Rome. See Conze, "Hermes-Cadmilos," in *Arch. Ztg.*, 1880.

MAIDENHEAD, a municipal borough and market-town in Berkshire, England, in the diocese of Oxford, 22½ miles from London, 13½ from Reading, and 6 from Windsor. It was formerly called *Maidenhythe*, a wharf for timber and a wooden bridge across the Thames having existed there from very early times. In 1352 Edward III. incorporated a guild to keep the bridge in repair. In 1400 the duke of Surrey and the followers of Richard II. held the bridge against the new king, Henry IV., and at nightfall made good their retreat. In July 1647 a meeting took place at the Greyhound Inn between Charles I. and his three children. The church, dedicated to St Andrew and St Mary Magdalene, was originally founded by Margaret of France in 1270, and it was rebuilt on the same site in 1724; but in 1826 it was entirely taken down, and a new church was erected at the east end of the High Street. A church dedicated to St Luke was erected in 1867, and enlarged in 1869. The town contains a small town-hall, a large hall recently erected for concerts and lectures, schools, almhouses, and Roman Catholic, Wesleyan, and Baptist places of worship. There are numerous charities for the education and maintenance of poor persons. The principal trades are in malt, meal, and timber. A fine stone bridge across the Thames was erected at a cost of £20,000 in 1772, connecting Berkshire with Buckingham. The scenery around Maidenhead is extremely picturesque, and several noblemen's seats are in the neighbourhood. Population in 1871, 6173; in 1881, 8219.

MAIDSTONE, a municipal and parliamentary borough, and the county town of Kent, England, situated almost midway between London and Dover. It lies principally on the eastern bank of the river Medway, the modern part spreading over the western slopes of a picturesque valley, which is intersected and environed by orchards and hop gardens. Although antiquaries have conjectured that Maidstone was a military station of the Romans, few Roman remains have been found in the neighbourhood. The Saxon spelling of the name was *Medwegestun*, "Medway's town." The manor, valued in Domesday Book at £35, 10s., had from a very early period belonged to the see of Canterbury. Archbishop Boniface in 1260 established a hospital here for poor pilgrims, the chapel of which, with modern additions, is again used for public worship. The parish church of St Mary, which had existed from Norman times, was demolished in 1395 by Archbishop Courtenay, who erected on the site thereof the present church of All Saints; he also, at a short distance, founded a college of secular canons, the ruins of which are an interesting specimen of 14th century architecture. From the reign of John until the Reformation the archbishops had here a residence, at which Stafford and Courtenay died; but the existing building known as the palace dates chiefly from Elizabethan times. The rectory, with the manor, passed into lay hands at the Reformation; and, having been a perpetual curacy for three hundred and twenty years, the living became a vicarage in 1866. All Saints is one of the largest parish churches in the kingdom, and contains, besides many excellent monuments, the richly carved sedilia and the twenty-eight oak seats used by the collegiate priests. The parish has, since 1837, been divided into nine ecclesiastical districts, each with a church. The grammar school was founded in 1549, and endowed with the estates of the local Corpus Christi fraternity, then dissolved; the hall in which the guild assembled still remains. Broadcloth and linen thread, introduced by Dutch settlers, were at one time manufactured here; but brewing and papermaking have long superseded these industries. Of the barges trading on the Medway, about sixty belong to Maidstone wharfingers. The river is crossed by a stone bridge of three arches, completed in 1879. A museum, with public library attached, was opened in 1858. The endowed charities yield an annual income of £3000. Since the beginning of the 17th century the Kent assizes have generally been held at Maidstone. From Saxon times down to 1830 condemned malefactors were executed, and all the great county meetings were held, on Penenden Heath, a common situated about a mile north-east of the town, and recently enclosed by the corporation. The area of the municipal borough is 4008 acres, of the parliamentary borough 4576 acres. The population has steadily increased during the present century; in 1801 it was 8027, in 1881 29,632.

With general history Maidstone has been intimately associated. Wat Tyler broke into the prison, liberated John Ball, the rebel preacher, and committed other depredations. Several of the leading inhabitants joined Jack Cade's rising. Sir Thomas Wyatt, who resided at Allington Castle, now an ivy-clad ruin a mile and a half north of the town, raised the standard of rebellion at Maidstone on 25th January 1554. As a punishment for their complicity with Wyatt, the burgesses were for the next five years deprived of their charter of incorporation. The rising of the Kentish royalists in 1648 collapsed at Maidstone, where, on the 1st June, Fairfax, after five hours' obstinate fighting, captured the town at midnight. Anciently governed by a portreve, Maidstone was first incorporated by Edward VI., and since the beginning of Elizabeth's reign it has sent two representatives to parliament. Andrew Broughton, one of its mayors, as clerk of the court which tried Charles I., read the fatal sentence to the king.

See Russell's *History of Maidstone*, and Poste's *History of the College of All Saints*.

MAIMANSINH, or MYMENSING, a district in the lieutenant-governorship of Bengal, India, lying between 23° 56′ and 25° 25′ N. lat., and 89° 43′ and 91° 18′ E. long., with an area of 6287 square miles, is bounded on the N. by the Gáro Hills, on the E. by Sylhet, on the S.E. by Tipperah, on the S. by Dacca, and on the W. by the river Jamuná, which separates it from Pabna, Bogra, and Rangpur districts. It is, for the most part, level and open, covered with well-cultivated fields, and intersected by numerous rivers. The Madhupur jungle is a slightly elevated tract, extending from the north of Dacca district into the heart of Maimansinh, almost as far as the Brahmaputra; its average height is about 60 feet above the level of the surrounding country, and it nowhere exceeds 100 feet. The jungle contains abundance of *sál*, valuable both as timber and for charcoal. During the cold season the open parts of the jungle afford grazing grounds for cattle. The only other elevated tract in the district is on the southern border, where the Susang hills rise. They are for the most part covered with thick thorny jungle, but in parts are barren and rocky. The Jamuná forms the western boundary of Maimansinh for a course of 94 miles. It is navigable for large boats throughout the year; and during the rainy season it expands in many places to 5 or 6 miles in breadth, overflowing a considerable portion of low-lying land. The Brahmaputra enters Maimansinh at its north-western corner near Karáibari, and flows south-east and south till it joins the Meghná a little below Bhairab Bázár. The gradual formation of *chars* and bars of sand in the upper part of its course has diverted the main volume of water into the present channel of the Jamuná, which has in consequence become of much more importance than the Brahmaputra proper. The Meghná only flows through the south-east portion of the district for a short distance. The eastern and south-eastern parts of the district abound in marshes. The wild animals include tigers, leopards, deer, bears, elephants, and an occasional rhinoceros. Small game is abundant.

The census of 1872 returned the population of Maimansinh at 2,349,917 (males, 1,187,962; and females, 1,161,955),—Mohammedans numbering 1,519,635; Hindus, 817,963; Christians, 124. Of aboriginal tribes the most numerous are the Hajongs (24,936) and Gáros (10,997). The semi-Hinduized aborigines number in all 205,592, of whom more than one-half are Chandáls (123,262), the most numerous caste in the district, employed as cultivators, fishermen, labourers, and menial servants. Among high-caste Hindus, Bráhmans number 33,414. Five towns contain upwards of 5000 inhabitants:—Maimansinh or Nasirábád, 10,068; Jamalpur, 14,302; Kisoriganj, 13,637; Sherpúr, 8015; and Dhanikhola, 6730. Ulákandi or Bhairab Bázár, although with only a population of 1500, is the most important commercial mart, with a large trade in jute and a well-supplied cattle-market. Rice, of which three crops are raised annually, forms the staple food crop of the district. Other agricultural products are wheat, oats, maize, pulses, linseed, mustard, *til*, indigo, tobacco, sugar-cane, *pán*, and jute. The last constitutes the chief commercial staple. Maimansinh suffers occasionally from blights and floods, but never to any serious extent. The chief imports are piece goods, raw cotton, wheat, betel nuts, chillies, sugar, and cattle; the exports consist of rice, jute, indigo, reed-mats, hides, brass and copper utensils, cheese, *ghí*, &c. Tobacco and muslins are also exported to a small extent. Besides a little muslin, the only manufactures are coarse silk cloth, *sitalpati* mats, cheese, and *ghí*. Apart from the rivers, means of communication are afforded by about 146 miles of good and 124 miles of inferior roads. Although the general revenue (£166,938 in 1880-81) has more than doubled in seventy-five years, the land revenue has remained almost stationary; in 1880-81 it was only £75,226, excise amounting to £23,652, and stamps to £48,680. Education in 1872-73 was afforded by 173 state-supported schools attended by 6372 pupils, besides 71 unaided schools, with 2425 pupils. Except towards the close of the rainy season, the climate is fairly healthy. The average annual rainfall is 105 inches.

MAIMBOURG, Louis (1610-1686), a French historical writer, was born at Nancy in 1610. At the age of sixteen he entered the Society of Jesus, and after completing his theological studies at Rome he became a classical master in the Jesuit college at Rouen. He afterwards devoted himself to preaching, but with only moderate success. After having taken some part in minor controversies he threw himself with energy into the dispute which had arisen as to the Gallican liberties; for his *Traité historique sur les prérogatives de l'Église de Rome* (1682) he was by command of Innocent XI. expelled from his order, but rewarded by Louis XIV. with a residence at the abbey of St Victor, Paris, and a pension. He died on August 13, 1686. His numerous works (exhaustively enumerated in the *Biographie Générale*) include histories of Arianism, the iconoclastic controversy, the Greek schism, Lutheranism, Calvinism, and of the pontificates of Leo I. and Gregory I.; they are mere compilations, written indeed in a very lively and attractive style, but inaccurate throughout, and wherever matters of controversy are touched on, specially untrustworthy.

MAIMONIDES (1135-1204). Among the great men to whom Mohammedan Cordova[1] has given birth—and these are not a few—the greatest is unquestionably Rabbenu Mosheh b. Maimun[2] Haddayyan.[3] Like the lives of so many great men, that of this "last of the *Geonim* as regards time and the first of them as regards worth"[4] is surrounded by a halo of fables, some of which, though fictitious, are instructive in many respects, whilst others are telling in dramatic effect and touching in the extreme. Some of these fables, however, are merely amusing, whilst others are simply ridiculous.[5] The present article confines itself to facts and a few criticisms founded on them.

"Rambam," or Maimonides, was born March 30, 1135, and died at Cairo, December 13, 1204; consequently he did not quite attain the age of seventy,[6]—a short space of life, when we take into consideration all the work he did for his contemporaries and all the works he left to posterity.

Like many other great and conscientious rabbis of all times, who considered it a sin to make of religious learning a means of gaining bread, Maimonides adopted the medical profession. That he must have greatly excelled in it is not merely known by the medical works he composed, but is best testified to by the fact that, although a Jew (and the times and the country he lived in were certainly not more tolerant than ours), he held the lucrative and important office of court-physician to Saladin of Egypt.

Maimonides was master of Greek-Arabic philosophy, as may be seen from his *Technical Terms of Logic*,[7] his *Guide*, and his other works. That he was a mathematician and astronomer of no mean standing appears from the *Maamar Ha'ibbur*[8] (calculations of the calendar, which he wrote at the age of twenty-two), the *Hilekhoth Kiddush Hahodesh* (in the book *Zemannim* of the *Mishneh Torah*), and the commentary on T. B., *Rosh Hasshanah*. That he was a great Talmudist we know from his commentary on the *Mishnah* and his *chef-d'œuvre* the *Mishneh Torah*. That he was, as philosopher and theologian, a profound thinker we know from his *Guide of the Perplexed* and his other works. To sum up in a few words the merits of Maimonides, we may say that, with all the disadvantages of the times in which he lived, he was the greatest theologian and philosopher the Jews ever produced, and one of the greatest the world has seen to this day. As a religious and moral character he is equalled only by a few and surpassed by none.

The works of Maimonides were composed by him partly in Hebrew and partly in the vernacular Arabic,—a portion of the latter eing translated into Hebrew by himself.

I. *Works composed by Maimonides in Hebrew.*

1. *Mishneh Torah*, *i.e.*, the systematic codification of the whole of the Jewish law, as it is to be found in the Bible, the *Mishnah*, *Tosephta*, *Mekhilta*, *Siphra*, *Siphre*, both *Talmudim*, the *Sheeltoth*, *Halakhoth Gedoloth*, the *Responsa* of the *Geonim*, the *Hilekhoth*, *Rab Al-phesi*, &c. This work is drawn up in fourteen (י״ד = *Yad*)

---

[1] Hence he is called "Al-Kortubi" (and not al-Kordovi, or Hakordovi) by Arabic writers, and "Hassephardi" by himself (preface to *Mishneh Torah*).

[2] From the initials of his name, with "R" (for "Rabbenu") prefixed, and his father's name with "B" (for son of) prefixed, the Jews call him RaMBaM; among Christians he is, *more Græco*, called *Maimonides*, from his father's name *Maimun* or *Maimon*.

[3] See end of the commentary on the *Mishnah* ("*Ani Mosheh bar Maimun Haddayyan*").

[4] So Maimonides is designated by the famous Enbonet Abram (or Yeda'yah Happenini Bederesi, *i.e.*, of Beziers) at the end of his *Behinath 'Olam*.

[5] Whoever wishes to know more of these fables may gratify his desire, if he knows Rabbinic, by reading Ibn Yahya's *Shalsheleth Hakkabbalah*; if he understands German, by reading Jost's *Geschichte*; and if he understands only English, by reading Benisch, *Two Lectures*, &c., London, 1847, 8vo.

[6] Note at the end of the author's commentary on T. B., *Rosh Hasshanah*, by his grandson R. David (*Hallebanon*, ii. p. 60).

[7] This work was translated from the Arabic into Hebrew by R. Mosheh Ibn Tibbon, and printed for the first time at Venice, 1550, 4to. The third edition (Frankfort-on-the-Oder, 1761, 4to) has a commentary by Mendelssohn.

[8] See the collection *Dibere Hakhamim* (Metz, 1849, 8vo), p. 23. The translation is by R. Mosheh Ibn Tibbon.

books, with a view to which fact and to the author's name (*Mosheh*) admiring and grateful posterity called it, from Deut. xxxiv. 12, *Hayyad Haḥazakah,*—a title which has eclipsed, if it has not actually superseded, that given to it by the author himself. Great has been the success of this work. If Maimonides has not succeeded in superseding by it the Babylonian Talmud (as some think was his purpose[1]), he has certainly succeeded (probably against his will) in making of it a second Talmud of Babylon in the Talmudic acceptation of this term.[2] The *Mishneh Torah* has become an arena of endless, though happily bloodless, strife. It is to this day a place of tournament for all Talmudists. The hundreds of folios on Rabbinic literature, written since the author's time, constantly draw the *Rambam*,[3] naturally or artificially, into the discussions they contain. To clear up a difficult *Rambam*, or to "answer a *Rambam*," *i.e.*, to remove an apparent difficulty in the *Mishneh Torah*, is the great test of the fitness or learning of a rabbi to this day. Moreover, all Sepharadim have received its *dicta*, though only *cum grano*, whilst the congregations of Arabia (as those of Yemen and others) not only live absolutely according to its teachings, but have actually neglected the study of the *Talmudim* through it. The work itself is to be found in MS. in numerous libraries (probably one of the oldest MSS. lying in the University Library of Cambridge, Add. 1564). Printed editions are also numerous, some without "strictures" (*Hassagoth*) and without a commentary, others with the "strictures" of the great rabbi[4] of the little town of Pesquiers (in Provence), others with commentaries varying from four to eight, and even more. The earliest edition, which has neither place nor date, appeared somewhere in Italy, about 1480; the second at Soncino, 1490; the third at Constantinople, 1509; the fourth, fifth, sixth (with the *Sepher Hammisvoth*, &c.), and seventh editions at Venice, 1524, 1550, 1550–51, and 1574–75 respectively; the eighth (with the *Antichristiana*) at Amsterdam, 1702–3, all in folio; the most recent and incomplete edition being that of Leipsic, 1862, 8vo. The *Mishneh Torah* stands, and has stood for centuries, even among non-Jews, in such respect that "parts of books" (*Halakhoth*) have been rendered into other languages, notably into Latin. Extracts from this work have been translated into English by the late H. H. Bernard of Cambridge (Cambridge, 1832, 8vo) and E. Soloweyczik of Poland (London, 1863, 8vo).

2. Commentary on the treatise of *Rosh Hasshanah* according to the Babylonian Talmud. We know from Maimonides himself that he commented on almost the whole of the second, third, and fourth *Sedarim* and on one treatise (*Hullin*) of the fifth *Seder* of the Babylonian Talmud. But of all this none but his *Rosh Hasshanah* has been preserved. This commentary is extant in four MSS., one of which, however, is a mere transcript, whilst two of the others are imperfect. The only edition existing (*Hallebanon*, ii. p. 61, &c.) is from these imperfect MSS. The one perfect MS. copy known to us is preserved in the University Library of Cambridge (Add. 494).

3. Some of the numerous letters ascribed to Maimonides. These are inextricably mixed up both with letters written by him in Arabic and translated by others into Hebrew, and with letters addressed to him by others.

4. Religious poetry. There is a short liturgical piece (it is recited on the first day of New Year by the Arabic-speaking Jews of Algiers, Tunis, &c.) which begins *Eth Sha'are Ratzon*, and which bears the acrostic *Ani Mosheh biribbi Maimon Ḥazaḳ*. It is an "'*Akedah*." But because there is a composition of the same nature and beginning, but of greater length and by another author ('Abbas Yehudah Shemuel), this is, in contradistinction, called '*Akedah Ketannah*. Since the name of Mosheh, however, is common among all Jews and that of Maimon among those of the Maghrib (see Schiller-Szinessy's Cambridge *Catalogue of the Hebrew Manuscripts*, ii. p. 28, note 2), this little poem may, perhaps, belong to another (and inferior) rabbi of this name. If it really does belong to our Maimonides, we have a key to his contempt for the liturgical poets.[5] Being a poor poet himself, he judged them by his own merits, or rather demerits.

II. *Works composed by Maimonides in Arabic.*

1. The commentary on the whole *Mishnah*. The author began this work whilst yet in Spain, continued it on his flight through Morocco, and finished it at his ease at Fostat (Cairo). The merit of this work is that the author explains therein the *Mishnah* in a very lucid and brief way; and, having privately digested the Talmudical controversies regarding each paragraph, he gives the result of it in the decision of the *Halakhah*. But this work has also its demerits. (1) It is occasionally incorrect in itself. (2) Being to most Talmudists accessible only in a translation, which they cannot gauge, the smallest clerical error produces confusion. (3) Nor were all the translators equally qualified for their task. Some were good Talmudists, but indifferent Arabic scholars; some were good Talmudists and good Arabic scholars, but not fine Hebraists. (For the translators see Schiller-Szinessy, *ut supra*, ii. pp. 16, 17.)

2. The *Sepher Hammisvoth* is a preliminary to the author's masterpiece, the *Mishneh Torah*. This small but important work has been twice translated,—first by R. Mosheh b. Shemuel b. Yehudah Ibn Tibbon (Tabbon?), and secondly by R. Shelomoh b. Yoseph Ibn Aiyúb. The former translation is known by printed editions[6] and the latter by MSS. Ibn Aiyúb's, though less known, is the more correct translation. There is a copy of it in the University Library of Cambridge (Add. 676, 2).

3. But the most important and most learned and to us the most interesting of Maimonides's Arabic works is the *Guide of the Perplexed* (Dalálatu 'l-Háirín in Arabic, and *Moreh Hannebokhim* in Hebrew). It is the result of deep research in Bible and Midrash on the one hand and in Greek philosophy, as interpreted by Aristotle and his followers, together with various religious systems, on the other. The purpose of its composition and publication was to reconcile Jewish theology with refined heathen philosophy. Maimonides deservedly held Aristotle in very high estimation; his traducers, however, said that he placed him in the *Guide* next to, if not above, Moses. No wonder, then, that religious Jews of a certain type in the author's lifetime took offence both at the book and the author. But serious warfare broke out only after Maimonides's death, which raged for more than a full century, and is not entirely extinguished even at this day. His followers, chiefly in Provence at the end of the 13th and the beginning of the 14th century, some of whom had only eyes for the master's negations and none for his affirmations, declared the whole history of the Bible to be mere symbolism. Abraham was, according to them, the Morphe, Sarah the Hyle, and so forth.[7] These absurdities were considered by the religious as highly irreligious, and provoked active opposition and even excommunication. These, in their turn, provoked again the strong remonstrance of the moderate middle party and the ultimate excommunication of the excommunicators by the excommunicated. But long before that time the *Guide* had been publicly burned,—an act quite un-Jewish, but in unison with an age which had more faith than knowledge, and which, dwelling in darkness, hated the light. People in our days cannot understand this; they cannot understand the fierce opposition to the *Guide*, and much less the attachment to it. They ask, Is this the great work of the great Maimonides? These explanations of the Scriptures we have long ago outgrown, and the philosophy it contains is not worth mention by the side of that of Schelling, Fichte, and Hegel! But the fact is that, if one wishes to form a proper estimate of this work, he must not merely read it, but earnestly study it. Then again, its contents must be viewed historically, *i.e.*, both in connexion with the theological and philosophical systems of past ages and with the influence it has exercised uninterruptedly from the time of its appearance down to almost our own days.[8] Isolated portions of it may have become antiquated. The symbolism of the Pentateuch and the meaning of the words of the prophetic books and Hagiographa may be clearer to us than they were in the author's time, by reason of our discoveries in science, our progress in philology, and our knowledge of history. Our knowledge of Greek philosophy may be much greater than Maimonides's was, owing partly to our acquaintance with the original writings of Aristotle and others, accessible to Maimonides only through a translation of a translation, and partly owing to our collation of numerous MSS., by which the errors are rectified of the copies from which the first translators made their version,—a rectification by which parts of the foundation and of the superstructure of the *Moreh* go down at one and the same time. But, when all this is considered, the *Guide* still remains a great work,—a product, indeed, of the Middle Ages, but truly immortal.[9]

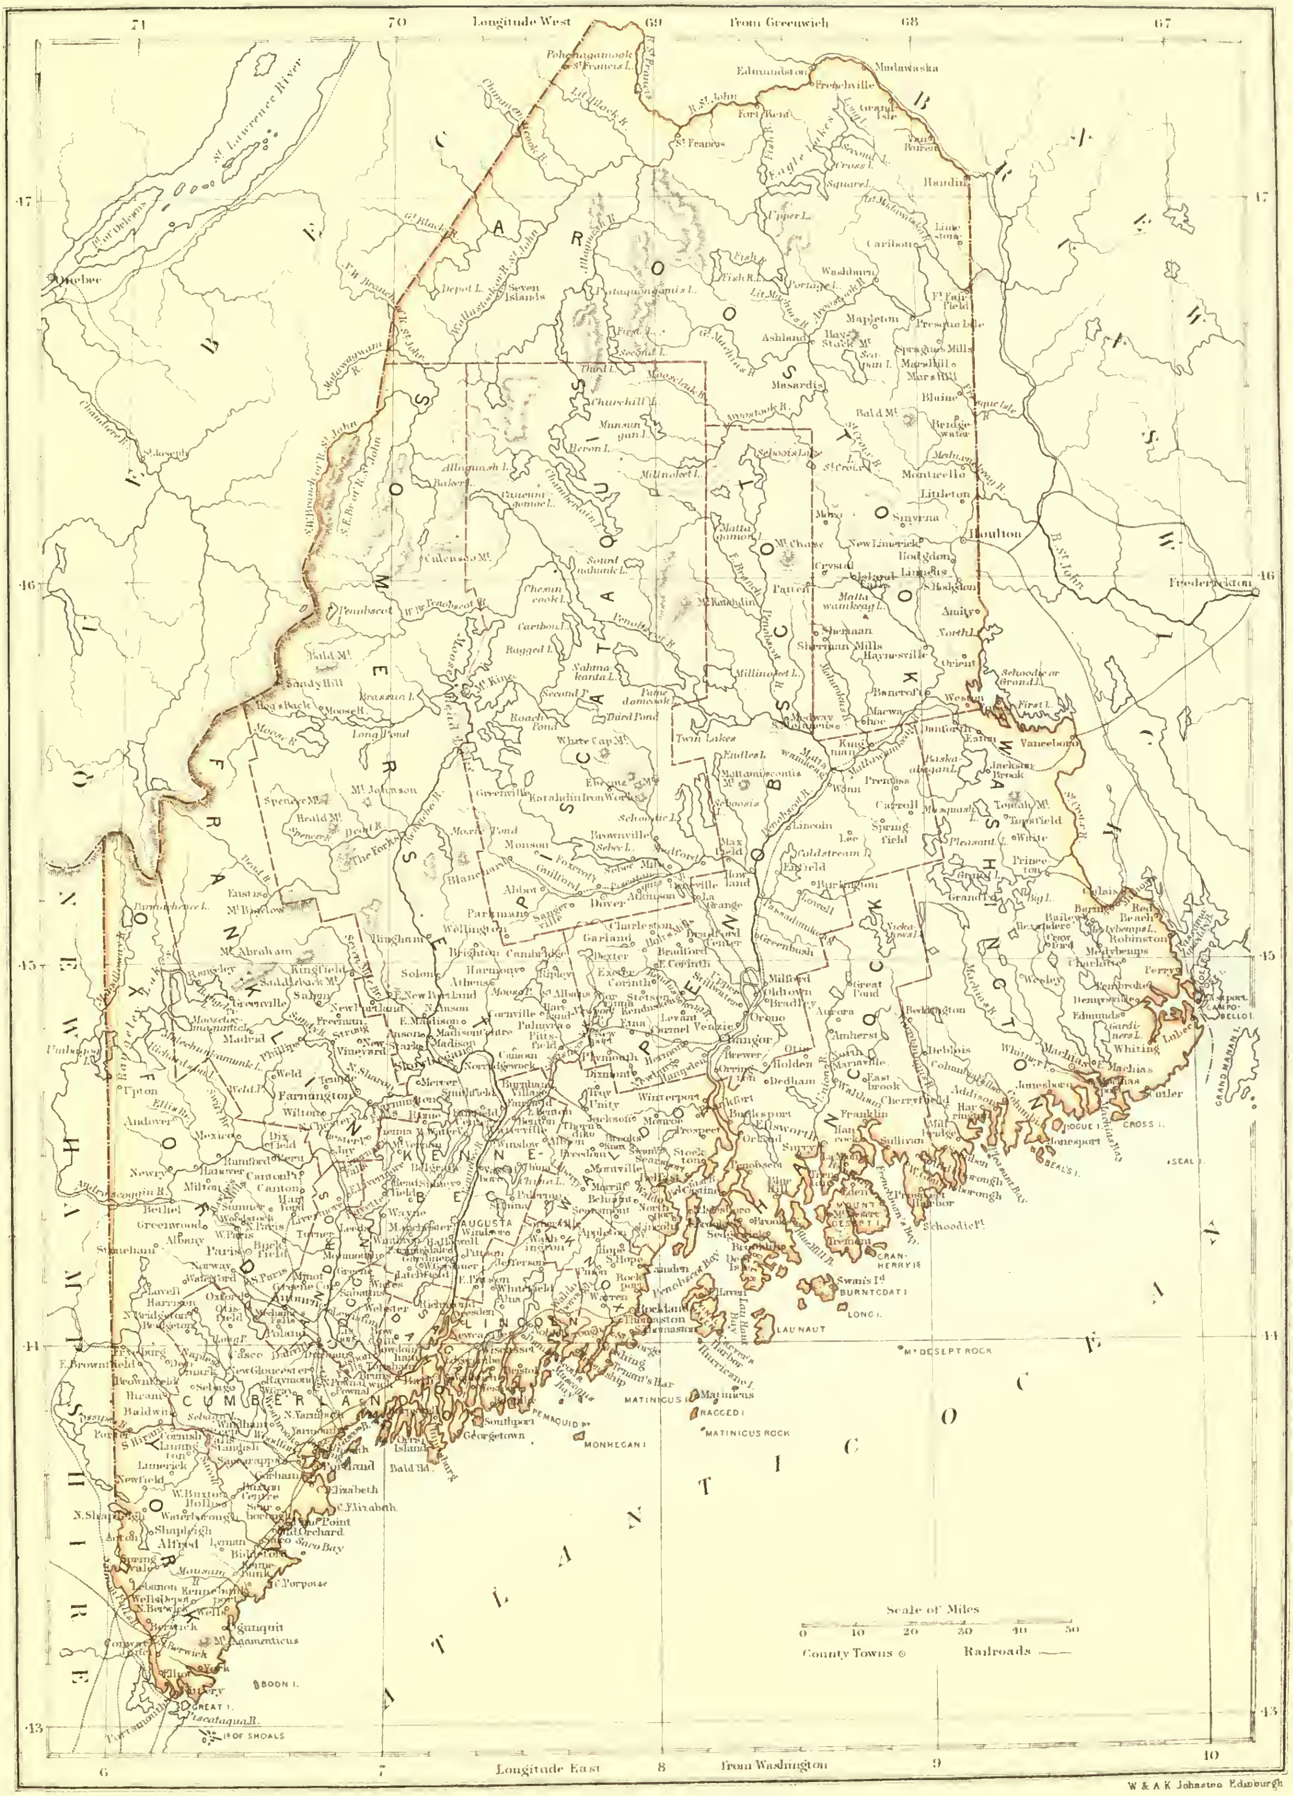
[3] So this work is commonly and especially called from the author's name.
[4] *R. Abraham Ben David* (*Rabad*) was the author's contemporary and the only literary man who ever conquered him, according to his own confession.
[5] See introduction to the *Sepher Hammisvoth*.
[6] The first edition appeared without place and date, but Constantinople about 1516, 4to.
[7] See Schiller-Szinessy, *Catalogue*, &c., i. p. 188, notes 1 and 2.
[8] Moses Mendelssohn, for example, became one of the greatest philosophers of his day through studying the *Moreh*.
[9] This book was till within the last few years known only through the translation of R. Shemuel b. Yehudah Ibn Tibbon, which has been printed numerous times, the *editio princeps* being without place or date, but somewhere in Italy (Bologna?) before 1480. There is, however, also another translation from olden times in existence. It is by the famous R. Yehudah Al-Harizi, and has been edited by Schlossberg (i., London, 1851; ii. and iii., Vienna, 1874 and 1879 respectively, all in 8vo). The late S. Munk has, however, surpassed in correctness both his predecessors in his *Guide des Égarés*, which contains the Arabic original with a French translation. It appeared at Paris, 1856–66, in 3 vols. 8vo.

MAINE.



W & A K Johnston Edinburgh

4. *Responsa* and other letters (*Teshuboth Sheeloth ve-Iggeroth*). These do not belong exclusively to Maimonides. The first edition came out without place or date, but at Constantinople about 1520, folio.

5. *Responsa* (printed under the title *Peer Haddor*) translated by R. Mordekhai Tammah, Amsterdam, 1765, 4to.

III. *Works composed by Maimonides in Arabic and translated into Hebrew by himself.*

1. The commentary on the *Mishnah* of the whole *Seder Tohoroth*. As is well known, the translation of this *Seder* has been hitherto regarded as anonymous. But the writer of this article has shown in the Cambridge *Catalogue, ut supra*, ii. p. 17, note 2, the high probability, amounting to a moral certainty, that nobody else could have been, and that Maimonides himself must have been, the translator of this *Seder*, which more than any other demanded the three necessary qualifications of a good translator.

2. The letter on the sanctification of the name of God (*Iggereth Hasshemad*, or *Maamar Kiddush Hasshem*[1]). Although the proofs which one can adduce for the translation by the author himself of this treatise are not so telling as those in the case just mentioned before, the moral certainty is not less. The treatise details (1) how much a Jew may yield, and how much he must resist, if forced to embrace another religion, and (2) that Mohammedanism is not a heathenish religion. It is generally held, though not quite conclusively proved, that Maimonides wrote this treatise *pro domo sua*, he and his family having been themselves forced to embrace Mohammedanism during the persecution by Ibn Tamurt. It ought to be borne in mind that the Jews generally look upon Christianity and Mohammedanism as having each taken a large share in their mother's (Judaism's) inheritance, and that, whilst the former looked more for her moral, the latter coveted her doctrinal possessions. Since morality, however, consists more in negatives than positives, and since doctrines are more openly challenged and openly avowed than morals, the Jews have always manifested less repugnance to profess, under pressure, Mohammedanism than Christianity.

There are other works both in Hebrew and in Arabic extant by our author. These relate mostly either to ritual affairs, and consist of letters to various rabbis, and colleges of rabbis, notably in the south of France, to congregations in Yemen and elsewhere, or to medical matters, and consist of short treatises, such as aphorisms, &c., but do not come up in interest to the great works already named. (S. M. S.-S.)

MAINE, a province of France, was bounded on the N. by Normandy, on the W. by Brittany, on the S. by Anjou and Touraine, and on the E. by Orléanais; along with the northern part of Anjou it is now represented by the departments of Sarthe and Mayenne. Together with a portion of Perche which was conterminous with it on the north-east, and the countship of Laval on the west, it constituted a great military government, of which Le Mans was the capital. Before the Roman conquest Maine was held by the Aulerci Cenomani, whence probably its name. Le Mans, a great city, was connected by the conquerors by good roads with Chartres, Orleans, Vendôme, Tours, Angers, Jublains (capital of the Aulerci Diablintes, inhabiting the western portion of Maine), and Sées. Under the later Cæsars the Cenomani became almost independent, and joined the Armorican republic. Christianity was first introduced in the 3d century by St Julian, first bishop of Le Mans. Down to the time of Hugh Capet the bishops were the real rulers of the country; but in consequence of the incursions of the Northmen, who came up the Sarthe and Mayenne, the erection of strongholds became necessary, and Hugh Capet made the countship of Maine hereditary in the person of Hugh I. One of the descendants of the latter, Count Herbert, having acknowledged the suzerainty of William, duke of Normandy, the people of Le Mans availed themselves of the absence of the Conqueror in England to rise against him, and were ultimately successful in gaining their freedom. Maine became united with Anjou by the marriage of its heiress with Fulk of Anjou, father of Geoffrey Plantagenet. Henry II. of England, the son of Geoffrey, was born at Le Mans. On the confiscation of the estates of King John, Maine passed to Philip Augustus of France; by Louis IX., the grandson of Philip, it was handed over in 1245 to Charles, count of Provence, afterwards king of Naples; and in 1328 it was reunited to the domains of the crown by Philip of Valois, who was count of Maine. It was again separated by his grandson Louis of Anjou, the brother of King Charles V. During the Hundred Years' War, Maine was a continual battlefield; the English were at last driven out by Dunois, who took possession of Le Mans in 1447. In 1481, on the death of Charles of Maine, the last scion of the house of Anjou, Maine was again united to the French crown by Louis XI. The province suffered much during the wars of religion; its strong places were dismantled by Henry IV. and Richelieu. At the Revolution the troops of La Vendée entered Maine, and took possession of Laval, Mayenne, and Le Mans at the end of 1793; after they had been defeated by the republican forces under Marceau and Westermann, their place was taken by the Chouans; and the pacification of the province, begun by General Hoche, was not completed until 1800. Towards the close of 1870 the second army of the Loire, retreating before the Prussians, was reformed in Maine, and in the neighbourhood of Le Mans one of the last great struggles in the Franco-German war took place in January 1871.

MAINE

MAINE, the most north-easterly of the United States, lies between 43° 4′ and 47° 27′ 33″ N. lat., and between 66° 56′ 48″ and 71° 6′ 41″ W. long. It is 302 miles in extreme length and 285 in width, with a total area of 33,040 square miles (of which 29,895 square miles are land), being nearly as large as all the other New England States combined. Its figure resembles that of a mountain peak, broken at the top. Its S.E. base rests on the Atlantic Ocean. On the E. and N. it has the province of New Brunswick, and on the N.W. the province of Quebec, while its southern half is bounded on the W. by the State of New Hampshire. Plate V.

Coast-line. The coast-line measured direct is about 225 miles in extent; but the numerous river mouths and indentations of the sea make an actual tide-water line of not less than 2500 miles. The headlands and far-stretching narrow points, together with innumerable outlying islands, give to the whole ocean front the appearance of a fringed and tasselled border. This striking feature, which gives peculiar interest in many ways to the coast of Maine, is chiefly the result of a southward glacial movement, which, coinciding with the trend of the rocks produced by a remote geologic upheaval, cut these fiord valleys far out into the sea, the prolongation of their edges being marked by islands, reefs, and scattered knobs of rock. In these deep bays and river mouths, and behind these outlying islands, are numerous harbours, convenient, safe, and capacious, and the poet is well within the truth who sings of "hundred-harboured Maine." There are no better harbours on the Atlantic coast than those of Portland and Wiscasset. The beaches and marshes and low grassy islands common in the west are scarcely found east of the Kennebec river, beyond which the shore becomes more and more bold, rising in the precipitous cliffs and rounded summits of Mount Desert and Quoddy Head to a height of from 1000 to 1500 feet. Drainage slopes. The general slope of the land surface falls from an extreme elevation of 2000 feet on the west, in the neighbourhood of the White Mountains, to 600 feet on the east. Two principal drainage slopes stretch respectively southward and northward from a watershed which crosses the State in a general easterly and westerly direction, at a distance of about 140 miles from the coast, while the northward slope has an extreme breadth of about 80 miles. The general direction of the rivers, as determined by these slopes, is about south-south-east for the southern slope and north-north-east for the northern. It is a noteworthy fact that the course of the principal rivers is at right angles to the general trend of the stratified rocks, throughout the large section where these are exhibited. The surface is hilly and rolling rather than mountainous. The Appalachian range, which becomes so prominent in the White Mountain group just westward of the State, seems to have broken its force there and to have strewn only a few scattered mountain masses across middle Maine and into New Brunswick. These all have a peculiar aspect, rising in conical peaks, heavily wooded at the base and bare at the summit. The most noteworthy is Mount Katahdin, with a height of 5385 feet (a little less than Mount Washington), and in its isolation and crater-like formation the most remarkable mountain in New England.

Mountains.

Lakes.

The lakes of Maine, situated for the most part among these mountain regions, are among its characteristic and most attractive features. They number more than 1570, with an aggregate area of 2300 square miles, about one-fifteenth part of the entire area of the State. The largest is Moosehead Lake, 35 miles long by 10 miles wide; but many others of less size are more picturesque. Their height above the sea-level is noticeable. Rangely Lake, at the head of the Androscoggin river, is 1511 feet high, this altitude being very nearly that of Lake Itasca at the head of the Mississippi; Moosehead, on the Kennebec waters, is 1023 feet in height, or nearly two-thirds as high again as Lake Superior at the source of the St Lawrence; Chamberlain Lake, on the headwaters of the St John, 926 feet, and Chesuncook, on the Penobscot, 900 feet high, are 400 or 500 feet above the level of Lake Winnepesaukee in New Hampshire. Most of the lakes of Maine lie within regions as yet unsettled, where nature's wild luxuriance and grandeur are still undisturbed by man. Few similarly habitable regions possess lakes in such numbers and of such size, variety of situation, and beauty of aspect and surroundings. They are, moreover, nearly all connected with the river systems of the State, and constitute vast reservoirs for evaporation, irrigation, and mechanical power.

Rivers.

All the principal rivers rise at great elevations—the Saco at an altitude of 1890 feet, the Androscoggin 3000, the Kennebec 2000, the Penobscot 2500, the St John 1980. The general drainage areas, however, fall off in height and increase in breadth in proportion as their location is easterly. The principal features of the water systems of Maine are the great amount of fall, the control of steady volume by the storage capacity of the lakes, and the situation of the best falls in the lower sections of the rivers where the volume is largest, and in many instances at the head of tide-waters where vessels may come to their very feet. The water-power of the State available for industrial purposes has been estimated by Walter Wells, in his valuable report on that subject, to amount to 1,229,200,000,000 cubic feet, with gross power of 4427 horse for each foot of fall, making a total of 2,656,200 horse-power.

Geology and minerals.

The important geological features are connected with the highly crystalline metamorphic condition of the strata, which rarely lie in horizontal position, but are upturned, bent, folded, and fractured. Fossiliferous rocks occur only in limited localities in the interior. In various places veins of silver-bearing galena and of copper are exposed. Granite of every variety and quality abounds in veins and in eruptive masses. The western portion of the State is largely granitic in its features, and a belt of the same rocks extends along the entire sea-coast. There are also beautiful varieties of syenite. In many places the granite is very coarse, so that the constituents can be separated, and each utilized for industrial purposes. The felspar, quartz, and mica often lie in large contiguous veins. Valuable beds of crystalline limestone are found in many places along the coast, and in the Aroostook region. Argillaceous slates as well as limestone occur in the interior and in the north. On the Piscataquis, a tributary of the Penobscot, the slate is suitable for writing-slates and pencils, blackboards, and tables, while large quantities of roofing slate are found throughout the whole region between the Kennebec and Penobscot. There are also some beds of marble well suited for building purposes. Some surface iron is found, especially in one locality in the interior known as the Katahdin iron-works, where the iron is remarkably pure owing to its freedom from sulphur and phosphorus. A bed of hæmatite is found in Aroostook county.

The soil is mostly of glacial origin, derived largely from boulders and a mixture of rocks transported from various and often distant localities. This drift is spread everywhere over the surface. Along the lake-beds and rivers are some alluvial soils and old flood-planes. Deposits of Quaternary marine clays occur along the south border, rising to the height of 200 feet above the sea. These clays were deposited during the Champlain epoch, at a time when the temperature of the water was much lower than at present, as is indicated by the fossil remains which abound in them. In the lower strata these remains of life are of the same species as are now found living in the Arctic seas. Skeletons of the walrus have been found in Portland and elsewhere. In the upper strata the remains of life indicate the same species as now exist on the coast. Isolated forms of life not elsewhere found north of Massachusetts occur in the north part of Quohaug Bay (north-east of Casco Bay), composed of various species which seem to be a remnant of former life on this coast. A family of living oysters is still found among the debris of giant progenitors in the Damariscotta river, east of the Kennebec; and remains of the oyster, quohaug, and scallop are abundant in the numerous and extensive shell-heaps found all along the coast.

Zoology.

In general it may be said that animal life in this State shows a mixture of northern and southern forms, and but little that is peculiar as compared with surrounding regions. The moose, caribou, and deer still roam in the vast forests in the north. The bear, wolf, catamount, wolverene, wild cat, fox, beaver, raccoon, marten, sable, woodchuck, rabbit, and squirrel keep at a due distance from man, and so still exist. Seals are found in many of the bays. Wild geese and ducks and other sea fowl frequent the lakes and bays in the migratory season, and eagles, ospreys, gulls, hawks, kingfishers, owls, plover, woodcock, partridges, pigeons, quails, blackbirds, robins, orioles, bobolinks, blue birds, swallows and sparrows in all variety, yellow birds, and humming birds are common. The inland waters teem with fish of various kinds—pickerel, togue, and bream, and, chief of all, the trout, whose beauty and size attract numbers of sportsmen; while in the rivers the sturgeon, bass, and salmon are still plentiful. Game laws protect several species of the fish, birds, and other animals. Along the coast the clam, mussel, and lobster are abundant, and in some places the horse-shoe crab is found. Of shore-fish the cunner, flounder, rock-cod, and sculpin are most common, while off shore cod, haddock, hake, herring, pollack, menhaden, porgy, and mackerel abound. The black fish and porpoise are not uncommon. Gigantic cuttle-fishes, measuring 40 feet and upwards in the long tentacles, and thus not inaptly termed sea-serpents, have sometimes been seen in these waters.

Forests.

The forests of Maine consist chiefly of pine, spruce, hemlock, and fir, although some oak is found along the coast, and other hard wood growth in the highlands of the Aroostook. The white cedar is common, especially in the low lands in the east and north-east. The hackmatack or black larch appears in the same localities. White and red oak, rock (or sugar) maple, white maple, white and yellow birch, white and brown ash, beech, cherry, basswood (linden), and poplar are the common deciduous trees. Chestnut and walnut are rare, and are found only near the south-west border. The majestic mast pine—the heraldic emblem of Maine, which has given it the sobriquet the "Pine Tree State"—is fast receding before the demands of commerce. Of fruit trees the chief is the apple. The plum, cherry, and pear are also natural. The peach thrives only in the south-west border. Species of grape, gooseberry, and currant are native, and others are cultivated with advantage. The blackberry, raspberry, and strawberry grow wild in profusion throughout the State.

ruits.

limate.

The climate of Maine, while on the whole cooler than might be expected from its mean latitude of 45° N., cannot be considered severe or unfavourable to health. The summer heats are tempered by the sea and the cool north winds. The winter cold has a constancy which makes it less severely felt than the changing temperature of more southern places. The air is also more dry and pure owing to the snow surface. The average winter temperature is about 20°, and remains pretty steadily below the freezing-point throughout the State for at least three months. By reason of the tides and the prevailing off-shore winds, which break up and drive off the ice, many of the harbours are unobstructed the winter through. The summers are short, giving something less than five months between frosts, even in the southern portion, but the heat sometimes rises for a few days to 100° Fahr. The average summer heat is 62°·5 Fahr. The lakes and forests of Maine attract great numbers of summer tourists, and the sea-coast is fast becoming lined with the cottages of summer residents from all parts of the country.

lealth.

The soil is well-drained, and the surface swept by sea breezes and winds from the forests and mountains of the north-west, which tend to banish malarious disease. The principal form of disease is phthisis or disease of the respiratory organs, the ratio of deaths therefrom being a little over 27 per cent. of the entire mortality. This has been called the "scourge of New England"; but in Old England the death-rate from this class of diseases is only a fraction less—26·6 per cent.

ldminis-
ration.

The old United States district court for Maine, constituted in 1779, remains; and Maine, New Hampshire, Massachusetts, and Rhode Island constitute the first district of the United States circuit court. The officers of these courts are a judge, district attorney, marshal, clerk, and reporter. Maine is also a district for the collection of United States internal revenue. There are seven United States forts in Maine, only one of which, Fort Preble, Portland, is fully garrisoned; and the United States navy yard, often called Portsmouth navy yard, is in Kittery, Maine.

Maine has two senators and four representatives in Congress, and six votes in the electoral college for choosing the president. The government of Maine rests on a constitution adopted in 1820, which closely resembles that of the other New England States. It is most liberal in respect to suffrage, every male citizen twenty-one years of age and upwards resident in the State for three months, except paupers, persons under guardianship, and Indians not taxed, being allowed to vote. The governor and legislature are chosen every two years, and the legislative sessions are also biennial. A council chosen by the legislature on joint ballot advises and assists the governor in the appointment of State officers, management of State institutions and lands, granting pardons, and other duties with which they may be charged by the legislature. The judiciary consists of a supreme court of eight members at a salary of $3000, with a reporter of decisions, appointed by the governor and council for seven years; the superior courts for Cumberland and Kennebec counties, whose judges are appointed in the same way; as also trial justices for the several counties with jurisdiction in minor cases; justices of the peace for the county, who are authorized to solemnize marriage, with other prescribed duties; and municipal and police judges. Each county elects judges of probate and insolvency, and registers of the same, a county attorney, clerk of court, sheriff, and county commissioners.

Militia.

The enrolled militia numbers 97,320. The present system keeps up an élite corps consisting of two regiments of volunteer infantry and one battery of light artillery, with two regiments of reserve infantry. Much pains is taken in the discipline and character of this small corps, and membership in it is regarded as honourable. The entire State militia is by existing orders constituted into one division under the command of a major-general, who is elected by concurrent ballot of the two houses of the legislature.

Reformatory and benevolent institutions.

Various reformatory, sanitary, and benevolent institutions are supported wholly or in part by the State. The State prison, with an average of one hundred and forty-six convicts, is managed on the "hard labour" and the "silent" system, at an annual expense of $30,000, which in some years is cancelled by the proceeds of the convicts' labour, chiefly employed in carriage and harness making. The hospital for the insane is an extensive establishment, with upwards of four hundred inmates and an increasing demand for more accommodation. The annual appropriation for State beneficiaries here is $40,000. An annual appropriation ($14,000) is made for the education of the deaf and dumb and the blind, and also ($1200) for the care of idiotic and feeble-minded persons in institutions out of the State.

Indians.

The remnants of two tribes of Indians still exist in Maine, with which the State is in public relations, the Penobscots, numbering about six hundred, and the Passamaquoddies, numbering five hundred. The former have their chief gathering place on the islands in the Penobscot river, and the latter on the shores of Passamaquoddy Bay and the St Croix river. Though classed usually as civilized, they are still virtually in tribal relations. Their status is determined by a series of treaties from early times, which are a curious mixture of notions of international rights and of wardship.

Maine liquor law.

The public policy which has culminated in the well-known prohibitory "Maine Law" began with the "Act to restrict the sale of intoxicating liquors," passed in August 1846. This was followed in 1851 by an "Act for the suppression of drinking houses and tippling shops," and by thirty-nine other statutes directed against liquor selling, drunkenness, and the habit of drinking in the community. The manufacture for sale of any intoxicating liquors, except cider, is forbidden. The sale of such liquor by the manufacturer is punished by imprisonment for two months and a fine of $100. Unadulterated cider in quantities of 5 gallons and upwards may lawfully be sold. No person is allowed to sell any intoxicating liquors, including wine, ale, porter, strong beer, lager beer, and all other malt liquors, also cider for tippling purposes, on a penalty for a first offence of $30 and costs, or imprisonment for thirty days; for a second offence $20 and costs and imprisonment for thirty days; third offence $20 and costs and imprisonment for ninety days. A common seller on conviction is punished for a first offence by fine of $100 and costs, or imprisonment for three months; for a second and subsequent offences $200 and costs, and four months' imprisonment. A person convicted of keeping a drinking house or tippling shop is punished by fine of $100 and costs, or imprisonment for three months, for a first offence, and the same with six months' additional imprisonment for every subsequent conviction. Any one injured in person, property, means of support, or otherwise by an intoxicated person may bring an action for damages against the person who sold the liquor; and the owner or lessee of the building where it was sold is jointly liable if cognizant of such use. Any person convicted of being intoxicated in the streets or in any house, or of disturbing the public peace or that of his own or any family, is punished by a fine of $10, or thirty days' imprisonment, and for the second offence $20 or ninety days. All intoxicating liquors kept for sale and the vessels containing them are contraband, and forfeited to the towns where seized, and are there to be destroyed. To provide for the necessary sale of such liquors a State commissioner is appointed by the governor and council to furnish to the municipal officers of towns pure, unadulterated intoxicating liquors to be sold for medicinal, mechanical, and manufacturing purposes. He is put under $10,000 bond, and is allowed 7 per cent. commission on his sales. Municipal officers may purchase what they deem necessary of such liquors, and appoint an agent to sell them for such purposes as have been named, and no other. This agent is forbidden to sell to any minor, soldier, Indian, or intoxicated person, or to any person of whose intemperate habits he has been notified by such person's relations or by the municipal officers. It is made the special duty of sheriffs and county attorneys to enforce the provisions of the laws relating to the sale of intoxicating liquors.

The history of this legislation is that of laws generally which are enacted rather from the high moral ends which they propose than from the sincere and settled judgment of the legislators, and which do not represent the average moral sentiment actually prevailing among the people in whose name they are enacted and are to be enforced. It was inevitable that towards an issue like this political parties should take an attitude not always sincere. The Maine law has not entirely suppressed drunkenness, or even liquor selling, but it has had a decided influence in that direction. It has also tended to make drinking disgraceful, and has removed much temptation from young men. The people would be reluctant to abolish it until they could see something better to put in its place.

Population.

The population of Maine has not increased at an equal ratio with the other States of the Union, as will be observed from the subjoined table. There is a constant emigration from the State of native-born people to other parts of the country, which is only about half made up for by immigration from the adjoining provinces and the Old World.

Census Years.	Total.	Males.	Females.	Density per sq. mile.
1790............	96,540	49,432	47,108	3·2
1800............	151,719	77,250	74,469	5·1
1810............	228,705	116,118	112,587	7·7
1820............	298,335	149,664	148,671	9·9
1830............	399,462	201,232	198,230	13·4
1840............	501,793	253,709	248,084	16·8
1850............	583,169	297,471	285,698	19·5
1860............	628,279	317,189	311,090	21·0
1870............	626,915	313,103	313,812	20·9
1880............	648,936	324,058	324,878	21·6

In 1880 the number of native-born was 590,053, and of foreign-born 58,883.

The following cities had in 1880 a population of 5000 and upwards :—Portland, Lewiston, Bangor, Biddeford, Auburn, Augusta, Bath, Rockland, Saco, Calais, Brunswick, Belfast, Ellsworth.

Divorces.

Divorces in Maine reach the highest ratio to the marriages, or to the population, of any State of which statistics are reported. The privilege of a jury trial favours the plaintiffs, and it is not easy to find a jury who will withhold a verdict for divorce.

Diminished birth-rate.

The birth-rate of the native or oldest and typical families of Maine has greatly fallen off, and the number of children of school age is diminishing, not only proportionately to the population but in positive numbers, the diminution for the last eleven years being 14,200.

Church statistics.

The latest reports as to the religious societies of Maine show that there are 242 Congregationalist churches, with a membership of 21,340 ; 261 Baptist churches, membership 20,954 ; Methodist 228, membership 20,774 ; Freewill Baptist 286, and membership 15,822 ; Christian 60, membership 6000 ; Universalist 41, membership 4500 ; Unitarian 21, membership (estimated) 2500 ; Episcopal 32, membership 2115 ; New Jerusalem 5, membership 341 ; others 9500 ;—total Protestant membership 103,846. There are 42 Roman Catholic churches, with a membership of 40,000. The tendency seems to be to a decrease of the Congregationalists, and a corresponding increase of the Free Baptists and Methodists.

Education.

Common school education in the State is widespread. In the number of citizens able to read and write it stands in the very front rank of States. Instruction in the public schools is not under ecclesiastical control, and is free to all between the ages of four and twenty-one, and compulsory upon all between the ages of nine and fifteen years for twelve weeks each year. Every city and town is required to raise and expend annually for schools not less than 80 cents for each inhabitant. The State meets this on its part by distributing, in proportion to the number of children of school age in each town, the income of a permanent school fund ($44,275,791), and by a State tax of 1 mill per dollar of valuation on the property in the State, and a tax of one per cent. on the average annual deposits in savings banks. The average cost of supporting the public schools is $1,240,000 a year. In the larger towns the schools are graded into primary, intermediate, and grammar schools. A system of free high schools was established in 1878, for which the State contributes a sum equal to that paid by the town, not exceeding $250. The whole sum appropriated in 1881 was $26,000. There are three normal schools, intended for the training of teachers in the common schools. For these tuition is free, and the annual appropriation required is $19,000. The State college of agriculture and mechanic arts may in some respects be considered the culmination of the public school system. A large farm and various workshops are here provided, and every facility afforded at the least possible expense for a good education, chiefly directed to the industrial arts, but still liberal in scope. There are three colleges, with the usual course of study leading to the degrees of bachelor and master of arts :—Bowdoin, founded by the old State of Massachusetts in 1794, and since liberally endowed by private benefactions, from which Hawthorne and Longfellow graduated ; Colby University, founded as Waterville College in 1820, and under the control of the Baptist denomination ; and Bates College, founded in 1863, in the interest of the Free Baptist denomination, with a fitting school and a theological seminary attached. The theological seminary at Bangor, under the care of the Congregationalists, is open to all denominations, and attracts many students from the adjacent provinces of Canada. The medical department of Bowdoin College is known as the medical school of Maine. It has an annual attendance of more than 100, and has graduated 1300. There are various societies which are of a nature to afford instruction. The Maine Historical Society is making interesting investigations, and preserving memorials and records of historical matters, and its publications are of much value.

Public debt.

The bonded debt of the State is $5,801,900, which matures on or before 1889. Deducting the sinking fund of $1,436,367, the actual balance of indebtedness is now (1882) $4,365,533. The local and municipal debt for all purposes, including aid to railroads, is $17,722,109.

Agriculture.

The total settled area of Maine is 17,900 square miles, of which 6000 have a population of 2 to 6 to the square mile, 3500 have 6 to 18, 5600 have 18 to 45, and 2800 have 43 to 90. Agriculture is still the most extensive occupation, engaging 83,000 of the people. There are 64,310 farms, with 1,864,136 acres of tillage. Of these 61,530 farms are occupied by their owners ; 24,640 contain over 100 acres each, and nearly as many have between 50 and 100 acres. The chief farm products are annually :—potatoes, 8,000,000 bushels ; hay, 1,200,000 tons ; butter, 14,103,960 lb ; cheese, 1,167,770 lb ; oats, 2,265,575 bushels ; maize, 960,633 bushels ; wheat, 665,714 bushels ; buckwheat, 382,701 bushels ; barley, 242,185 bushels ; rye, 26,398 bushels ; wool, 2,776,404 lb ; milk sold, 3,720,783 gallons.

Forest tracts.

The remaining unsettled area is mostly unbroken forest. At present this region only furnishes material for lumbering. The pine has been cut back to the headwaters of the rivers, and the chief material is spruce and hemlock, with some cedar. The principal shipping port is Bangor on the Penobscot, where the amount surveyed has been 200,000,000 feet a year.

Fisheries.

In fisheries the State stands second in the Union. There are 12,662 persons directly employed in fisheries, but it is estimated that 48,000 people are dependent chiefly on this business. The sea fish taken are cod, hake, haddock, pollack, herring, mackerel, and holibut. The amount taken is 206,778,693 lb annually. There are establishments for preparing oil from the menhaden, &c., where 168,732 gallons a year are produced. The canning of fish is a considerable industry ; and in the lobster canning business this State has a monopoly. The catch in 1879 was for Maine 14,234,182 lb, and that bought of British fishermen 10,588,578 lb. In the home establishments 1,830,200 cans were put up, and in those worked in the British Provinces on account of Maine owners 2,198,024 cans. A recent but rapidly growing interest is that of sardine canning, chiefly carried on at Eastport. In 1880 there were 1328 persons employed in this industry, with an annual product of 7,550,868 cans and 8365 barrels. The river fish chiefly taken are salmon, shad, alewives, and smelts. Much interest is taken in restocking the lower rivers, especially with salmon, shad, and bass. The Penobscot is the only river on the Atlantic coast of the United States from which a supply of sea salmon eggs can be obtained for propagation. An association of the United States with the States of Maine, New Hampshire, Massachusetts, and Connecticut appoints agents for procuring these eggs, which are distributed in proportion to the respective contribution of funds. The great hatchery is at Orland, where also there is one for the eggs of the land-locked salmon ; there is another at Grand Lake Stream, owned by the same association. The black bass and alewives have also been distributed in the lower ponds and streams.

Other industries.

The other native products are lime, quarried stone,—both for building and for monumental purposes—slate, iron, and copper. Ice is cut and shipped to various parts of the world, to the amount annually of 350,000 tons, and the value, when ready for transportation, of $600,000. Maine was long distinguished for her shipbuilding ; and, though of late years this industry has greatly fallen off, yet in the building of wooden ships the State probably holds her old rank. The shipping owned in Maine is mostly engaged in foreign commerce, or in coasting to and from distant States. There are 12,000 sailors in this service. There are 1022 miles of railroad in Maine. Of manufactories there are 24 cotton-mills, running 696,564 spindles, and employing 11,844 persons, of whom 7010 are women ; and 97 woollen-mills of all kinds, employing 3265 persons, of whom 1160 are women. The other chief industries are flouring mills, leather tanneries, boot and shoe making, paper making, and iron working of various kinds.

History.

The shores of what is now sometimes called the Gulf of Maine, whose waters stretch between Cape Sable and Cape Cod, attracted much attention from the early voyagers and explorers, as many glowing accounts remain to testify. The Cabots, under English auspices, visited this region in 1497 ; Verrazano, representing the French, in 1524 ; Gomez in the name of Spain in 1525, giving his name to Penobscot river and bay. In 1526 the Frenchman Thevet followed ; he states that before that time the French had a fort 30 miles up the river, named Norumbega. The enterprise of Sir Walter Raleigh and Sir Humphrey Gilbert first reveals a purpose on the part of Englishmen to colonize these shores. Gosnold (1602), Pring (1603), and Weymouth (1605) had made some explorations, but a century had passed and no European power had gained a foothold on the Atlantic coast north of Florida. But in 1603 Henry IV. of France granted a charter to De Monts, a Protestant gentleman of his household, of all North America between 40° and 46° N. lat. In 1604 De Monts established a settlement on what is now Neutral Island, in the St Croix river. In 1605 James I. of England granted to some English gentlemen all the territory between 34° and 45° N. lat. The portion between 40° and 45° was thus the subject of a double grant, to parties naturally antagonistic. The latter parallel, striking nearly at the mouth of the St Croix, includes almost all the southern half of Maine, and brought what was practically at that time the whole of Maine to be the theatre of the disputed jurisdiction. The French did not indeed claim further west than the Kennebec river, the limit of their actual occupation; but the English endeavoured by sporadic and violent sallies to hold, if not by occupation at least by desolation, to the St Croix river, the extreme north-east boundary of their claim. The Indians, already exasperated by the wrongs received from roving English shipmasters and traders, were easily persuaded to make alliance with the French, and this double frontier was a scene of strife for the space of one hundred years. The English with much earnestness of purpose proceeded to plant a colony in 1607, under the guidance of George Popham, brother of the chief-justice of England, and Captain Gilbert Raleigh, whose name indicates his lineage and spirit. This colony they planted with solemn ceremonies on a point at the mouth of the Kennebec. The little town rose rapidly, with its fort and its church in due order. They also built a vessel, the "Virginia of Sagadahock," the first vessel built by Europeans in America. The colony grew discouraged by their winter experiences, and the next year broke up, most of the colonists returning to England. It appears, however, that they did not utterly forsake their object, for scattered settlements still remained and increased about the Point and Bay of Pemaquid and the island of Monhegan, midway between the Kennebec and Penobscot. This region became a centre of trade and a base of operations, being the headquarters of the famous Captain John Smith, where he built a fleet of boats in 1614, and explored the adjacent coast, which he named New England. In 1620 a new impulse found expression in the great charter of New England, given to Sir Ferdinando Gorges and others, who proceeded to lay out their plans on a large scale. Two years afterwards a patent under this charter conveyed to Gorges and Captain John Mason the country between the Merrimac and Kennebec and 60 miles inland, which they proposed to call the province of Maine. In 1629 they divided their possession, Gorges taking the portion between the Piscataqua and the Kennebec.

The great council of New England surrendered their charter in 1635, and in the division of its territory Gorges retained his portion previously granted, while the region between the Kennebec and the St Croix and the St Lawrence rivers, though still claimed by the French as part of Acadia, was given to Sir William Alexander, earl of Stirling, and this was to be called the county of Canada. Gorges named his tract the county of New Somersetshire, and immediately commenced the administration of government, setting up a court at Saco (1636) under direction of his kinsman, William Gorges. In 1639 he obtained from Charles I. a new and extraordinary charter, confirming to him his province of Maine under that name, and under the feudal tenure of a county palatine, Gorges, as lord palatine, being invested with vice-regal powers. In 1641 he established a capital and court at Georgiana (now York), the first chartered city in America. But it was no easy task to administer government or hold a jurisdiction in his palatinate. The great council of New England, before breaking up, had granted not less than nine patents, conveying territory already included in Gorges's thrice-granted jurisdiction, to various parties, who had made vigorous beginnings to improve their holdings and confirm their claims. In like manner the council had made two important grants within the jurisdiction of Sir William Alexander, so that difficulties arose in that quarter also. In this confusion of jurisdiction Massachusetts, under a new construction of the extent of her chartered rights, laid claim to a line which included nearly all the settled portion of Gorges's territory, and by a farther extension she claimed the coast as far east as Penobscot Bay. This latter she named the county of Devonshire, and set up a court at Pemaquid (1674). This latter territory had been conveyed by the earl of Stirling to the duke of York, afterwards James II. of England. This was organized by James as the county of Cornwall, and was afterwards represented in the general assembly in New York (1683). In 1677, however, the claim of Massachusetts in Maine being contested and decided adversely to her, she took the occasion to buy of the heirs of Sir Ferdinand Gorges all his right, title, and interest in Maine for £1250. Matters were still more complicated by the persistent efforts of the Dutch to gain possession of the east coast, who had now (1676) effected a lodgment on the shores of Penobscot Bay; but they were finally driven off. The troubled state of things in England prevented Massachusetts from profiting very much by her purchase in Maine, and at last the new charter of William and Mary (1691) merged all the provinces of Plymouth, Massachusetts, Maine, Sagadahock, and Acadia under one title and jurisdiction, "the province of Massachusetts Bay."

That part of Acadia east of the St Croix was five years afterwards ceded back to the Crown. Thus Maine, with the St Croix for its eastern boundary, became an integral part of the Province, afterwards the State, of Massachusetts Bay. From that time for over one hundred years the history of Maine is merged in that of Massachusetts. Although its people were not of the religious or political faith of the Puritan colony, and for that reason had been shut out of the famous New England confederacy of 1643, yet they were true Englishmen, and stood manfully for the common cause. Not only was Maine an exposed frontier and battleground, during the long struggle of the English against the Indians and the French, but its citizens bore a conspicuous part in the expeditions beyond its borders. Two of these were commanded and largely manned by men of Maine. Port Royal was taken by Sir William Phipps and Louisburg by Sir William Pepperell. In fact these expeditions were such a drain on Maine population that Massachusetts was called upon to send men to garrison the little forts that protected the homes left defenceless by the men who had gone to the front. The great losses and destruction of these wars kept this portion of the province back from its natural increase.

In the stand made for the rights of Englishmen, which led to revolution and independence, Maine was behind none. Two years before the battles of Lexington and Concord its towns had offered themselves "as a sacrifice if need be to the glorious cause of liberty." Some, it is true, were deep-rooted in sympathy with the mother country, and these retired eastward, first beyond the Penobscot and afterwards beyond the St Croix. This war made Maine again an outpost and frontier. That same picturesque and commanding promontory of Castine in Penobscot Bay, which had been once the most eastern post held by the Pilgrims of Plymouth and afterwards the western advanced post of the French in Acadia, was now the stronghold of the English in this region, as against the Americans. Early in the war (1775) the chief town, Falmouth (now Portland), was bombarded and nearly destroyed. Some patriots the same year attacked a king's ship off Machias, and after a desperate struggle the British flag was struck to Americans for the first time on sea or land. Maine was fully and honourably represented in the war by a division of the Massachusetts line. It had also representatives in Congress, and some eminent officers and patriots of the Revolution resided within its borders. In fact, to all intents and purposes except in name, Maine was one of the original States of the Union.

At the close of the war, the old spirit of independent personality and self-government made a forcible expression. The people sought to be separated from Massachusetts, and to make their laws and their history in their own name. There were two parties, however, and the troubles which agitated the whole country at that time, postponed action on this issue, and Maine continued almost forty years longer an integral part of Massachusetts, but was at no time a dependent province of that State. At the conclusion of peace there was a large immigration into Maine, chiefly of soldiers of the Revolution, who strengthened the already vigorous character of the people. Everything prospered until the Embargo Act of 1808, cutting off commerce and the coast trade, struck Maine in a vital point. Its shipping at this time amounted to 150,000 tons, its exports to a million dollars a year. The war with England, which soon followed, almost destroyed these interests. Other industries, however, were stimulated. Manufactories of woollen, cotton, glass, of iron and other metals were set on foot, only to be ruined by the influx of British goods, which followed the new peace. It was a discouraging time, and one or two unusually severe winters threatened the only industries which the war and peace had spared, while in 1815–16 not less than 15,000 people emigrated to Ohio. In 1820 Maine was recognized as a separate State of the Union. Its population was then about 300,000, and its chief industries, agriculture, lumbering, and shipbuilding, were in prosperous course. Its encouragement of manufactures was slow. A prejudice against great corporations long kept Maine from entering largely at the auspicious time into those industrial enterprises which have built up neighbouring States. It is only within recent years that the State has begun to take proper advantage of its unsurpassed facilities for manufacturing. The difficulties about the north-eastern boundary had increased with each year since the treaty in 1783. Great Britain had gradually obtained possession of considerable territory within the line claimed by the States under the treaty, and after the war of 1812 laid claim to territory which had long been under the actual jurisdiction of Massachusetts. The question assumed national and international importance. The Government of the United States, apparently desirous of gratifying Great Britain, offered Maine 1,200,000 acres of land in Michigan to yield its claim, but the proposition only roused indignant protest in the State, which culminated in the sending of a military force to defend its territory. Finally, however, considerations of national policy urged at Washington induced Maine to acquiesce in a treaty, which took away a large area additional to that already silently yielded, amounting in all to 5500 square miles,—an area greater by 600 square miles than the State of Connecticut, and by

1680 square miles than the States of Rhode Island and Delaware combined.

In the war against secession the service of the State was prompt and efficient. Maine sent to the front 72,000 men, of whom not less than 20,000 gave their lives for the cause. These volunteers were distributed in thirty-two regiments of infantry, two regiments of cavalry, one regiment of artillery, one battalion of sharpshooters, and 6764 enlistments in the navy. The whole amount of State and municipal debt incurred in raising and equipping these troops was about $12,000,000. The United States afterwards reimbursed the State to the amount of $668,284, most of which was applied to form a sinking fund for extinguishing the war debt at maturity. The State also provided pensions for its disabled soldiers and their families. (J. L. C.)

MAINE DE BIRAN, FRANÇOIS-PIERRE-GONTHIER (1766–1824), a distinguished philosopher of France, the son of a physician, was born at Bergerac November 29, 1766. After studying with distinction under the *doctrinaires* of Perigueux, he entered the life-guards of Louis XVI., and was present at Versailles on the notable 5th and 6th of October 1789. On the breaking up of the *garde du corps*, Maine de Biran retired to his patrimonial inheritance of Grateloup, near Bergerac, where his sequestered residence and limited income preserved him from the horrors of the Revolution. It was at this period that, as he says himself, he "passed *per saltum* from frivolity to philosophy." The forced leisure of this fearful time decided the vocation of his life. He combined, in a more than ordinary degree, subtle sensitiveness to external influences with singular acuteness in surveying and analysing internal phenomena. The modes of the mind and their organic causes or conditions were alike submitted to his scrutiny. He began his philosophical studies with psychology, and he made psychology the study of his life. When the Reign of Terror was succeeded by calmer days, Maine de Biran was called to take part in the administrative and political affairs of his country. After his exclusion from the council of the Five Hundred on being suspected of royalism, he took part with his friend Lainé in the commission of 1813, which gave expression for the first time to direct opposition to the will of the emperor. After the Restoration he held the office of treasurer to the chamber of deputies, and habitually retired during the autumn recess to his native district to pursue his favourite study. He died 16th July 1824.

Maine de Biran's philosophical reputation has suffered from two causes—the obscure, laboured quality of his style, and the unfortunate mode of publication of his writings. In all his work there is evidence of thorough originality of thinking, but in the expression of his thoughts this very originality is so far a disadvantage in that it imposes on him a mode of exposition little calculated to attract and retain the attention of a reader. During his life, moreover, but few, and these the least characteristic of his works, were formally published. An essay on habit (*Sur l'Influence de l'Habitude*, 1803), a critical review of Laromiguière's lectures (1817), and the philosophical portion of the article Leibnitz in the *Biographie Universelle* (1819) appeared during his lifetime. A long memoir on the analysis of thought (*Sur la Décomposition de la Pensée*), crowned by the Institute in 1805, was sent to press, but, for some reason, was not finally printed. His manuscripts, very large in quantity, were not made accessible in their entirety to Cousin when that writer desired to prepare a collective edition of De Biran's works. In 1834 the writings above enumerated, together with the important essay entitled *Nouvelles considerations sur les rapports du physique et du moral de l'homme*, were published by Cousin, and in 1841 there were added three volumes by the same editor, under the title *Œuvres philosophiques de Maine de Biran*. The manuscripts from which Cousin had prepared this edition were, however, in a most imperfect condition, and it was known that some memoirs to which De Biran attached the greatest importance were still in obscurity. In 1845 a large mass of manuscript was placed by De Biran's son in the hands of F. M. E. Naville. The labour of preparing these for publication, interrupted by the death of Naville in 1846, was continued by his son, E. Naville, and completed, with the aid of M. Debrit, in 1859. The *Œuvres inédites de M. de Biran*, 3 vols., rendered it possible for the first time to obtain a connected view of a very remarkable monument of philosophical development. In these volumes the most important work is that entitled *Essai sur les fondements de la psychologie et sur ses rapports avec l'étude de la nature*, which represents the completest stage of De Biran's thinking. A later stage is represented by the fragments of a projected work entitled *Nouveaux Essais d'Anthropologie*, in which the psychology of the earlier treatise is developed in the direction of a somewhat mystical metaphysic.

De Biran's first essays in philosophy were written avowedly from the point of view of Locke and Condillac, but even in them he was brought to signalize the essential fact on which his later speculation turns. Dealing with the formation of habits, he is compelled to note that passive impressions, however transformed, do not furnish a complete or adequate explanation. With Laromiguière he distinguishes attention as an active effort, of no less importance than the passive receptivity of sense, and with Butler distinguishes passively formed customs from active habits. Prolonged meditation, evidenced in the occasional writings, prize essays, and the like of the subsequent years, brought him to the far-reaching conclusion that Condillac's notion of passive receptivity as the one source of conscious experience was not only an error in fact but an error of method,—in short, that the mechanical mode of viewing consciousness as formed by external influence was fallacious and deceptive. For it he proposed to substitute the genetic method, whereby human conscious experience might be exhibited as growing or developing from its essential basis in connexion with external conditions. The essential basis he finds in the real consciousness of self as an active striving power, and the stages of its development, corresponding to what one may call the relative importance of the external conditions and the reflective clearness of self-consciousness, he designates as the affective, the perceptive, and the reflective. These stages are characterized with much skill and psychological acuteness, and in connexion therewith De Biran treats most of the obscure problems which arise in dealing with conscious experience, such as the mode by which the organism is cognized, the mode by which the organism is distinguished from extra-organic things, and the nature of those general ideas by which the relations of things are known to us—cause, power, force, &c. His views are always suggestive, and the best recent psychology in France is but a reproduction of some of them.

In the latest stage of his speculation De Biran distinguishes the animal existence from the human, under which the three forms above noted are classed, and both from the life of the spirit, in which human thought is brought into relation with the supersensible, divine system of things. This stage, as above said, is left imperfect. Altogether De Biran's work presents a very remarkable specimen of deep metaphysical thinking directed by preference to the psychological aspect of experience. It is almost a solitary instance of an effort to treat psychology in a wide and philosophical manner.

The *Œuvres inédites* of De Biran by Naville contain an introductory study. Special monographs on him are—Merten, *Étude critique sur Maine de Biran*, 1865; E. Naville, *Maine de Biran, sa vie et ses pensées*, 2d ed., 1874; Gèrard, *Maine de Biran, essai sur sa philosophie*, 1876.

MAINE-ET-LOIRE, a western department of France, lying between 47° and 47° 50′ N. lat., and between 15′ E. and 1° 20′ W. long., consists of the southern portion of the former province of Anjou, and is bounded on the N. by the departments of Mayenne and Sarthe, on the E. by Indre-et-Loire, on the S. by Deux-Sèvres and Vendée, on the W. by Loire-inférieure, and on the N.W. by Ille-et-Vilaine. The extreme length from north-east to south-west is about 78 miles; the breadth from north to south ranges from 25 to 50 miles, and the area is 2750 square miles. The capital, Angers, lies 162 miles south-west from Paris. The department is made up of two distinct regions, the line of demarcation running from south-east to north-west, and passing through Angers; that to the south consists of granites, felspars, and a continuation of the geological formations of Brittany and Vendée; to the north, on the contrary, schists, limestone, and chalk prevail. The general elevation of the latter region is but small, and none of its eminences exceed 330 feet in height; the former, on the contrary, has a surface richly varied with deep winding valleys clothed with woods and thickets, though the highest points are under 700 feet. The department belongs entirely to the basin of the Loire, which traverses it from east to west by a valley varying in breadth from about 1 to 5 miles; the bed is wide but shallow, and full of islands, the depth of the water in summer being at some places little more than 2 feet. The floods which occur are sudden and destructive.

The chief affluent of the Loire within the department is the Maine, formed a little above Angers by the junction of the Mayenne and the Sarthe (the latter in turn having previously received the waters of the Loir). All three rivers are navigable. Other tributaries of the Loire are the Thouet (with its tributary the Dive), the Layon, the Èvre, the Divatte on the left, and the Authion on the right. The latter, which has a course parallel to that of the Loire, has been supposed, but erroneously, to occupy an ancient bed of that river. The Mayenne is joined on the right by the Oudon, which can be navigated below Segré. The Erdre, which joins the Loire at Nantes, and the Moine, a tributary of the Sèvre-Nantaise, both take their rise within this department. The climate, which is very mild, shares the characteristics both of the Sequanian and of the Armorican districts. The mean annual temperature of Angers is 3° Fahr. above that of Paris; the rainfall at the same place is only 18·64 inches, but rises to 23·6 inches farther down the river, and 27·75 as the sea is approached. Notwithstanding this deficiency of rain, the frequent fogs, combined with the peculiar nature of the soil in the south-east of the department, produce a degree of moisture which is highly favourable to meadow growths. The winter colds are never severe, and readily permit the cultivation of certain trees which cannot be reared in the adjoining departments.

Of the entire area more than one-half is arable; one-tenth is occupied by meadows; and considerably smaller areas are occupied by woods, vineyards, and heath respectively. Oxen number 225,000, pigs 100,000, and sheep 68,500; these figures represent a considerable commercial activity, as most of the animals are purchased out of neighbouring departments for the purpose of being fattened. Cholet alone exports annually 100,000 cattle, 150,000 or 200,000 sheep, and 25,000 or 30,000 pigs. The number of horses in the department is 55,000, chiefly of a race much used for light cavalry service. The cavalry school is at Saumur within this department. The production of cereals is in excess of the consumption; there are extensive areas in the valleys of the Loire and Sarthe under hemp, and linseed and colza oil are produced in quantity. The legumes of Saumur and Angers are specially prized. The wine of the department (14,000,000 gallons in 1880) is fairly good, and the white wine of Saumur is exported and sold as sparkling champagne (about 6,000,000 bottles yearly). Cider is produced, and large quantities of apples, pears, and plums are exported to the markets of Paris, England, and Russia. Floriculture is an important industry, and the forests of oak and beech abound in game (stag, roebuck, wildboar). Near Angers are slate quarries in which 3250 workmen are employed; and the "Layon-et-Loire" coal-bed produced in 1881 15,288 tons of coal and anthracite, which, however, did not supply the demand of the department. There are sandstone quarries in the arrondissements of Saumur and Baugé. Cholet, the chief manufacturing town, is famous for its pocket-handkerchiefs; it has also manufactures of linen cloths, flannels, and cotton stuffs, worsted and cotton thread factories, and bleaching works. Similar manufactures are carried on at Angers; the speciality of Saumur is the making of enamels and beads, in which it employs 600 workmen, producing goods to the annual value of 1,500,000 francs. The population of the department was 517,258 in 1876, being an increase of 141,714 since 1801. There are five arrondissements,—Angers, Baugé, Cholet, Saumur, and Segré. The capital is Angers.

MÁINPURÍ, or MYNPOOREE, a district in the lieutenant-governorship of the North-Western Provinces, India, between 26° 52′ 30″ and 27° 30′ N. lat., and 78° 27′ 45″ and 79° 28′ 30″ E. long., is bounded on the N. by Etah, on the E. by Farrukhábád, on the S. by Etawah, and on the W. by Muttra and Agra, and has an area of 1697 square miles, of which 949 are cultivated, and 190 cultivable. It consists of an almost unbroken level plain, intersected by small rivers, but unvaried by any greater elevations than a few undulating sand ridges. It is wooded throughout with mango groves, and isolated clumps of *bábul* trees occasionally relieve the bareness of its saline *usar* plains. On the south-western boundary the Jumna flows in a deep alluvial bed, sometimes sweeping close to the high banks which overhang its valley, and at others leaving room for a narrow strip of fertile soil between the river and the upland plain. From the low-lying lands thus formed a belt of ravines stretches inland for some 2 miles, often covered with jungle, but affording good pasturage for cattle. Moving north-eastward from this point, one reaches in succession the small rivers Aganga, Sengar, Rind, Isan, and Káli Nadi, most of which supply water to a small tract on either side, besides giving origin to rich deposits of cultivable silt. The Etawah and Cawnpur branches of the Ganges canal intersect the district for irrigation purposes, and the Lower Ganges canal, when completed, will furnish additional facilities in the same direction.

The census of 1872 returned the population of the district at 765,783 (males, 426,955; females, 338,828). The Hindus numbered 724,663, Mohammedans 40,965, Christians 85. Among high-caste Hindus, the Bráhmans number 67,072, and form a wealthy landholding class. Rájputs are returned at 60,155, amongst whom the Chauhans form the largest clan. They have long formed the aristocratic class of the district, and in 1872 owned 44 per cent. of the total area. Much of their hereditary property is, however, passing out of their hands into those of merchants and traders. Of the lower castes, the most important are the Ahírs, numbering 123,358, who own over 12 per cent. of the soil. For many centuries this tribe consisted of lawless robber hordes, who held the fastnesses of the Jumna ravines; and, though they have now been reduced to a comparatively industrial life, they still continue to afford the local authorities much trouble and anxiety. The Chamárs, 103,193 in number, are mere hewers of wood and drawers of water for the landholding classes, who held them in a condition of absolute serfdom under native rule. Other important Hindu tribes are Káchhis (72,898), Lodhás (53,658), Gadariyas (28,047), and Kahárs (25,273). The Moslems are for the most part poor and without social influence. Only four towns in the district contain a population exceeding 5000: Máinpurí, 21,117; Shikohábád, 10,069; Bhongáon, 6271; and Karhál, 5574.

Máinpurí is one of the districts where the question of female infanticide has long engaged the attention of Government, and even as late as 1872 this practice was so common as in a great measure to account for the large preponderance of males in the general population. In 1842 measures were first introduced for the supervision of the Chauhán Rájputs and Phátak Ahírs, among whom the practice was most common. Every female birth had to be duly reported and authenticated, together with a subsequent report on the child's health. Illness had to be immediately announced to the police, who held an investigation. These rules remained in force until supplemented by those of the Infanticide Act of 1870. In 1843 there was not a single female child among these tribes; in 1847 there were but two hundred and ninety-nine. In 1851 a convention of the heads of clans was held, when a body of rules was drawn up and subscribed to, but they were never observed. In 1865 a census of the Chauhán and Phátak villages was held, when six of the former were found without a single female infant. In some cases a daughter had never been known in the village. In 1870 it was found necessary to impose more stringent rules, and a special Infanticide Act was passed by the viceregal council. Inquiries instituted in connexion with the census of 1872 revealed the fact that many other tribes than the Chauháns and Pháţaks were implicated in the practice. In 1875, although a large proportion of the community had so far reformed in this respect as to be exempted from the special supervision provided by the Infanticide Act, there were still two hundred and seventy-six villages on the "proclaimed list" under the surveillance of a specially organized police, maintained by a tax levied on the guilty communities.

In Máinpurí almost every acre of available soil is under tillage. The total area under cultivation at the date of the last settlement was 607,991 acres. *Kharíf* or rain crops included cotton, 48,901 acres; *joar*, 120,497; *bájra*, 74,028; indigo, 5369; with a little maize, rice, hemp, &c., making up a total of 299,850 acres. *Rabí*, or spring crops were the following:—wheat, 105,488 acres; barley, 60,443; wheat and barley mixed together, 66,488; with gram, poppy, &c., making a total of 282,376 acres. There were also 17,523 acres under sugar-cane. Of the 607,360 acres cultivated in 1881, 337,726 were unirrigated, 180,415 were irrigated by private individuals, and 89,219 by Government. Two-thirds of the land is held by tenants with rights of occupancy, and one-third by tenants-at-will. Máinpurí suffers little from floods or blights, but in former years it used to be severely afflicted by drought. The means of communication, added to the large and increasing irrigation system, are now probably sufficient to protect the district from extreme distress in years of famine.

The district trade is almost entirely of a rural character. The chief exports are cotton, grain, indigo, *ghí*, and miscellaneous agricultural produce; while metals, English piece goods, sugar, pedlar's wares, tobacco, and rice are imported. Cotton thread is largely manufactured, and there is some trade in bangles, *hukás* or pipes, inlaid wood-work, and other fancy articles. Saltpetre is refined at several factories. The district is thoroughly supplied with land and water communications. Good metalled roads connect all the principal towns and villages; the East Indian Railway runs for 23 miles through the south-western angle; the navigable branch of the Ganges canal intersects the central plateau; and the natural highway of the Jumna skirts the district to the south.

The gross amount of assessment in 1880–81 was £115,132. Education was afforded in 1880–81 by 151 schools with 4146 pupils. The climate is hot but not excessively sultry during the summer months, and damp or foggy during the cold weather rains. The average annual rainfall for the five years ending 1870–71 was 32·20 inches. The chief endemic disease is malarial fever.

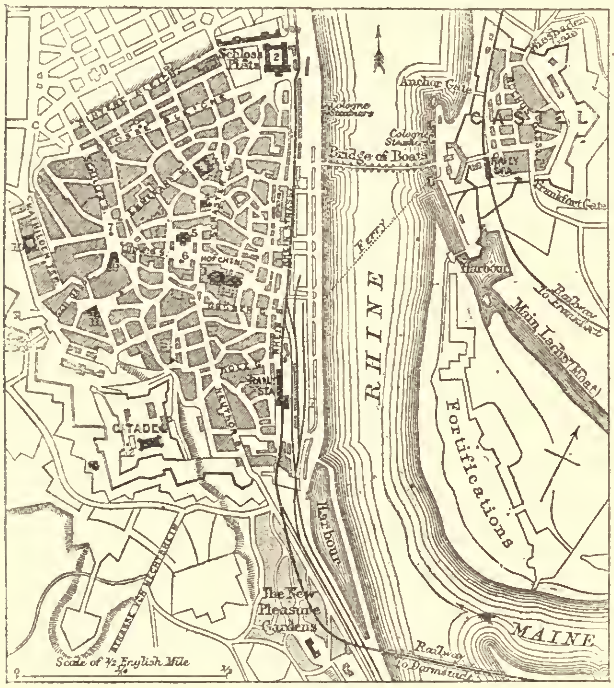
Máinpurí anciently formed part of the great kingdom of Kanauj, and after the fall of that famous state it was divided into a number of petty principalities, of which Rápri and Bhongáon were the chief. In 1194 Rápri was made the seat of a Moslem governor. Máinpurí fell to the Mughals on Bábar's invasion in 1526, and, although temporarily wrested from them by the short-lived Afghán dynasty of Sher Sháh, was again occupied by them on the reinstatement of Humáyún after the victory of Pánipat. Like the rest of the lower Doáb, Máinpurí passed, towards the end of the last century, into the power of the Mahrattas, and finally became a portion of the province of Oudh. When this part of the country was ceded to the British in 1801, Máinpurí town became the headquarters of the ex-extensive district of Etawah, which was in 1856 reduced by the formation of Etah and Máinpurí into separate collectorates. On the outbreak of the mutiny in 1857, the regiment stationed at Máinpurí revolted, and attacked the town, which was successfully defended by the few Europeans of the station for a week, until the arrival of the Jhánsí mutineers made it necessary to abandon the district.

MÁINPURÍ, the chief town and headquarters of the above district, is situated in 27° 14′ 15″ N. lat., 79° 3′ 5″ E. long., and had a population in 1872 of 21,117, viz., Hindus, 17,596; Mohammedans, 3435; Christians and "others," 146. The town consists of two separate portions, Máinpurí proper and Mukhamganj; the former traditionally dates from the prehistoric period of the *Mahábhárata*, while the latter was founded by Rájá Jaswant Sinh in 1803. Holkar plundered and burned part of the town in 1804, but was repulsed by the local militia. Since the British occupation the population has rapidly increased, and many improvements have been carried out. The Agra branch of the Grand Trunk Road runs through the centre, and forms a wide street lined on both sides by shops, which constitute the principal bazaar. Besides the usual Government offices, &c., in the civil station, the chief buildings are the police station, opium warehouses, jail, post-office, dispensary, two large schools, American Presbyterian mission, church, reading-rooms; there are two public gardens. The town carries on a considerable trade in cotton, indigo seed, country produce, and iron; and there is a manufacture of wooden articles inlaid with wire.

MAINTENON, FRANÇOISE D'AUBIGNÉ, MARQUISE DE (1635-1719), the second wife of Louis XIV., and unacknowledged queen of France for the last thirty years of his reign, was born in a prison at Niort on November 27, 1635. Her father Constant d'Aubigné, was the son of Agrippa d'Aubigné, the famous friend and general of Henry IV., and had been imprisoned as a Huguenot malcontent, but her mother, a fervent Catholic, had the child baptized in her religion, her sponsors being the Duc de la Rochefoucauld, father of the author of the *Maxims*, and the Comtesse de Neuillant. In 1639 Constant d'Aubigné was released from prison and took all his family with him to Martinique, where he died in 1645, after having lost what fortune remained to him at cards. Madame d'Aubigné returned to France, and from sheer poverty unwillingly yielded her daughter to her sister-in-law, Madame de Villette, who made the child very happy, but, unfortunately for her, converted or pretended to convert her to Protestantism. When this was known, an order of state was issued that she should be entrusted to Madame de Neuillant, her godmother. Every means, every indignity even, was now used to convert her back to Catholicism, but at the last she only yielded on the condition that she need not believe that the soul of Madame de Villette was lost. Once reconverted, she was neglected, and sent home to live with her mother, who had only a small pension of 200 livres a year, which ceased on her death in 1650. The Chevalier de Meré, a man of some literary distinction, who had made her acquaintance at Madame de Neuillant's, discovered her penniless condition, and introduced his "young Indian," as he called her, to Scarron, the famous wit and comic writer, at whose house all the literary society of the day assembled. The wit, who was of good legal family, and had a kind heart, took a fancy to the friendless girl, and offered either to pay for her admission to a convent, or, though he was deformed and an invalid, to marry her himself. She accepted his offer of marriage, and became Madame Scarron in 1651. For nine years she was not only his most faithful nurse, but an attraction to his house, where she tried to bridle the licence of the conversation of the time. On the death of Scarron in 1660, Anne of Austria continued his pension to his widow, and even increased it to 2000 livres a year, which enabled her to entertain and frequent the literary society her husband had made her acquainted with; but on the queen-mother's death in 1666 the king, in spite of all the efforts of her friends, refused to continue her pension, and she prepared to leave Paris for Lisbon as lady attendant to the queen of Portugal. But before she started, she met Madame de Montespan, who was already, though not avowedly, the king's mistress, at the Hôtel d'Albret, and the lady in question took such a fancy to her that she obtained the continuance of her pension, which put off for ever the question of going to Portugal. Madame de Montespan did yet more for her, for when, in 1669, her first child by the king was born Madame Scarron was established with a large income and a large staff of servants at Vaugirard to bring up the king's children in secrecy as they were born. In 1674 the king determined to have his children at court, and their governess, who had now made sufficient fortune to buy the estate of Maintenon, accompanied them. The king had now many opportunities of seeing Madame Scarron, and, though at first he was prejudiced against her, her even temper showed so advantageously against the storms of passion and jealousy exhibited by Madame de Montespan that she grew steadily in his favour, and had in 1678 the gratification of having her estate at Maintenon raised to a marquisate, and herself entitled Madame de Maintenon by the king himself. Such favours brought down the fury of Madame de Montespan's jealousy, and Madame de Maintenon's position was almost unendurable, until, in 1680, the king severed their connexion by making the latter second lady in waiting to the dauphiness, and soon after Madame de Montespan left the court. The new "amie" used her influence on the side of decency, and the queen openly declared she had never been so well treated as at this time, and eventually died in Madame de Maintenon's arms in 1683. The queen's death opened the way to yet greater advancement; in 1684 she was made first lady in waiting to the dauphiness, and in the winter of 1685, or, Voltaire says, in January 1686, she was privately married to the king by Harlay, archbishop of Paris, in the presence, it is believed, of Père la Chaise, the king's confessor, the Marquis de Montchevreuil, the Chevalier de Forbin, and Bontemps. No written proof of the marriage is extant, but that it took place is nevertheless certain. Her life during the thirty years of her second married life must be studied from more than one side, and can be so fully from her letters, which are masterpieces even of an age when Madame de Sevigné wrote, and of which many authentic examples are extant. As a wife she is wholly admirable; she had to entertain a man who would not be amused, and had to submit to that terribly strict court etiquette of absolute obedience to the king's inclinations which Saint-Simon so vividly describes, and yet be always cheerful, and never complain of weariness or ill-health. Her political influence has probably been overstated, but it was supreme in matters of detail. The ministers of the day used to discuss and arrange all the business to be done with the king beforehand with her, and it was all done in her cabinet and in her presence, but the king in more important matters often chose not to consult her. Such mistakes as, for instance, the replacing of Catinat by Villeroi may be attributed to her, but not whole policies,—notably, according to Saint-Simon, not the policy with regard to the Spanish succession. Even the revocation of the edict of Nantes and the Dragonnades have been laid to her charge, but there can be no doubt that, in spite of ardent Catholicism, she retained a liking for her father's religion, and opposed, if not very vigorously, the cruelties of the Dragonnades. She was probably afraid to say much, or peril her great reputation for devotion, which had in 1692 obtained for her from Innocent XII. the right of visitation over all the convents in France. Where she deserves blame is in her use of her power for personal patronage, as in compassing the promotions of Chamillart and Villeroi, and the frequent assistance given to her brother Comte Charles d'Aubigné. Her influence was on the whole a moderating and prudent force, and the king, when he wanted her advice, used to say, "Qu'en pensez votre Solidité?" or "Consultons la Raison." Her social influence was not as great as it might have been owing to her holding no recognized position at court, but it was always exercised on the side of decency and morality, and it must not be forgotten that from her former life she was intimate with the literary people of the day, and never deserted her old friends. Side by side with this public life, which wearied her with its shadowy power, occasionally crossed by a desire to be recognized as queen, she passed a nobler and sweeter private existence as the foundress of St Cyr. Madame de Maintenon was a born teacher; she had so won the hearts of her first pupils that they preferred her to their own mother, and was similarly successful later with the young and impetuous Duchesse de Bourgogne, and she had always wished to establish a home for poor girls of good family placed in such straits as she herself had experienced. As soon as her fortunes began to mend she started a small home for poor girls at Ruel, which she afterwards moved to Noisy, and which was the nucleus of the splendid institution of St Cyr, which the king had endowed in 1686 at her request out of the funds of the Abbey of St Denis. She was in her element there. She herself drew up the rules of the institution; she examined every minute detail; she befriended her pupils in every way; and her heart often turned from the weariness of Versailles or of Marly to her "little girls" at St Cyr. It was for the girls at St Cyr that Racine wrote his *Esther* and his *Athalie*, and it was because he managed the affairs of St Cyr well that Chamillart became controller-general of the finances. The later years of her power were marked by the promotion of her old pupils, the children of the king and Madame de Montespan, to high dignity between the blood royal and the peers of the realm, and it was doubtless under the influence of her dislike for the Duc d'Orleans that the king drew up his will, leaving the personal care of his successor to the Duc de Maine, and hampering the Duc d'Orleans by a council of regency. On or even before her husband's death she retired to St Cyr, and had the chagrin of seeing all her plans for the advancement of the Duc de Maine overthrown by means of the parlement of Paris. However, the regent Orleans in no way molested her, but on the contrary visited her at St Cyr, and continued her pension of 48,000 livres. She spent her last years at St Cyr in perfect seclusion, but an object of great interest to all visitors to France, who, however, with the exception of Peter the Great, found it impossible to get an audience with her. On April 15, 1719, she died, and was buried in the choir at St Cyr, bequeathing her estate at Maintenon to her niece, the only daughter of her brother Charles, and wife of the Maréchal de Noailles, to whose family it still belongs. Such was the life of the extraordinary woman who kept till the last the heart of Louis XIV., marked by a virtue almost amounting to prudery, in strong contrast to the generations which preceded and followed her, by a love of power, and a use of it which can indeed be excused by her early life, but which was not exercised for the good of France, and by a religious devotion which was narrow, if not violently fanatical, but sweetened throughout by her ardent love for her "little girls," whom she had saved from the difficulties of life, and whom she loved with all a mother's love.

La Beaumelle published the *Lettres de Madame de Maintenon*, but much garbled, in 2 vols. in 1752, and on a larger scale in 9 vols. in 1756. He also in 1755 published *Mémoires de Madame de Maintenon*, in 6 vols., which caused him to be imprisoned in the Bastille. Next must be noted *Madame de Maintenon peinte par elle même*, by Madame Suard, 1810; *Histoire de Madame de Maintenon*, by Lafont d'Aussonne, 1814; *Lettres inédites de Madame de Maintenon et la princesse des Ursins*, 1826, reviewed by Sainte-Beuve, *Causeries du Lundi*, vol. v.; and *Histoire de Madame de Maintenon*, by the Duc de Noailles, 1848-58. All materials for her life have, however, been superseded by Théophile Lavallée's *Histoire de St Cyr*, reviewed in *Causeries du Lundi*, vol. viii., and by his edition of her *Lettres historiques et édifiantes*, &c., in 7 vols., and of her *Correspondance Générale*, in 4 vols., which latter must, however, be read with the knowledge of many forged letters, noticed in P. Grimblot's *Faux Autographes de Madame de Maintenon*. Saint-Simon's fine account of the court in her day and of her career is contained in the twelfth volume of Chéruel and Regnier's edition of his *Mémoires*. (H. M. S.)

MAINZ, or MENTZ (in French, MAYENCE), the largest town in the grand-duchy of Hesse-Darmstadt, one of the strongest fortresses in Germany, and formerly the seat of an archbishop and elector, is situated on a rising ground on the left bank of the Rhine, nearly opposite the influx of the Main. The fortifications, which consist of three *enceintes* with a series of outlying forts, embrace the small town of Castel on the opposite bank, and have recently been widened so as to admit of a large extension of the town. Mainz is connected with Castel by a bridge of boats, and the Rhine is also spanned there by a railway bridge. The interior of the town consists chiefly of narrow and irregular streets, but the oldest part of all, to the west, was almost entirely destroyed by the explosion of a powder-magazine in 1857, and has been rebuilt in a much improved style. There are also several handsome modern streets on the side next the Rhine, which is bordered by a fine quay, upwards of 300 feet in breadth. To the south lies the Neue Anlage, a park laid out on the site of the chateau of Favorite, where the duke of Brunswick signed his famous manifesto to the French people in 1792. The principal object of historical and architectural interest in Mainz is the grand old cathedral, an imposing Romanesque edifice with numerous Gothic additions and details. It was originally erected between 975 and 1009, but has since been repeatedly burned down and rebuilt, and in its present form dates chiefly from the 12th, 13th, and 14th centuries. The largest of its six towers is 300 feet in height. The whole building was restored by order of Napoleon in 1814, and another thorough renovation has been recently in progress. The interior contains the tombs of Boniface, the first archbishop of Mainz, of Frauenlob the minnesinger, and of most of the archiepiscopal electors. Mainz possesses other eight Roman Catholic churches, the most noteworthy of which are those of St Ignatius, with a finely painted ceiling, and St Stephen, built in 1318, and restored after the explosion of 1857. The old electoral palace, erected in 1627–78, now contains valuable collections of Roman and Germanic antiquities, a picture gallery, and a library of 130,000 volumes, including several productions of Gutenberg, Fust, and Schöffer. Among the other principal buildings are the palace of the grand-duke, built in 1731–39 as a lodge of the Teutonic Order, the theatre, the arsenal, the Government house, the commandant's residence, and several fine private houses. A handsome statue of Gutenberg, by Thorwaldsen, was erected at Mainz in 1837,



Plan of Mainz.

1. Cathedral.	5. Theatre.	9. Government House.
2. Palace.	6. Gutenberg's Monument.	10. St Stephen's Church.
3. Courts of Justice.	7. Schiller's Monument.	11. Action Beerhouse.
4. Town-House.	8. Neubrunnen.	12. Eichelstein.

and the town is also embellished with a statue of Schiller and two architectural fountains. Mainz still retains many relics of the Roman period, the most important of which is the Eigelstein, a monument believed to have been erected by the Roman legions in honour of Drusus. It stands within the citadel, which occupies the site of the Roman castrum. A little to the south-west of the town are the remains of a large Roman aqueduct, of which upwards of sixty pillars are still standing. The educational and scientific institutions of Mainz include an episcopal seminary, a gymnasium, a society for literature and art, a musical society, and an antiquarian society, the fine collection of which has been mentioned above. The university, founded in 1477, was suppressed in 1791.

The site of Mainz would seem to mark it out naturally as a great centre of trade, but the illiberal rule of the archbishops and its military importance seriously hampered its commercial and industrial development, and prevented it from rivalling its neighbour Frankfort. It is now, however, the chief emporium of the Rhenish wine traffic, and also carries on an extensive transit trade in grain, timber, flour, and oil. The natural facilities for carriage by water are supplemented by seven railways. The principal manufactures of Mainz are leather goods, furniture, carriages, chemicals, musical instruments, and carpets, for the first two of which it has attained a wide reputation. Mainz is the seat of the administrative and judicial authorities of the province of Rheinhessen, and also of a Roman Catholic bishop. The population in 1880 amounted to 61,322, including a garrison of about 8000 men. Fully two-thirds are Roman Catholics. Castel has about 5000 inhabitants.

Mainz, one of the oldest cities in Germany, was originally a Celtic settlement. Its strategic importance was early recognized by the Romans, and in 13 B.C. Drusus, the son-in-law of Augustus, erected a fortified camp (*castrum*) there, to which a smaller *castellum* (the modern Castel) on the opposite bank was afterwards added. The Celtic name became Latinized as *Maguntiacum* or *Moguntiacum*, and a town, *Maguntia*, gradually arose, which became the capital of Germania Superior. In the "Völkerwanderungen," or migrations of peoples during the gradual dissolution of the Roman empire, Mainz was destroyed on different occasions by the Alemanni, the Vandals, and the Huns (451 A.D.). Christianity seems to have been introduced at an early period, and soon after its recovery from the last of these calamities we find it the seat of a bishop. In the middle of the 8th century, under Boniface, the see became an archbishopric, to which the primacy of Germany was annexed. Charlemagne built a bridge here and granted the town important privileges, and in the following centuries it was the seat of several diets and ecclesiastical councils. In 1254 Mainz was the head and mainspring of the league of Rhenish towns, and had attained to such a pitch of commercial prosperity that it was known as the "Goldene Mainz." Soon after this time it is believed that the population was as numerous as at the present day. In 1462, during the strife between the rival archbishops Diether von Isenburg and Adolph von Nassau, Mainz espoused the cause of the former, but was taken by the latter, who had the support of the emperor, lost its imperial privileges, and was henceforth subject to the archbishops. Many of its citizens were driven into exile, and carried into other lands a knowledge of the art of printing, which had been invented at Mainz by Gutenberg in 1440. In the Thirty Years' War Mainz was occupied by the Swedes and the French. In 1792 it enthusiastically welcomed the principles of the French Revolution, and opened its gates to the Republican troops under General Custine. It was recaptured in the following year, but was ceded to France by the peace of Campo Formio in 1797. In 1814 it was restored to Germany and handed over to the grand-duchy of Hesse, remaining, however, a fortress of the German Confederation, garrisoned in common by Prussian, Austrian, and Hessian troops. Since 1871 it has been a fortress of the German empire.

For further information consult Schaab, *Geschichte der Stadt Mainz*, 1841–44; K. Klein, *Mainz und seine Umgebungen*, 1868; Bockenheimer, *Beiträge zur Geschichte der Stadt Mainz*, 1874, and *Mainz und Umgebungen*, 1880; Werner, *Der Dom von Mainz und seine Denkmäler*, 1827–36. (J. F. M.)

MAISTRE, JOSEPH DE, diplomatist and polemical, writer was born at Chambéry on the 1st April 1754, and died at Turin on the 26th February 1821. The family was an ancient and noble one, enjoying the title of count, and is said to have been of Languedocian extraction. The father of Joseph was president of the senate of Savoy, and held other important offices. Joseph himself, after studying at Turin, received various appointments in the civil service of Savoy, finally becoming a member of the senate. In 1786 he married Françoise de Morand. The invasion and annexation of Savoy by the French Republicans made him an exile. He did not take refuge in that part of the king of Sardinia's domains which was for the time spared; but betook himself to the as yet neutral territory of Lausanne. There, in 1796, he published his first important work (he had previously written certain discourses, pamphlets, letters, &c.), *Considérations sur la France*. In this he developed his views, which were those of a Legitimist, but a Legitimist entirely from the religious and Roman Catholic point of view. The philosophism of the 18th century, as shown in its political views, or rather the second as a consequence of the first, was Joseph de Maistre's life-long object of assault.

After the still further losses which, in the year of the publication of this book, the French Revolution inflicted on Sardinia, Charles Emmanuel summoned Joseph de Maistre to Turin, and he remained there for the brief space during which the king retained a remnant of territory on the mainland. Then he went to the island of Sardinia itself, and held office at Cagliari. In 1802 he was appointed envoy extraordinary and minister plenipotentiary at St Petersburg, and journeyed thither the next year. Although his post was no sinecure, its duties were naturally less engrossing than the official life, with intervals of uneasy exile and travelling, which he had hitherto known, and his literary activity was great. He only published a single treatise, on the *Principe générateur des Constitutions;* but he wrote his best and most famous works, *Du Pape*, *De l'Église Gallicane*, and the *Soirées de St Pétersbourg*, the last of which was never finished. *Du Pape*, which the second-named book completes, is a treatise in regular form, dealing with the relations of the sovereign pontiff to the church, to temporal sovereigns, to civilization generally, and to schismatics, especially Anglicans and the Greek Church. It is written from the highest possible standpoint of papal absolutism. The *Soirées de St Pétersbourg*, so far as it is anything (for the arrangement is somewhat desultory), is a kind of *théodicée*, dealing with the fortunes of virtue and vice in this world. It contains two of De Maistre's most famous pieces, his panegyric on the executioner as the foundation of social order, and his acrimonious, and in part unfair, but also in part very damaging, attack on Locke. The *Du Pape* is dated May 1817; on the *Soirées* the author was still engaged at his death. Besides these works he wrote an examination of the philosophy of Bacon, some letters on the Inquisition (an institution which, as may be guessed from the remarks just noticed about the executioner, was no stumbling-block to him), and, earlier than any of these, a translation of Plutarch's "Essay on the Delay of Divine Justice," with somewhat copious notes. After 1815 he returned to Savoy, and was appointed to high office, while his *Du Pape* made a great sensation. But the world to which he had returned was not altogether in accordance with his desires. He had domestic troubles; and chagrin of one sort and another is said to have had not a little to do with his death by paralysis at no very advanced age. Most of the works mentioned were not published till after his death, and it was not till 1851 that a collection of *Lettres et Opuscules* appeared, while even since that time fresh matter has been published.

Joseph de Maistre was one of the most powerful, and by far the ablest, of the leaders of the Neo-Catholic and anti-revolutionary movement. The most remarkable thing about his standpoint is that, layman as he was, it was entirely ecclesiastical. Unlike his contemporary Bonald, Joseph de Maistre regarded the temporal monarchy as an institution of altogether inferior importance to the spiritual primacy of the pope. He was by no means a political absolutist, except in so far as he regarded obedience as the first of political virtues, and he seldom loses an opportunity of stipulating for a tempered monarchy. But the pope's power is not to be tempered at all, either by councils or by the temporal power or by national churches, least of all by private judgment. The peculiarity of Joseph de Maistre is that he supports his conclusions, or if it be preferred his paradoxes, by the hardest and heaviest argument. Although a great master of rhetoric, he never makes rhetoric do duty for logic. Every now and then it is possible to detect fallacies in him, but for the most part he has succeeded in carrying matters back to those fundamental differences of opinion which hardly admit of argument, and on which men take sides in consequence chiefly of natural bent, and of predilection for one state of things rather than for another. The absolute necessity of order may be said to have been the first principle of this thinker. He could not conceive such order without a single visible authority, reference to which should settle all dispute. He saw that there could be no such temporal head, and in the pope he thought that he saw a spiritual substitute. The anarchic tendencies of the revolution in politics and religion were what offended him. It ought to be added that he was profoundly and accurately learned in history and philosophy, and that the superficial blunders of the 18th century *philosophes* irritated him as much as their doctrines. To Voltaire in particular he shows no mercy.

A good and complete edition of De Maistre has yet to appear. Of the two works named as his masterpieces, *Du Pape* is to be found in the *Bibliothèque Charpentier*, and the *Soirées de St Pétersbourg* is printed in two volumes, the fifteenth edition, so-called, bearing date Lyons, 1878. (G. SA.)

MAISTRE, Xavier de, the younger brother of Joseph, was born at Chambéry in October 1763, and died at St Petersburg on the 12th June 1852. He served when young in the Piedmontese army, and wrote his *Voyage autour de ma Chambre* when he was in garrison at Turin. This, a delightful fantasy piece which may have owed something to the example of Sterne in its conception, but which is quite original in execution, he showed to his brother Joseph, and on his approval it was published at Turin in 1794. Xavier, however, shared the politics and the loyalty of his brother, and the annexation of Savoy, followed as it was at no long date by the extinction of Piedmontese independence, made him quit his country. He served in the victorious Austro-Russian campaign in which Suwaroff performed such wonders, and accompanied the marshal to Russia. For a time he was in very reduced circumstances, and is said to have supported himself by painting. But on his brother's arrival in St Petersburg he was introduced to the minister of marine. He was appointed to several posts in the capital, but also saw active service, was wounded in the Caucasus, and attained the rank of major-general. He married a Russian lady and established himself in his adopted country, even after the overthrow of Napoleon, and the consequent restoration of the Piedmontese dynasty. For a time, however, he lived at Naples, but he returned to St Petersburg and died there. He was only once at Paris (in 1839), when Sainte-Beuve, who has left some pleasant reminiscences of him, met him. Besides the *Voyage* already mentioned, Xavier de Maistre's works (all of which are of very modest dimensions) are *Le Lépreux de la Cité d'Aoste*, a touching little story of human misfortune, *Les Prisonniers du Caucase*, a powerful sketch of Russian character, *La Jeune Sibérienne*, and the *Expédition Nocturne*, a sequel to the *Voyage autour de ma Chambre.* But his *Voyage* is, with the *Lépreux*, his title to fame. Both have a certain resemblance to Sterne, the first in its quaintness and desultory arrangement, the second in its sentiment. Xavier de Maistre is, however, much less artificial than his forerunner, especially in his pathos, and he is also much better bred. His style is of remarkable ease and purity. The works of Xavier de Maistre, with the exception of some brief chemical tractates, are usually printed in a single volume, which figures in the collections of Charpentier, Garnier, &c.

MAITLAND, a town of Australia, in New South Wales, 93 miles north of Sydney, in the valley of Hunter river, and communicating with Newcastle and Port Hunter both by steamboat and railway. It consists of two distinct municipalities—East Maitland, incorporated in 1862, and West Maitland, in 1863. The former, which is the seat of a Roman Catholic bishop, contains a court-house, a large prison, and a mechanics' institute; the latter a court-house, an excellent hospital (Campbell's Hill), a school of arts with a considerable library, a benevolent asylum, a theatre, and a Dominican nunnery. The district is a rich agricultural country, growing maize, barley, oats, wheat, tobacco, grapes, and oranges; coal and shale are regularly worked near the town; and a good trade is carried on with the interior townships. The inhabitants number 7881, East Maitland having 2500 and West Maitland 5381.

MAITLAND, John (1614–1682), earl and afterwards duke of Lauderdale in the peerage of Scotland, was a great-grandson of Sir Richard Maitland (*q.v.*). In early life a Presbyterian, he attended the Westminster Assembly in 1643 as an elder of the Church of Scotland; and he was a party to the surrender of Charles I. to the English army in 1645. Soon afterwards, changing his politics, he became a zealous supporter of the royal cause, and promoter of the Engagement for raising forces for the king's rescue. He was taken prisoner at the battle of Worcester; and, on being set at liberty in 1660, he repaired to the Hague and accompanied Charles II. to Scotland. From 1663 he was virtually ruler of Scotland,—at first moderate in his counsels, but afterwards severe in his measures against the Covenanters. In 1672 he was made duke of Lauderdale and a Knight of the Garter; and he had also an English peerage conferred on him (with the title of earl of Guildford) in 1674. One of the administrative council known as the "Cabal," he eventually fell into disgrace, and died in 1682. His dukedom and English honours expired with him; the earldom of Lauderdale passed to his brother Charles, and is still in possession of his descendants. The voluminous correspondence of Lauderdale, which is still extant, shows that, in addition to a remarkable power over men of all classes, great watchfulness and resolution, and very clear ideas of what was needed to keep Scotland peaceful and in a state of usefulness for further ends, he was possessed of no slight learning.

MAITLAND, Sir Richard (1496–1586), an early Scottish lawyer and poet, was born in 1496. His father, William Maitland of Lethington and Thirlstane, fell at Flodden; his mother was a daughter of George, Lord Seton. He studied law at the university of St Andrews, and afterwards in France. He was in 1552 one of the commissioners to settle matters with the English about the debatable lands on the borders, and about that time had the honour of knighthood conferred upon him. In 1554 he was made an extraordinary lord of session. About 1561 he seems to have lost his sight, but this did not render him incapable of attending to public business, as he was the same year admitted an ordinary lord of session by the title of Lethington, and in 1562 was nominated lord privy seal. He resigned this latter office in 1567, in favour of John, prior of Coldingham, his second son, but he sat on the bench till he attained his eighty-eighth year. He was an amiable and accomplished man, and died in 1586, aged ninety, after having been employed in public offices for upwards of seventy years. His eldest son, William, forms the subject of next article. His second son, John, was a lord of session, and was made a lord of parliament in 1590, by the title of Lord Maitland of Thirlstane, in which he was succeeded by his son John, also for some time a lord of session, who was created earl of Lauderdale in 1624. The latter was the father of John Maitland, duke of Lauderdale, noticed above. One of Sir Richard's daughters, Mary, assisted her father in his studies, and also wrote verses.

The poems of Sir Richard Maitland, none of them lengthy, are somewhat satirical, and are principally directed against the abuses of his time. He must, however, be regarded as the industrious collector and preserver of many pieces of ancient Scottish poetry. These were copied into two large volumes, one in folio and another in quarto, the former written by himself, and the latter by his daughter. After being in the possession of his descendant the duke of Lauderdale, these volumes were purchased at the sale of the duke's library by the celebrated Samuel Pepys, who was one of the first collectors of rare books in England. They have since been preserved in the Pepysian Library, Magdalene College, Cambridge. They lay there unnoticed for many years till Bishop Percy published one of the poems in his *Reliques of English Poetry*. Several of the pieces were then transcribed by John Pinkerton, who afterwards published them under the title of *Ancient Scottish Poems, comprising Pieces written from about* 1420 *till* 1586, *with Notes and a Glossary*, 2 vols. 8vo, London, 1786. Sir Richard left in manuscript a history of the family of Seton, and a volume of legal decisions collected by him between the years 1550 and 1565. Both are preserved in the Advocates' Library, Edinburgh, and the latter work is still unpublished. The *Poems* of Sir Richard Maitland were printed in 1830 by the Maitland Club, a literary society, founded in Glasgow in 1828, which took its name from him. The MS. used for the purpose was one preserved in the Drummond collection in the library of the university of Edinburgh. It seems to have been written shortly before the year 1627, when it was presented by Drummond to the library. In 1829 there was also printed for the club *The History of the House of Seytoun* to the year 1559, with a continuation to 1687 by Alexander, Viscount Kingston.

MAITLAND, William (*c.* 1525–1573), best known in Scottish history by the name of his father's estate of Lethington, near Haddington, where he resided, was the eldest son of Sir Richard Maitland, noticed above. Born about 1525, and partly educated in France, he was at an early age initiated into public life. He was made secretary of state by Mary of Guise in 1558; but the favour with which he regarded the views of the reforming party soon exposed him to the queen mother's resentment. He became one of the "lords of the congregation," and was also one of the Scottish commissioners who negotiated with Queen Elizabeth regarding the terms on which she would agree to aid the Reformers. Soon after Mary's arrival in Scotland, he was employed in two embassies to England, and was made first an extraordinary and then an ordinary lord of session. He had a controversy with Knox, whom he accused in the General Assembly of 1564 of teaching seditious doctrine. He went again to England as ambassador to notify the queen's marriage to Darnley, and was implicated both in the conspiracy against Rizzio and in the Kirk of Field tragedy, though he was also a member of the secret council at which the depositions of Darnley's murderers were taken, and signed the act of council accusing Mary of being the author of the crime. He fought against the queen at Langside, but at the conference at York identified himself in a measure with her interests. At the instance of the regent Murray he was in 1569 arrested as a participant in the king's murder, and would have been brought to trial but for a ruse of Kirkcaldy of Grange, who, as commander of Edinburgh Castle, conveyed him thither as a prisoner. The two principal representatives of Mary's cause, Lethington and Grange, who may be described as the forlorn hope of the captive queen, held the castle of Edinburgh for some time against the regent Morton and an English force; and, when surrender became a matter of necessity, they made their submission, not to the regent, but to the English queen. Kirkcaldy was executed; but Maitland died in prison, it was generally believed of poison administered by his own hand, on 9th June 1573. "Secretary Maitland" was a man of great learning and power of repartee, wanting in integrity, but skilled in intrigue, and reputed the most accomplished and most versatile statesmen that his country has produced; in the opinion of his contemporaries his capacities were too great for the narrow sphere of Scottish politics.

MAITTAIRE, Michel (1668–1747), bibliographer and editor, was a native of France, and was born in 1668. On the revocation of the edict of Nantes his parents, who were Protestants, removed to England, where he was educated at Westminster and at Christ Church, Oxford, graduating in 1696. From 1695 to 1699 he taught in Westminster School, but afterwards devoted himself exclusively to private teaching and editorial work. He died on August 4, 1747.

Maittaire was a great lover of books, but no critic; and his numerous editions take rank only as compilations. His works include *De Græcæ Linguæ Dialectis*, 1706; *Stephanorum Historia, vitas ipsorum et libros complectens*, 1713; *Historia Typographorum* *aliquot Parisiensium, vitas et libros complectens*, 1717; *Annales Typographici*, 9 vols. 4to, The Hague, Amsterdam, and London, 1719-41; *Marmora Oxoniensia*, 1732; editions of a large number of Latin authors (Lucretius, Phædrus, Sallust, Terence, &c.), as well as an edition of Anacreon (1725), and *Miscellanea Græcorum aliquot scriptorum Carmina*, 1722.

MAIZE, or INDIAN CORN, *Zea Mays*, L., from ζεά or ζειά, which appears to have been "spelt" (*Triticum spelta*, L.), according to the description of Theophrastus, is of the tribe *Phalarideæ* of the order *Gramineæ* or grasses. It is unknown in the native state, but is most probably indigenous to tropical America (Endlicher, *Gen. Pl.*, No. 742). Small grains of an unknown variety have been found in the ancient tombs of Peru. Bonafous, however (*Histoire naturelle du Maïs*), quotes authorities (Bock, 1532, Ruel and Fuchs) as believing that it came from Asia, and maize was said by Santa Rosa de Viterbo to have been brought by the Arabs into Spain in the 13th century. A drawing of maize is also given by Bonafous from a Chinese work on natural history, *Li-chi-tchin*, dated 1562, a little over sixty years after the discovery of the New World. It is not figured on Egyptian monuments, nor was any mention made of it by Eastern travellers in Africa or Asia prior to the 16th century. On the authority, however, of Mr J. Crawford, who resided for nine years in Java, Bonafous says it had been cultivated from a very ancient period in the Asiatic islands under the equator, and that it was received thence into China, and so passed westwards into India and Turkey, hence its name of "Turkey corn," under which title Gerard in 1597 figured and described seven kinds, as well as one called "Corne of Asia." Both Gerard and Bonafons think that it first came from the East, but that on the discovery of America it was reintroduced into Europe from that country. The former observes:—"These kinds of graine were first brought into Spaine, and then into other provinces of Europe out of Asia, which is in the Turkes Dominions; as also out of America and the Ilands adioyning from the East and West Indies and Virginia, &c." Humboldt and others, however, do not hesitate to say that it originated solely in America. It had been long and extensively cultivated there at the period of the discovery of the New World. The plant is monœcious, producing the staminate (male) flowers in a large feathery panicle at

FIG. 1.—Male.

FIG. 2.—Male.

the summit, and the (female) dense spikes of flowers, or "cobs," in the axils of the leaves below, the long pink styles hanging out like a silken tassel. They are invested by the sheaths of leaves, much used in packing oranges in South Europe, and the more delicate ones for cigarettes in South America. The accompanying figures are after Nees von Esenbeck, *Gen. Pl. Fl. Germ.* Fig. 1 shows a branch of the terminal male inflorescence. Fig. 2 is a single spikelet of the same, containing two florets, with the three stamens of one only protruded. Fig. 3 is a

FIG. 3.—Female.

spike of the female inflorescence, protected by the sheaths of leaves,—the blades being also present. Usually the sheaths terminate in a point, the blades being arrested. Fig. 4 is a spikelet of the female inflorescence, consisting of two outer glumes, the lower one ciliated, which enclose two florets,—one barren (sometimes fertile), consisting of a flowering glume and pale only, and the other fertile, containing the pistil with elongated style. The mass of styles from the whole spike is pendulous from the summit of the sheaths, as in fig. 3. Fig. 5 shows the fruit or grain.

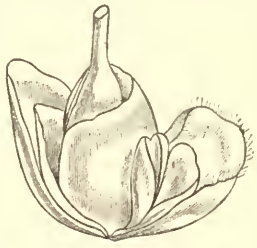


FIG. 4.—Female.

More than three hundred varieties are known, which differ more among themselves than those of any other cereal. Some come to maturity in two months, others require seven months; some are as many feet high as others are inches; some have kernels eleven times larger than others. They vary similarly in shape and size of ears, colour of the grain, which may be white,

FIG. 5.—Grain.

yellow, purple, striped, &c., and also in physical characters and chemical composition,—in short, in all those characters in which the different species of a genus differ among themselves. The varieties grown most abundantly in the United States may be roughly grouped into four great classes. The "Flint" varieties are most common east of Lake Erie and north of Maryland, and the "Dent" varieties are the common ones west and south of these points. The "Horsetooth" varieties are grown extensively only in the south, and there they are grown along with the dent. These three classes pass into each other by every gradation, and the grain from all is similar in chemical composition. The "Sweet" varieties are not grown for the ripe grain, but for boiling corn, and that the stalks may serve as "corn fodder." "Green corn" was an important food with the native Indians. Many of the tribes celebrated its season with religious ceremonies and festivals. In the large cities of America "green corn" is a table luxury, but in the smaller towns and country districts it is an important article of food. Chemical analysis, as well as common experience, shows that this is a very nutritious article of food, being richer in albuminoids than any other cereals when ripe (calculated in the dry weight). It is capable of being grown in the tropics from the level of the sea to a height equal that of the Pyrenees, and in the south and middle of Europe, but it cannot be grown in England with any chance of profit, except perhaps as fodder. Frost kills the plant in all its stages and all its varieties; and the crop does not flourish well if the nights are cool, no matter how favourable the other conditions. Consequently it is the first crop to disappear as one ascends into the mountain regions, and comparatively little is grown west of the great plains of North America. In Brittany, where it scarcely ripens the grain, it furnishes a strong crop in the autumn upon sandy soil where clover and lucern will yield but a poor produce. It prefers a deep, rich, warm, dry, and mellow soil, and hence the rich bottoms and fertile prairies of the Mississippi basin constitute the region of its greatest production. Illinois leads in total amount, producing in 1879 nearly 326 millions of bushels, or 105 bushels per head of population. The region of chief production in the United States may be described as a rude ellipse 900 miles long from east to west by 600 miles wide, with Springfield (the capital of Illinois) as its centre. This region produces annually from 1000 to 1400 millions of bushels, or nearly three-fourths of the total crop of the country.

As an article of food, maize is one of the most extensively used grains in the world. Although rich in nitrogenous matter and fat, it does not make good bread. A mixture of rye and corn meal, however, makes an excellent coarse bread, formerly much used in the Atlantic States, and a similar bread is now the chief coarse bread of Portugal and some parts of Spain. When the harder "flint" varieties are roasted, the grains "pop," the skin bursts, and the white interior swells up, emitting a pleasant odour. It is either baked into cakes called *tortilla* by the Indians of Yucatan, or made into a kind of porridge, as in Ireland. When deprived of the gluten it constitutes oswego, maizena, or corn flour (see Letheby's *Lectures on Food*, p. 19; and *Foods*, by E. Smith, 156). Maize contains more oil than any other cereal, ranging from 3·5 to 9·5 per cent. in the commercial grain. This is one of the factors in its value for fattening purposes. In distilling and some other processes this oil is separated and forms an article of commerce. When maize is sown broadcast or closely planted in drills, the ears may not develop at all, but the stalk is richer in sugar and sweeter, and this is the basis of growing "corn-fodder." The amount of forage that may be produced in this way is enormous; 50,000 to 80,000 ℔ of green fodder are grown per acre, which makes 8000 to 12,000 ℔ as field-cured. Sugar and molasses have from time to time been manufactured from the corn stalks, but at present this manufacture is not commercially successful.

In the treeless western prairies maize is often grown for fuel, as in many places fuel can be procured so cheaply in no other way. A hundred bushels of ears is equal in heating power to a cord of the best hard wood, and may be grown for a price less than a cord of hard wood brings in the large cities. The use of corn in the industries, as the raw material for the manufacture of alcohol, whisky, starch, glucose, oil, and various food products, increases year by year, with the increase of facilities for production and the increasing applications of chemistry to the arts.

For fuller details see a paper by Professor W. H. Brewer, Yale Col., Conn., from which some of the above details are taken, as well as the *Special Report on Cereal Products*, Washington, 1882, and the 38th *Annual Report* of the New York State Agricultural Society, 1878. (G. H.)

MAJLÁTH, JÁNOS or JOHN, COUNT (1786-1855), Hungarian historian and poet, was born at Pest on the 5th of October 1786. First educated at home, he subsequently studied philosophy at Eger (Erlau) and law at Györ (Raab), his father, Count Joseph Majláth, an Austrian minister of state, eventually obtaining for him an appointment in the public service. The weakness of his eyesight having rendered it necessary for him a few years later to resign the Government secretaryship to which he had been promoted, Majláth turned his attention to literature, especially devoting himself to historical research, and the translation into German of Magyar folk-tales, and of selections from the works of the best of his country's native poets. Moreover, as an original lyrical writer, and as an editor and adapter of old German poems, Majláth showed considerable talent; and, in general, his activity as an author was remarkable, his various literary productions in German and Hungarian amounting together to more than sixty volumes. During the greater part of his life he resided either at Pest or Vienna, but a few years before his death he removed to Munich, where he fell into a state of destitution and extreme despondency. Seized at last by a terrible infatuation, he and his daughter Henriette, who had long been his constant companion and amanuensis, determined to put an end to their dependent position by drowning themselves in the Lake of Starnberg, a few miles south-west of Munich. This fatal resolution was carried into effect on the 3d of January 1855.

It is generally admitted that in his great historical treatises Count Majláth has failed in a critical discrimination between the merely mythical or poetical and the true historical element,—the former not unfrequently being allowed to unduly influence and obscure the latter. The political tendency of his writings, moreover, has been objected to, especially by his own countrymen, as being too conservative and over-favourable to Austria. Of his historical works the most important are the *Geschichte der Magyaren* (Vienna, 1828-31, 5 vols.; 2d ed., Ratisbon, 1852-53), and his *Geschichte des österreichischen Kaiserstaats* (Hamburg, 1834-50, 5 vols.). Specially noteworthy among his metrical translations from the Hungarian are the *Magyarische Gedichte* (Stuttgart and Tübingen, 1825); and *Himfy's auserlesene Liebeslieder* (Pest, 1829; 2d. ed., 1831; see KISFALUDY, SÁNDOR). A valuable contribution to folk-lore appeared in the *Magyarische Sagen, Märchen, und Erzählungen* (Brünn, 1825; 2d ed., Stuttgart and Tübingen, 1837, 2 vols.).

MAJOLICA. See POTTERY.

MAJOR, or MAIR, JOHN (*c.* 1470-1550), a theological and historical writer, was born at the village of Cleghorn, near North Berwick, Scotland, about the year 1470. After a short period spent at Cambridge, he entered the university of Paris in 1493, studying successively at the colleges of St Barbe and Montaigu, and graduating as master of arts in 1496. Promoted to the doctorate in 1505, he lectured in philosophy at Montaigu College for some time, and had several distinguished auditors. From 1518 to 1522 he held the office of principal in the university of Glasgow, John Knox being among the number of those who attended his lectures there; he was afterwards removed to St Andrews, where George Buchanan was one of his pupils in 1525. He appears again to have returned to France for some time, but we find him once more at St Andrews in 1530, where he was head of St Salvator's College from 1533 until his death, which took place about 1550.

He wrote *In Libros Sententiarum commentarius*, Paris, 1509-19; *De Historia Gentis Scotorum libri sex*, Paris, 1521; *Commentarius in Physica Aristotelis*, Paris, 1526; and *In Quatuor Evangelia Expositiones Luculentæ*, Paris, 1529. By Knox he is spoken of as having been in his day an oracle in religious matters; and it has been conjectured that both the great Reformer and Buchanan were largely indebted to him for their advanced opinions on political and ecclesiastical questions. His writings do not now, however, possess any interest or importance apart from this circumstance; and even Buchanan has allowed himself to speak of his old preceptor as "Joannes solo cognomine major."

MAJORCA. See BALEARIC ISLANDS.

MAJORIANUS, JULIUS VALERIUS, emperor of the West from 457 to 461, was the successor of Avitus. He had been a distinguished soldier under Aetius, and also after the death of that general; for his election to the purple he was indebted to the powerful Count Ricimer, patrician of Rome. To put a stop to the harassing incursions of the Vandals he, in 458, resolved to lead an expedition against Genseric himself; for this purpose he got together a large army, composed chiefly of barbarians, and, passing the Alps in November 458, made Lyons, and afterwards Arles, his headquarters until the preparations for the invasion of Africa had been completed. Having during his stay in Gaul succeeded in pacifying Theodoric, he, in the beginning of 460, crossed the Pyrenees for the purpose of joining his armament at Carthagena. Genseric, however, after all overtures for peace had been rejected, succeeded through the treachery of certain officers in surprising the Roman fleet, most of the ships being either taken or destroyed. Majorianus returned at once to Gaul, where he made peace with Genseric in the following year. Soon afterwards, while at Tortona in Lombardy, he was surrounded by partisans of Ricimer, and compelled to abdicate (August 2, 461). He died, most probably by violence, five days afterwards, and was succeeded on the throne by Severus. He was the author of several laws, which, "remarkable for an original cast of thought and expression, faithfully represent the character of a sovereign who loved his people, who sympathized in their distress, who had studied the causes of the decline of the empire, and who was capable of applying (as far as such reformation was practicable) judicious and effectual remedies to the public disorders" (Gibbon, *Decline and Fall*, chap. 39).

MAKALLÁ, or MACULLA, a port on the south coast of Arabia, in 14° 31′ N. lat. and 49° 13′ E. long. The town, which appears to be of no great antiquity, is described by Wellsted as built on a low projecting point, with many lofty and substantial houses, and a suburb of huts, chiefly inhabited by slaves, Somalis, and Arab sailors, on the slopes leading up to a lofty chalk-hill (Jebel el-Kára) which overhangs the town. The Arab inhabitants are of the Beni 'Isá tribe. The Somali traders do not settle permanently in Makallâ, but they form an important element in the population. There are also Indian residents (Banians). The harbour is good, and the town, which may be regarded as the port of Hadramaut, rose during the decline of Aden to the rank of the chief emporium between India and the Somali coast. It still exports, among other productions of Hadramaut, tobacco, mother-of-pearl, and incense to Jeddah and shark fins to India, but has lately declined in the general transformation of the character of the Eastern trade. According to the latest Arabic accounts (see Badger in the *Academy*, March 4, 1882), the town contains about a thousand houses. Makallâ is governed by a prince or nakîb who is esteemed one of the chief minor potentates of that coast. The present prince Salah el-Kesádí has made himself quite independent of the surrounding Bedouins, and is even reported to have made conquests in the interior.

MAKKARÍ. Abu'l-'Abbâs Ahmed ibn Mohammed el-Makkarí, Arabic historian, was born at Tilimsán (Tlemcen) in Algeria, towards the close of the 16th century, and studied at Fez, where he remained occupied with literary pursuits till, for some unknown cause, he was driven into exile and, after visiting Mecca, settled in Cairo. In 1628 he came to Damascus after a pilgrimage to Jerusalem. Warmly received by the scholars there, he delivered lectures on the traditions of the Prophet, and in the evenings entertained his friends with stories of the glories of Moslem Spain, a subject of interest to all Arabs, and especially to those of Syria. His friends made him promise to reduce his narrative to writing, and on returning to Cairo he devoted three years to this task. He had divorced his wife and made other preparations to settle definitively in Damascus when death overtook him in 1631.

Makkary's great work, *The Breath of Perfume from the Branch of Green Andalusia, and Memorials of its Vizier Lisán el-Dín ibn el Khatíb*, consists, as the name indicates, of two parts. The first is a general history and description of Mohammedan Spain, mainly in the form of analecta from a number of authors, with many verses interspersed. This part, which is of great historical value, was published in an (incomplete) English version by P. de Gayangos (London, 1840-43) and in Arabic by Wright, Krehl, Dozy, and Dugat (*Analectes sur l'histoire et la littérature des Arabes d'Espagne*, Leyden, 1855, 1856, 1858, 1861). An edition in four volumes, published at Cairo (1863), contains also (in vols. iii. and iv.) the life of the famous statesman and author Lisán el-Dín, vizier of Granada (*ob.* 1374). Further references to literature are given by Pertsch, *Arab. Hdschr. zu Gotha*, No. 1697. Among other works of Makkarí a commentary on the *prolegomena* of Ibn Khaldún is mentioned (H. Kh., 8043).

MAKÓ, a corporate town of Hungary, and capital of the trans-Tisian county of Csanád, is situated near the right bank of the Maros, about 15 miles east-south-east of Szeged, in 46° 13′ N. lat., 20° 28′ E. long. The town consists of the three wards of Buják, Szent-Lörincz (Saint-Lawrence), and Ujváros (New Town), and has, besides the usual official buildings connected with the administration of a county, Roman and Greek Catholic, Lutheran, and Calvinist churches, and a synagogue; also an elegant (Calvinist) gymnasium, the bishop of Csanád's palace and gardens, royal and circuit courts of law, barracks, tax and salt offices, a timber trading agency, a manufactory of agricultural implements, and numerous mills. The surrounding country is fertile. The communal lands are extensive, and afford excellent pasturage for horses and sheep, as also for large herds of horned cattle, for the size and quality of which Makó has obtained a high repute. An abundance of fish and aquatic fowl is supplied by the Maros, the water of which river is used also for drinking purposes, that from the wells being unpalatable. The town is protected from inundations of the Maros by a powerful dike, but the commune nevertheless sometimes suffers during the spring floods (see HUNGARY, vol. xii. p. 363). The population, which is chiefly agricultural, amounted in 1880 to 30,077,[1] mostly Magyars by nationality. A great part of the business of the town is in the hands of Jews.

MAKRÍZÍ. Takí el-Dín Ahmed ibn 'Alí el Makrízí (1364[2]-1441), one of the most meritorious of Arabic historians and archæologists, was descended on both sides from families of scholarly distinction. His hereditary surname of Makrízí, by which he is usually known, was derived from Makríz, a suburb of Ba'lbek, with which town his paternal ancestors had been connected. Takí el-Dín himself was born in Cairo, and spent his life mainly in Egypt, where he was brought up as clerk in a Government office, and at a later date he became *Mohtesib* (a sort of police officer in charge of the markets) for Cairo and northern Egypt, and afterwards inspector of the Kalánesí foundation at Damascus. He declined the post of cadi in the latter town. He was, however, mainly engrossed in scholarly pursuits as a traditionist and a jurisconsult, but especially as an indefatigable student of history. He is reproached by his contemporaries for a somewhat inordinate zeal in theological controversy, but otherwise passed a quiet and uneventful life. Makrízí's literary activity was very great; he was not a man of original power, and his books are largely compilations, in which he is not always scrupulous in naming the sources to which he is indebted, but his learning was vast, his observation accurate, and his

[1] Roman Catholics, 11,178; Greek Catholics, 1456; Greek Eastern Church, 50; Calvinists, 15,492; Lutherans, 445; Jews, 1452; Unitarians, 4.

[2] The year of his birth is variously given as 760, 766, 769 A.H.; but 766 A.H. (1364 A.D.) is the date best authenticated.

judgment sagacious. His most important work is the historical and topographical description of Egypt (*El-Mawá'iẓ wa'l-I'tibár fí dhikr el-Ḥiṭaṭ wa'l-Áthár*), of which an edition in 2 vols. folio has appeared at Búlák (1270 A.H., 1854 A.D.). This is in many respects a monumental work; the elaborate description of mediæval Cairo is of unique interest.[1] It has enjoyed a great reputation, having even been translated into Turkish.

Besides this work Makrízí wrote a variety of other books bearing on Egypt. The unfinished *Mukaffá* is a vast alphabetical cyclopædia of Egyptian biography; three volumes of the author's autograph are at Leyden (DCCCXX of the printed catalogue), and one is at Paris. He also wrote three works on the history of Egypt under the Moslems. An imperfect copy of the second in the author's autograph, containing the history of the Fatimites, is at Gotha (Pertsch, No. 1652; Kosegarten, *Chrest.*, p. xvii.), while the third (history of the Ayyúbite and Mameluke sovereigns) has been in great part translated by Quatremère (*Histoire des Sultans Mamlouks de l'Egypte*, 2 vols., 1837–45). Of a biographical dictionary of Makrízí's contemporaries one autograph volume is preserved at Gotha (No. 1771). A number of minor works of our author are known in Europe in MS., and several have been published, viz., on the *Moslems in Abyssinia*, by Rink, 1797; on *Mohammedan Coinage*, by Tychsen, 1797, and French translation by De Sacy, 1797; on *Arab Weights and Measures*, by Tychsen, 1800; on the *Arabic Tribes that Migrated to Egypt*, by Wuestenfeld, 1847; *History of Hadramaut*, by Noskowy, 1866. Of a great work on the earliest history of the Arabs part at least is still known in Egypt.

For further details as to Makrízí and his writings see the contemporary biographies published by De Sacy (*Chrest. Arabe*) and Hamaker (*Spec. Cat. Cod. Lugd. Bat.*), and the introduction to Quatremère's work already named.

MALABAR, a district in the Madras presidency, India, between 10° 15′ and 12° 18′ N. lat., and 75° 14′ and 76° 52′ E. long., is bounded on the N. by South Kánara, on the E. by Coorg, the Nílgiri hills, and Coimbatore district, on the S. by Cochin and Travancore states, and on the W. by the Arabian Sea. The extreme length is 145 miles, while the breadth varies from 25 miles in the north to 70 miles in the south; the area is 5763 square miles. Malabar is singularly diversified in its configuration; from the eastward, the great range of the Western Gháts, only interrupted by the Palghát gap, looks down on a country broken by long spurs, extensive ravines, dense forests, and tangled jungle. To the westward, gentler slopes and downs, and gradually widening valleys closely cultivated, succeed the forest uplands, till, nearer the seaboard, the low laterite table-lands shelve into rice plains and backwaters fringed with cocoa-nut palms. The coast runs in a south-easterly direction, and forms a few headlands and small bays, with a natural harbour in the south at Cochin. In the south there is considerable extent of table-land. The mountains of the Western Gháts run almost parallel to the coast, and vary from 3000 to 7000 feet in height. One of the most striking features in the country is the Palghát gap, a complete opening in the Western Gháts some 25 miles across. The chief rivers are the Beliapatam, Kota, Mahe, Beypur, Kadelundi, and Ponáni. One of the most characteristic features of Malabar is an all but continuous chain of lagoons or backwaters lying parallel to the coast, which have been formed by the action of the waves and shore currents in obstructing the waters of the rivers. Of these backwaters the most important are the Kavái and Beliapatam in the north, the Payangadi, Quilandi, and Elatur in the middle, and the Chetwái and Kodungalúr in the south. Connected as they are by artificial canals, they form a cheap and abundant means of transit; and a large local trade is carried on by inland navigation. Fishing and fishcuring is an important industry, the value of the exports of salt fish to Ceylon being about £20,000 per annum. The forests are extensive and of great value, but they are almost entirely private property. The few tracts which are conserved have come into Government hands by escheat or by contract. Wild animals include the elephant, tiger, panther, bison, *sambhar*, spotted deer, hog, Nílgiri ibex, hyæna, and bear. Small game is very abundant.

The census of 1872 returned the population of the district at 2,261,250, namely, Hindus, 1,637,914; Mohammedans, 581,609; Europeans, 2579; Eurasians, 5409; native Christians, 32,280; Jains, 31; and "others," 1428. The Moplás or Mapilas, who form a leading section of the Mohammedans, are the descendants of Malayalam converts to Islám, mainly confined to the coast tract. They are fanatical and bigoted, and their outrages, partly fanatical and partly agrarian, have for long been a distinct feature in Malabar history. Many of these outbreaks have necessitated the use of European troops for their suppression. A few Syrian Christians are found in the south of the district, where they have one church. The Roman Catholics have several churches and villages, the chief occupation of the people being fishing and cultivating vegetables. The existing Roman Catholic mission dates from 1656, having been founded by the Carmelites. The Protestant Basel mission, established in 1839, has founded churches and schools at Calicut, Cannanore, Tellicherri, and Palghát, with branch establishments at Chombla and Todakel. The native Christian population is steadily increasing, mainly through the conversion of low-caste Hindus, who gain in social position by the change. The five largest towns, which are all municipalities, are Calicut, the capital, population 48,338; Palghát, 31,115; Tellicherri, 20,479; Cochin, 13,588; and Cannanore (Kananúr) town and cantonment, 10,265.

In 1880-81 926,359 acres were under cultivation, and 2,869,965 were returned as cultivable. Rice, which occupied 580,281 acres in 1881, forms the principal food crop, but it is also largely imported from neighbouring districts. Other crops are *cholam*, *ragi*, *chama*, gingelly seed, castor-oil seed, gram, coffee, pepper, ginger, arrowroot, cardamoms, chillies, onions, cocoa-nut, areca nut, cinnamon, &c. Cocoa-nut gardens form one of the greatest sources of commercial wealth; the value of the exported produce from Madras in 1880-81 was £141,800, chiefly from Malabar, this being a decrease of 18 per cent. on the year preceding. Pepper and spices yield over a quarter of a million. As a rule, the peasantry are well off and free from debt. The district is not liable to blight, flood, or drought. When, however, the neighbouring districts to the east suffer from scarcity, Malabar, which ordinarily imports grain, is affected by the prevalence of high prices.

The district is fairly supplied with means of communication, and possesses 400 miles of good metalled roads, besides minor cart tracks. The water communication provided by the backwaters and their canals has already been referred to. The Madras railway traverses the southern part of the district for a total distance of 89 miles from Walliar to Beypur. Except cloth weaving, and the making of tiles, bricks, &c., at the mission stations at Calicut and Cannanore, and the weaving of coarse cotton cloths and mats at Palghát, there are no local manufactures worthy of mention. The weaving of calico, which derived its name from Calicut, seems to have altogether died out; while unsuccessful attempts have been made to manufacture canvas at Beypur and silk at Palghát. The principal seats of commerce are Calicut, Cannanore, Tellicherri, Cochin, Palghát, and Badagara. In 1876–77 the value of the imports (which were abnormally increased by the famine demand for rice) amounted to £1,765,200, of which £1,118,000 was for rice; exports £2,466,000, of which £960,000 represented coffee. European banks are represented at Calicut, Cochin, and Tellicherri.

The revenue has largely increased of late years. In 1880–81 the land revenue amounted to £176,062, and the gross revenue to £332,628. The number of pupils connected with the various schools at the same date was 20,971. The principal educational institutions are the provincial school at Calicut, the mission school at Tellicherri, the Palghát high school, and the "Kerala Vidya Sala," recently established by the zamorin, for the instruction of the young noblemen of his family and of other influential persons in the district. Nearly one hundred schools are exclusively confined to Moplás. There are several printing presses at Calicut and Cochin, and at the latter port are published two English and two Malayalam newspapers. The climate of the district is, on the whole, healthy; the rainfall is heavy, averaging 120 inches a year, of which about 80 inches fall in June, July, and August. The temperature varies from 60° in December to about 92° in the hot weather in May. The principal diseases are small-pox, dysentery, and fever.

MALACCA. The town of Malacca lies on the south-west coast of the Malay Peninsula, in 2° 14′ N. lat. and

[1] Various extracts have been published in Europe, *e.g.*, the *History of the Copts*, in Arabic and German, by Wuestenfeld (Gött., 1845). For other extracts, list of MSS., &c., see Pertsch, *Arab. Handschriften zu Gotha*, No. 1675; and *Cat. Codd. MSS. Or. Mus. Brit.*, p. 156.

102° 12′ E. long. It is situated on a small river bearing its name, which separates it into two parts. That on the right bank is occupied by the old Dutch town, and that on the left by the business quarter, which is connected with the former by a small bridge, and is chiefly inhabited by Chinese and native traders. The view of Malacca from the harbour is picturesque and pleasing to the eye. From Flagstaff Hill on the left—whose slopes are always of a bright emerald green—to St John's Hill on the right, on which stand the ruins of the old "Dutch redoubt,"—hidden in a mass of wild vegetation,—stretches for a distance of about half a mile a row of spacious dwelling houses belonging to European and wealthy Chinese and Arab residents. These houses are roofed with neat red tiles, and have windows opening to a stone verandah facing the sea. Each house is surrounded by a large "compound," laid out with a flower garden in front and a "plantation" or orchard at the back. Adjoining this European quarter lies a large suburb of native and other dwellings almost concealed in a dense forest of beautiful fruit trees. Behind this we see a prominent green hill, formerly used as a fort, and now as a Chinese burial-ground, and beyond this the horizon is hemmed in by a long chain of the Bruong and Rumbow Hills, while far in the extreme east rises the jagged cone of Mount Ophir, blue as sapphire in the distance.

Since the destruction (in 1807) of the old Portuguese fort erected by Albuquerque, the "antiquities" of Malacca are reduced to a mere name. At the foot of Flagstaff Hill, however, are the remains of the massive wall which surrounded the hill, with an arched and carved gateway. On the summit of the hill, where a fine view is had of the harbour and the Water Islands, are the ruins of the first Christian church planted in Malayan territory, and also a portion of the old convent. At the back of this hill to the right may be noted the barracks, hospital, and convict lines, and passing under some fine "ansana" trees—the shady elms of the East—we reach the garden of the old Dutch stadthouse, and then a green square, facing which are the court-house and other Government buildings, and the old Dutch church. All these buildings have sloping roofs covered with small square tiles after the Dutch style of architecture of the 16th century. This is quite a unique example of Dutch domestic architecture in the East, and several of the adjoining streets still bear their Dutch designation, as "Heren Straat," "Jonker Straat," &c. The stadthouse is approached by a fine flight of stone steps, forming a covered way to the upper rooms. These are occupied by the governor of the Straits Settlements and the judge during their annual or biennial visits, and those in the lower story are used as Government offices. From the interesting ruins of the Dutch redoubt on St John's Hill an extensive view may be had of the country running around and to the north and south of Malacca. Its general aspect in the immediate vicinity is that of a flat country covered with luxuriant "dusoons" or plantations of fruit trees, and extensive forests of tall timber; beyond this is an open country, interspersed with extensive plantations of tapioca, which at a distance resemble fields of clover; then follow rice-fields, and marshes or fens, and at the foot of the hills patches of virgin forest, the whole being walled in by a range of blue hills. The climate of Malacca is very healthy, and the thermometer in the shade ranges from 72° to 84° or even 90° Fahr. The population, which is not very large, consists of Malays of the surrounding countries, of Malacca Portuguese (the mixed descendants of early Portuguese settlers), of Chinese proper and a large number born of Malay mothers. There is also a sprinkling of natives of India and of Arabs. The Malacca Portuguese employ themselves as fishermen, servants, and clerks; the rest are chiefly engaged in agricultural and commercial pursuits.

In consequence of its shallow harbour, Malacca has been completely outstripped as a seaport by Singapore and Penang, though it still carries on a brisk trade with the surrounding countries in Malacca canes, stuffed birds of beautiful plumage, poultry, and large quantities of the most luscious fruits. The import and export returns show a large apparent increase in the trade,—the imports in 1880 amounting to $3,817,848 (£812,308), and the exports to $3,634,640, as against an average of $2,505,175 and $2,577,020 respectively for 1869–72; and, though Malacca has been a drag on the revenue of the colony generally, a marked increase is shown in the principal items of revenue, viz., in land rents, tenths in paddy, tapioca, and fruits, royalty on timber, and survey fees. In 1880 the revenue was $182,323, and the expenditure $174,333, while the income and expenditure of the municipality in the same year were $22,428 and $18,899 respectively. The Government is improving the drainage of the country by clearing its natural water course. The municipality has no debts, and the general progress of the settlement during the year ending 1880 must be regarded as satisfactory, with an increase under almost every heading of revenue that bids fair to continue.

See C. A. Cameron, *Our Tropical Possessions in Malayan India*, and *Papers Relating to H. M. Colonial Possessions*, 1879–1881.

MALACHI. According to the title (Mal. i. 1) the last book of the minor prophets contains the word of Jehovah to Israel by the hand of Malachi. The word מַלְאָכִי may either be an adjective, "angelic," or may signify "the angel (messenger) of Jehovah." In either case it seems a strange (though hardly an impossible) name for a man to bear, and from the time of the Septuagint, which translates "by the hand of His messenger," it has often been doubted whether Malachi is the real name of the author, or only an epithet assumed by himself, or attached by the collector to a work which he found anonymous (so Ewald), with reference to iii. 1.[1] A Hebrew tradition given in the Targum of Jonathan, and approved by Jerome, identifies Malachi with Ezra the priest and scribe; but, though this opinion is ingeniously supported by reference to ii. 7, where the priest and custodian of the law is called the messenger of Jehovah of hosts, it is unlikely that Ezra's name would have been lost had he been the real author.[2]

The tradition, however, may at least be taken as implying the perception of a real affinity between the prophet and the great restorer of the law. The religious spirit of Malachi's prophecy is that of the prayers of Ezra and Nehemiah. A strong sense of the unique privileges of the children of Jacob, the objects of electing love (i. 2), the children of the Divine Father (ii. 10), is combined with an equally strong assurance of Jehovah's righteousness amidst the many miseries that pressed on the unhappy inhabitants of Judæa. At an earlier date the prophet Haggai had taught that the people could not expect Jehovah's blessing while the temple lay in ruins. In Malachi's time the temple was built (i. 10) and the priests waited in their office, but still a curse seemed to rest on the nation's labours (iii. 9). To Malachi the reason of this is plain. The "law of Moses" was forgotten (iv. 4 [iii. 22]); let the people return to Jehovah, and He will return to them. It was vain to complain, saying, "Every one that doeth evil is good in the eyes of Jehovah," or "Where is the God of judgment?"—vain to ask "Wherein shall we return?" Obedience to the law is the sure path to blessing (ii 17–iii. 12).

---

[1] Stade (*Z. f. ATliche Wiss.*, 1882, p. 308; comp. 1881, p. 14) thinks that the title in Mal. i. 1 is by the same hand as that in Zech. xii. 1, and that both are copied from Zech. ix. 1, under the misconception that משׂא was to be construed with the following words.

[2] The LXX. rendering of i. 1 gave rise to strange fancies. Jerome and Cyril mention that some supposed the prophet to have been an angel in bodily form; and the *Vitæ Prophetarum* of Pseudo-Epiphanius have a "word-myth" to the effect that his prophecies were regularly confirmed by an angelic apparition. The same book will have it that Malachi was of the tribe of Zebulon, born in a town Sopha or Sophera, had his name from his great beauty, and died young.

It is not easy to say whether the law to which Malachi recalls the people is that which was established by the covenant taken under Ezra, or whether the prophet wrote before that event. It is at least the Deuteronomic law that is most familiar to him, as appears from his use of the name Horeb for the mountain of the law, and the Deuteronomic phrase "statutes and judgments"[1] (iv. 4), from his language as to tithes and offerings (iii. 8, 10, comp. Deut. xii. 11, xxvi. 12),[2] and especially from his conception of the priesthood as resting on a covenant with Levi (ii. 4 *sq.*). The abuses of which he particularly complains are such as were found rampant by Ezra and Nehemiah,—marriage with foreign women (ii. 11, comp. Ezra ix., Neh. xiii. 23 *sq.*, Deut. vii. 3) and failure in payment of sacred dues (iii. 8 *sq.*, comp. Neh. x. 34 *sq.*, xiii. 10 *sq.*, Deut. xxvi. 12 *sq.*). Add to this that the position of the priests had fallen into contempt (ii. 9), and that the oral law is still one of their chief trusts (ii. 6 *sq.*), and we shall be disposed to conclude that, if Malachi's work did not precede the reformation of Ezra, it must have fallen very little later, and before the new order was thoroughly established.[3] The prophecy of Joel shows the new theocracy in much fuller development.

The object of Ezra and Nehemiah was to establish the law by means of the organs of government under warrant from the Great King. Malachi looks for reformation in another direction. He calls the people to repentance, and he enforces the call by proclaiming the approach of Jehovah in judgment against the sorcerers, the adulterers, the false swearers, the oppressors of the poor, the orphan, and the stranger. Then it shall be seen that He is indeed a God of righteous judgment, distinguishing between those that serve Him and those that serve Him not. The Sun of Righteousness shall shine forth on those that fear Jehovah's name; they shall go forth with joy, and tread the wicked under foot. The conception of the day of final decision, when Jehovah shall come suddenly to His temple (iii. 1) and confound those who think the presumptuous godless happy (iii. 15), is taken from earlier prophets, but it receives a special character from an application of a thought based on Isa. xl. 3. The day of Jehovah would be a curse not a blessing if it found the nation in its present state, the priests listlessly performing a fraudulent service (i. 7–ii. 9), the people bound by marriage to heathen women, while the tears of the daughters of Israel, thrust aside to make way for strangers, cover the altar (ii. 11–16), all faith in divine justice gone (ii. 17, iii. 14 *sq.*), sorcery, uncleanness, falsehood, and oppression rampant (iii. 5), the house of God deprived of its dues (iii. 8), and the true fearers of God a little flock gathered together in private exercises of religion (perhaps the germ of the later synagogue) in the midst of a godless nation (iii. 16). That the day of Jehovah is delayed in such a state of things is but a new proof of His unchanging love (iii. 6), which refuses to consume the sons of Jacob. Meantime He is about to send His messenger to prepare His way before Him. The prophet Elijah must reappear to bring back the hearts of fathers and children before the great and terrible day of Jehovah come. Elijah was the advocate of national decision in the great concerns of Israel's religion; and it is such decision, a clear recognition of what the service of Jehovah means, a purging of His professed worshippers from hypocritical and half-hearted service (iii. 3) that Malachi with his intense religious earnestness sees to be the only salvation of the nation. In thus looking to the return of an ancient prophet to do the work for which later prophecy is too weak, Malachi unconsciously signalizes the decay of the order of which he was one of the last representatives; and the somewhat mechanical measure which he applies to the people's sins, as for example when he teaches that if the sacred dues were rightly paid prosperous seasons would at once return (iii. 10), heralds the advent of that system of formal legalism which thought that all religious duty could be reduced to a system of set rules. It was left to a greater Teacher to show that hypocrisy and vain religion might coexist with Pharisaic exactness in the observance of the whole letter of the law. Yet Malachi himself is no mere formalist. To him, as to the Deuteronomic legislation, the forms of legal observance are of value only as the fitting expression of Israel's peculiar sonship and service, and he shows himself a true prophet when he contrasts the worthless ministry of unwilling priests with the pure offering of prayer and praise that rises from all corners of the Hebrew dispersion (i. 11), or when he asserts the brotherhood of all Israelites under their one Father (ii. 10), not merely as a ground of separation from the heathen, but as inconsistent with the selfish and cruel freedom of divorce current in his time. It is characteristic of later Judaism that an arbitrary exegesis transformed this anticipation of the doctrine of marriage laid down in the gospel into an express sanction of the right of the husband to put away his wife at will.[4]

The style of Malachi, like his argument, corresponds in its generally prosaic character to that transformation or decay of prophecy which began with Ezekiel; and Ewald has rightly called attention to the fact that the conduct of the argument already shows traces of the dialectic manner of the schools. Yet there is a simple dignity in the manner not unworthy of a prophet, and rising from time to time to poetical rhythm.

The exegetical helps to the study of Malachi are mainly the same as have been already cited in the article HAGGAI. Reference may also be made to the lengthy commentary of Reinke (Roman Catholic), 1856; to M. Sänger, *Maleachi, eine exegetische Studie*, 1867; and among older commentaries to that of Pococke (2d ed., 1692). (W. R. S.)

MALACHITE, an ore of copper, presenting in its finer varieties a beautiful green colour which has led to its use as an ornamental stone. It is chemically a hydrated basic carbonate of copper, and appears to have been formed in most cases by the action of meteoric agencies on native copper, red oxide of copper, copper pyrites, and other ores. Upon these minerals the malachite frequently forms an incrustation. Although occasionally found in crystals belonging to the monoclinic system, its usual mode of occurrence is in stalactitic and stalagmitic forms,—frequently with a globular, botryoidal, or mammillated surface; while in other cases it forms compact and even earthy masses. The stalagmitic varieties display, when fractured, a beautiful internal structure, being made up of concentric zones of light and dark tints; and it is upon this structure that much of the beauty of polished malachite depends. The colours include various shades of apple-green, emerald-

[1] Malachi had the law of Deuteronomy in its present historical frame-work (the opening chapters), according to which all "the laws and statutes" apart from the Decalogue were given to Moses for Israel upon Horeb. This description would not hold good of the priestly legislation, which accordingly is hardly contemplated in Mal. iv. 4.

[2] Malachi indeed assumes that the "whole tithe"—the Deuteronomic phrase for the tithe in which the Levites shared—is not stored in each township, but brought into the treasury at the temple. But this was a modification of the Deuteronomic law naturally called for under the circumstances of the return from Babylon, and Neh. x. and xiii. produce the impression that it was not introduced for the first time by Ezra and Nehemiah, though the collection of the tithe was enforced by them.

[3] As the "governor" in i. 8 is hardly Nehemiah, Köhler and other recent writers think of the period between Nehemiah's first and second visit to Jerusalem, when the evils complained of by the prophet broke out afresh.

[4] In ii. 16 the Targum renders "If thou hatest her put her away," and this translation seems to be intended by the Massoretic punctuation. We should probably point שָׂנֵא in the sense of Arabic *makrûh*, used of actions not illegal but offensive to right feeling.

green, and verdigris-green. Certain varieties of the mineral exhibit, when fractured, a finely fibrous texture and soft silky lustre. The name *malachite* is derived from μαλαχή (the mallow), in allusion to the resemblance of the colour of the mineral to that of mallow leaves. Malachite was probably one of the green minerals described by Theophrastus under the general name of σμάραγδος, or emerald. It is believed to have been the *smaragdus medicus* of Pliny, while the *molochitis* of that author does not appear to have represented our modern malachite. Malachite is a mineral of very wide geographical distribution, being found more or less abundantly in the upper part of most deposits of copper ore. The finer varieties, such as lend themselves to purposes of ornament, are, however, found only in Siberia, in Australia, and at Bembe on the west coast of Africa. Probably the finest deposits in the world were those discovered some years ago in Prince Demidoff's mines at Nijni Tagilsk, in the government of Ekaterinburg, on the Siberian side of the Ural mountains. The mineral is highly prized in Russia for use in mosaic work, and for the manufacture of vases, snuff-boxes, and other small ornaments. Magnificent examples of malachite work, in the shape of mantelpieces, folding doors, tables, chairs, and other articles of furniture, have occasionally been executed. Such objects are veneered with thin slabs of malachite ingeniously fitted together so as to preserve the pattern, and having the interspaces between the component pieces filled up with a cement formed of small fragments of the malachite itself. The mineral is sawn into slabs, ground smooth with emery, and finally polished with tripoli. Although its degree of hardness is only from 3·5 to 4, it takes an excellent polish. It is rather denser than marble, its specific gravity being 3·7 to 4; but it is much more difficult to work, in consequence of its tendency to break along the planes of deposition. Malachite is occasionally used for cameo-work, but not with great success; some fine antique cameos in malachite are, however, known. The mineral has also been ground to powder, and used as a pigment under the name of mountain-green. The coarser masses are extensively used as ores of copper, malachite containing about 57 per cent. of metal. The mineral called azurite or chessylite, a hydrated basic carbonate of copper closely resembling malachite, save in colour, is occasionally known as blue malachite.

MALACHY, ST (*c.* 1094–1148), otherwise known as Maelmaedog Ua Morgair, for some time archbishop of Armagh, and afterwards papal legate in Ireland, was born of noble parentage at Armagh about the year 1094, early gained a high reputation for sanctity, and was ordained to the priesthood at the age of twenty-five (thirty being at that time, according to his biographer St Bernard, the canonical age). For some time he was employed as vicar by Archbishop Celsus or Ceallach of Armagh, and in this capacity was successful in effecting throughout the diocese many important reforms in the direction of increased conformity with the usage of the Church of Rome; afterwards he undertook the government of the decayed monastery of Bangor or Benchor, in what is now known as county Down, and made it a flourishing seminary of learning and piety. When thirty years of age he was chosen and consecrated bishop of Connor; after the sack of that place by the king of Ulster he withdrew into Munster and built the monastery of Ibrac. Meanwhile he had been designated by Celsus (in whose family the see of Armagh had been hereditary for many years) to succeed him in the archbishopric; reluctantly but dutifully in the interests of reform he accepted the dignity, and thus became involved for some years in a struggle with the so-called heirs. Having finally settled the diocese he, as had been previously stipulated by himself, was permitted to return to his former diocese, or rather, it having in the meanwhile been divided, to the smaller and poorer portion of it, the bishopric of Down, where he reorganized a house of regular clergy. In 1139 he set out from Ireland with the purpose of soliciting from the pope the pallium for the archbishop of Armagh; on his way to Rome he visited Clairvaux, and thus began a life-long friendship with St Bernard, who survived to write his biography. Malachy was received by Innocent II. with great honour, and made legate in Ireland, though he did not at once obtain the pallium; on his way homeward he revisited Clairvaux, and took with him from thence four members of the Cistercian order, by whom the abbey of Mellifont was afterwards founded in 1141. For the next eight years after his return from Rome Malachy was active in the discharge of his legatine duties, and in 1148 he received from the bishops of Ireland a commission to return to Rome and make fresh application for the pallium; he did not, however, get beyond Clairvaux, where he died on November 2, 1148. The object of his life was realized four years afterwards, in 1152, during the legateship of his successor (see IRELAND, vol. xiii. p. 255). Malachy was canonized by Clement IV.

MALAGA, a maritime province of Spain, one of the eight modern subdivisions of Andalucia, is bounded on the W. by Cadiz, on the N. by Seville and Cordova, on the E. by Granada, and on the S. by the Mediterranean, having an area of 2823 square miles, and a population (1877) of 500,231. The rise from the sea is rapid, and the average elevation of the province is considerable. Of the numerous sierras may be mentioned that of Alhama, separating the province from Granada, and at one point rising above 7000 feet; its westward continuation in the Sierra de Abdalajis and the Axarquia between Antequera and Malaga; and not far from the Cadiz boundary the Sierras de Ronda, de Mijas, de Tolox, and Bermeja, converging and culminating in a summit of nearly 6500 feet. The principal river is the Guadalhorce, which rises in the Sierra de Alhama, and after a westerly course past the vicinity of Antequera, bends southward through the wild defile of Peñarrubia and the beautiful vega or vale of Malaga, falling into the sea near that city. The only other considerable stream is the Guadiaro, which has the greater part of its course within the province, and flows past Ronda. The mountains are rich in minerals,—lead, nickel, and (in the neighbourhood of Marbella) iron being obtained or obtainable in large quantities. There are much frequented warm springs of sulphuretted hydrogen at the baths of Carratraca. Though the methods of agriculture are for the most part rude, the yield of wheat in good seasons is considerably in excess of the local demand; and large quantities of grapes and raisins, oranges and lemons, figs and almonds, are annually exported. The oil and wines of Malaga are also highly esteemed; and in recent years, especially since the phylloxera invasion, the growth of the sugar-cane has developed into a considerable industry. In 1880 the total production of wine within the province was estimated at about 5,250,000 gallons; of this amount about 1,575,000 gallons were exported (1,000,000 gallons to Great Britain and the continent of Europe, and the remainder chiefly to South America and the Spanish colonies). In 1879 about 1,400,000 gallons of olive oil were exported, chiefly to the Baltic. The sugar produced in 1880 was calculated to amount to about 5650 tons. The internal communications of the province are in many parts, owing to the broken nature of the surface, very defective; it is traversed, however, from north to south by the Cordova-Malaga Railway, which sends off a branch, recently made continuous, from Bobadilla to Granada. The only towns with a population exceeding 10,000 are Malaga (the capital), Antequera, Ronda, and Velez Malaga.

Malaga, the capital of the above province, and, next to Barcelona, the most important seaport of Spain, is finely situated on the Mediterranean coast, at the southern base of the group of hills known to history as the Axarquia, and at the eastern extremity of the fertile vega of Malaga (36° 43′ N. lat., 4° 25′ W. long.). The population in 1877 was 115,882. In the clearness of its sky, which a cloud rarely obscures, and the beautiful sweep of its bay, Malaga has sometimes been compared to Naples. The climate is one of the mildest and most equable in Europe, the mean annual temperature being 66°·7 Fahr. (55°·6 in winter, 80°·4 in summer); the yearly average of rainy days is thirty-nine, and the rainfall is slightly under 16 inches. The town lies principally on the left bank of a mountain torrent, the Guadalmedina ("river of the city"); the streets near the sea are spacious and comparatively modern, but those in the older part of the town, where the buildings are huddled around the ancient citadel, are narrow, winding, and often dilapidated. There are various squares or plazas and public promenades: of the former the most important are the Plaza de Riego

Plan of Malaga.

1. Cathedral. | 2. Custom House. | 3. Prison. | 4. Hospital.

(containing the monument to General Torrijos, who, along with forty-eight others, was executed in Malaga in 1831) and the Plaza de la Constitucion; adjoining the quay is the fine Paseo de la Alameda. The town has no public buildings of commanding importance architecturally or historically. The cathedral, on the site of the ancient mosque, was begun about 1528, in the Græco-Roman style; after the works had been once and again interrupted and resumed, it was completed to its present state in the 18th century, and is in consequence an obtrusive record of the degeneration of Spanish architecture. The woodwork of the choir, however, is worthy of attention. The church of El Cristo de la Victoria contains some relics of the siege by the "Catholic kings." Of the old Moorish "Atarazanas" or arsenal only a single horse-shoe gateway now remains, the rest of the site being chiefly occupied by an iron structure used as a meat and provision market; the "Alcazaba" or citadel has entirely disappeared. The castle of Gibralfaro, on a bold eminence to the north-east, dating from the 13th century, is still in fairly good preservation. The harbour, which in the beginning of the present century was deep enough to float a line-of-battle ship, has in recent years been permitted to silt up, so that it is not now safe for vessels drawing more than 18 feet to enter. These are consequently obliged to lie in the roads outside, and receive and discharge cargo by means of lighters. New harbour works were begun in 1880, but from time to time have been suspended, and only some 280 yards of the new eastern mole (about one-fourth of the intended length) have been constructed in October 1882. The trade of the port is chiefly in the products of the province,—lead, wine, raisins, oranges, lemons, figs, and esparto being the staples. The most active period is from the middle of August to the end of October. In 1880 the total quantity of muscatel raisins exported was estimated at 1,864,000 boxes (of 25 ℔ each), 35,500 frails (of 25 ℔), and 15,000 barrels (of 50 ℔); of this amount more than half was sent to the United States of America, and the remainder to other countries (chiefly Great Britain, France, and Germany). In the same year 50,000 boxes of lemons and 21,500 boxes of oranges were shipped, besides 20,000 barrels of muscatel grapes. The wine exported in 1879 was only 1,400,000 gallons as against 3,108,000 in 1878; the lead 310,251 cwts. as against 481,021 cwts. in 1878. The olive oil is sent chiefly to the Baltic. The principal imports are coal (41,822 tons in 1878), codfish, timber, pig-iron, hardware, machinery, and rails.

Malaga is the Μάλακα of Strabo (iii. 156) and Ptolemy (ii. 4, 7), and the *Malaca fœderatorum* of Pliny (iii. 3). The place seems to have been of some importance even during the Carthaginian period; under the Romans it became a municipium, and under the Visigoths an episcopal see. After the battle of Guadalete it passed into the possession of the Arabs, and soon came to be regarded as one of the most important cities of Andalucia. It was attached to the caliphate of Cordoba, but on the fall of the Omayyad dynasty it became for a short time the capital of an independent kingdom; afterwards it was dependent on Granada. In 1487 it was taken and treated with great harshness by Ferdinand and Isabella after a protracted siege. In 1810 it suffered much from the French general Sebastiani.

MALARIA, an Italian colloquial word (from *mala*, bad, and *aria*, air), introduced into English medical literature by Macculloch (1827) as a substitute for the more restricted terms marsh miasm or paludal poison. By very general consent the word is understood to mean an actual poisonous substance existing as a separate entity, and giving rise to the definite unhealthy condition of body known by a variety of names, such as ague, intermittent (and remittent) fever, marsh fever, jungle fever, hill fever, "fever of the country," and "fever and ague." By a figure of speech, the name of malaria is often applied to the disease itself; strictly speaking, the effects on the human body are "malarial fever," or manifestations of the "malarial process." The existence of a specific malaria-poison is a pure hypothesis; and it has been attempted by a respectable minority to dispense with the hypothesis of an actual poisonous agent, and to find the cause of intermittents and remittents in the excessive and sudden abstraction of heat through damp and cold after sunset from the bodies of individuals who had previously endured great solar heat. In either view, the unknown cause of ague is denoted with sufficient etymological accuracy by the word malaria.

A single paroxysm of simple ague is much the same in all countries, temperate, subtropical, or tropical. It may come upon the patient in the midst of good health, or it may be preceded by some *malaise.* The ague-fit begins with chills proceeding as if from the lower part of the back, and gradually extending until the coldness overtakes the whole body. Tremors of the muscles, more or less violent, accompany the cold sensations, beginning with the muscles of the lower jaw (chattering of the teeth), and extending to the extremities and trunk. The expression has meanwhile changed: the face is pale or livid; there are dark rings under the eyes; the features are pinched and sharp, and the whole skin shrunken; the fingers are dead white, and the nails blue. All those symptoms are referable to spasmodic constriction of the small surface arteries, the pulse at the wrist being itself small, hard, and quick. In the interior organs there are indications of a compensating accumulation of blood, such as swelling of the spleen, engorgement (very rarely rupture) of the heart, with a feeling of oppression in the chest, and a copious flow of clear and watery urine from the congested kidneys. The body temperature will have risen suddenly from the normal to 103° or higher. This first or cold stage of the paroxysm varies much in length; in temperate climates it lasts from one to two hours, while in tropical and subtropical countries it may be shortened. It is followed by the stage of dry heat, which will be prolonged in proportion as the previous stage is curtailed. The feeling of heat is at first an internal one, but it spreads outwards to the surface and to the extremities; the skin becomes warm and red, but remains dry; the pulse becomes softer and more full, but still quick; and throbbings occur in exposed arteries, such as the temporal. The spleen continues to enlarge; the urine is now scanty and high-coloured; the body temperature still rises (up to 104° or 105° or even higher); there is considerable thirst; and there is the usual intellectual unfitness, and it may be confusion, of the feverish state. This period of dry heat, having lasted three or four hours or longer, comes to an end in perspiration, at first a mere moistness of the skin, passing into sweating that may be profuse and even drenching. Sleep may overtake the patient in the midst of the sweating stage, and he awakes, not without some feeling of what he has passed through, but on the whole well, with the temperature fallen almost or altogether to the normal, or it may be even below the normal, the pulse moderate and full, the spleen again of its ordinary size; the urine that is passed after the paroxysm deposits a thick brick-red sediment of urates. The three stages together will probably have lasted six to twelve hours. The paroxysm is followed by a definite interval in which there is not only no fever, but even a fair degree of bodily comfort and fitness; this is the intermission of the fever. Another paroxysm begins at or near the same hour next day (quotidian ague), or the interval may be forty-eight hours (tertian ague), or seventy-two hours (quartan ague). It is the general rule, with frequent exceptions, that the quotidian paroxysm comes on in the morning, the tertian about noon, and the quartan in the afternoon. Another rule is that the quartan has the longest cold stage, while its paroxysm is shortest as a whole; the quotidian has the shortest cold stage and a long hot stage, while its paroxysm is longest as a whole. The point common to the various forms of ague is that the paroxysm ceases about midnight or early morning. Quotidian intermittent is on the whole more common than tertian in hot countries; elsewhere the tertian is the usual type, and quartan is only occasional.

If the first paroxysm should not cease within the twenty-four hours, the fever is not reckoned as an intermittent, but as a remittent.

Remittent is a not unusual form of the malarial process in tropical and subtropical countries, and in some localities or in some seasons it is more common than intermittent. It may be said to arise out of that type of intermittent in which the cold stage is shortened while the hot stage tends to be prolonged. A certain abatement or remission of the fever takes place, with or without sweating, but there is no true intermission or interval of absolute apyrexia. The periodicity shows itself in the form of an exacerbation of the still continuing fever, and that exacerbation may take place twenty-four hours after the first onset, or the interval may be only half that period, or it may be double. A fever that is to be remittent will usually declare itself from the outset: it begins with chills, but without the shivering and shaking fit of the intermittent; the hot stage soon follows, presenting the same characters as the prolonged hot stage of a quotidian, with the frequent addition of bilious symptoms, and it may be even of jaundice and of tenderness over the stomach and liver. Towards morning the fever abates; the pulse falls in frequency, but does not come down to the normal; headache and aching in the loins and limbs become less, but do not cease altogether; the body temperature falls, but does not touch the level of apyrexia. The remission or abatement lasts generally throughout the morning; and about noon there is an exacerbation, seldom ushered in by chills, which continues till the early morning following, when it remits or abates as before. A patient with remittent may get well in a week, under treatment, but the fever may go on for several weeks; the return to health is often announced by the fever assuming the intermittent type, or in other words, by the remissions touching the level of absolute apyrexia. Remittent fevers (as well as intermittents) vary considerably in intensity; some cases are intense from the outset, or pernicious, with aggravation of all the symptoms—leading to stupor, delirium, collapse, intense jaundice, blood in the stools, blood and albumen in the urine, and, it may be, suppression of urine followed by convulsions. The severe forms of intermittent are most apt to occur in the very young, or in the aged, or in debilitated persons generally. Milder cases of malarial fever are apt to become dangerous from the complications of dysentery, bronchitis, or pneumonia. Severe remittents (pernicious or bilious remittents) approximate to the type of yellow fever, which is conventionally limited to epidemic outbreaks in western longitudes and on the west coast of Africa. Blood in the urine has been described by several recent writers as distinctive of a form of bilious remittent occurring at a number of malarious localities in the tropical zone of both hemispheres. The remittent type occurs wherever and whenever the malarial conditions are severe; when it has appeared in colder climates, it has usually been at the height of an epidemic of intermittent. With all the foregoing statements, it should be borne in mind that anomalies are frequent.

Of the mortality due to malarial disease a small part only is referable to the direct attack of intermittent, and chiefly to the fever in its pernicious form. Remittent fever is much more fatal in its direct attack; it often kills in the first few days, according to its initial intensity or the severity of the complications. But probably the greater part of the enormous total of deaths set down to malaria is due to the *malarial cachexia*. The malarial cachexia may be either the sequel of one or more actual attacks of fever, or it may arise insidiously in those who inhabit a malarious district and have never experienced the sharp paroxysms of fever. In the latter case, malaria is almost as much an ethnological as a pathological factor. The dwellers in a malarious region like the Terai (at the foot of the Himalayas) are miserable, listless, and ugly, with large heads and particularly prominent ears, flat noses, tumid bellies, slender limbs, and sallow complexions; the children are impregnated with malaria from their birth, and their growth is attended with aberrations from the normal which practically amount to the disease of rickets. The malarial cachexia that follows definite attacks of ague consists in a state of ill-defined suffering, associated with a sallow skin, enlarged spleen and liver, and sometimes with dropsy.

Nearly allied to the malarial cachexia is the so-called state of *masked ague*. Many common ailments have been set down to malaria, without sufficient reason; but there is hardly any doubt that intermittent paroxysms of *neuralgia*, especially of the supra-orbital nerve (*brow-ague*) and of the infra-orbital (*tic douloureux*), are often malarial in origin. These non-febrile effects are apt to follow exposure to malaria; they occur (not exclusively) in those who have had fever and ague; they are sometimes accompanied by suggestions of the cold, and hot, and sweating stages of the true paroxysm; and they often yield to the great anti-malarial remedy, quinine. Such patients have the general ill-health and suffering, as well as the pallor, of the malarial cachexia.

The morbid anatomy of malarial fevers is chiefly confined to congestions and enlargements (with textural changes) of the spleen and liver. One of the most salient pathological facts is the occurrence of black pigment in the blood, and deposits of it in the spleen, liver, and other parts. The malarial process sometimes leads to ulcerations and sloughing of the mucous membrane of the great intestine, not distinguishable from those of dysentery. The malarial fever of Rome is often associated with more or less of swelling and, it may be, even ulceration of the lymphatic follicles of the small intestine, as in typhoid fever; the same anatomical condition was associated with much of the malarial fever of the American Civil War (typho-malaria).

Geographical Distribution and Prevalence.—Malaria has been estimated to produce one-half of the entire mortality of the human race; and, inasmuch as it is the most frequent cause of sickness and death in those parts of the globe that are most densely populated, the estimate may be taken as at least rhetorically correct.

In the British Islands, sporadic cases of ague may occur anywhere; but malaria is not now endemic except in a few localities, among which may be mentioned certain parishes on the Essex side of the Thames estuary. In France there are several districts that are still notoriously malarious. In the interior these are chiefly found in the valley of the Loire (Sologne) and of its tributary the Indre (Brenne), and also in the valley of the Rhone, more particularly near the confluence of the Saône (Dombes, Bresse). France has two great coast regions of malaria,—the one on the Atlantic seaboard, from the estuary of the Loire to the Pyrenees, with especial intensity in the Charente, and the other on the Mediterranean coast, from the Pyrenees to the Rhone delta. The most considerable malarious district of Switzerland is in the Rhone valley from Sion to the Lake of Geneva. In Germany, the upper valley of the Rhine and the sources of the Danube have a certain character for malaria; but it is chiefly on the western seaboard of Schleswig-Holstein and in the moors and marshes of Oldenburg, Hanover, and Westphalia that the disease is endemic. Scarcely any province of Holland can be said to be quite free from it, while Gröningen, Friesland, and Zealand (with brackish marshes) are the most unhealthy. The parts of Belgium that are almost or altogether exempt are the high-lying districts of Brabant, Namur, and Liége. In Sweden, malaria is endemic in the central depression of the country (especially on the shores of Lake Wener), and it has of late years spread northwards in epidemic outbreaks. For the countries of southern and eastern Europe (Spain and Portugal, Italy, Hungary and other Danubian states, Turkey, Greece, southern Russia), the language used to describe the prevalence of malaria has to be pitched in a somewhat higher key. There are certain pestilential districts of those countries where almost the half of the population suffers from ague, and there are even limited areas which are too malarious to be inhabited. The lower basin of the Danube (from above Vienna to the Black Sea), and the basin of its tributary the Theiss, are in the first rank. Both sides of the Adriatic have malarious localities, the chief being the delta of the Po and the Gulf of Comaccio; among other unhealthy parts of Italy are the strip of coast from Pisa to Civita Vecchia (Maremma), the Roman Campagna, the Pontine Marshes, the neighbourhood of Capua, and the Neapolitan and Calabrian coasts. Sicily is highly malarious, both in the plains and in the higher districts; and that is equally the character of Sardinia, Corsica, and the Balearic Isles. Greece, the Ionian Islands, and Crete take a high place among European malarious countries; there are also numerous unhealthy localities on the shores of the Caspian and Black Seas and in Asia Minor. For countries in both hemispheres situated between 35° N. and 20° S., to describe the prevalence of malaria in detail would be practically to give the whole geography within those latitudes. The regions of special intensity are the west coast of Africa, the American seaboard (with the West Indies) from the Gulf of Mexico to Pernambuco, parts of India (the Terai, the Doab, the Sunderbunds), parts of Sumatra, of Java, and of Borneo. Gibraltar, Malta, Aden, Singapore, and Manila enjoy a comparative immunity from fever; the healthiest islands of the West Indies are Barbados, St Vincent, and Antigua.

In England, the fen district of the eastern counties, Romney Marsh in Kent, and the marsh district of Somerset have in great part ceased to be malarious within recent memory; and there has been a proportionate improvement, through drainage, in most parts of Holland, in some of the malarious districts of France and Italy, and in Algiers. Portsmouth in England and Rochefort in France are examples of towns that have entirely lost their evil repute for malaria; and there are many towns in the United States, as well as in the East, which are much less malarious than they used to be. Wherever malarial fevers have become less frequent, they have also become milder in type. On the other hand, malaria has become intense where it was formerly unimportant or altogether unknown. It is incredible that the Roman Campagna could have been so malarious at the time of the empire as it is now; places on the coast, such as Ostia and Palo (Alsium), which are now almost uninhabitable in summer, were then the favourite summer resorts of the rich; while the Campagna, which is now almost entirely given up to pasturage, was not only densely populated, but was even specially commended as salubrious. In North Africa, Asia Minor, and the East, malaria has taken possession of the ruined sites of ancient cities, and of large tracts of land that must have been at one time highly cultivated, but are now treeless, barren, and sometimes marshy. Of recent years malaria has appeared in Réunion and Mauritius, and it has reappeared in Connecticut; in the two islands the associated circumstances are somewhat complicated, but they relate to changes in the cultivated area. The reappearance of ague in New England and the recent appearance of a form of masked ague in New York and elsewhere are at present unaccounted for. Earthquakes were said by older writers to have brought malaria to a locality; a recent and well-authenticated instance is that of Amboyna in the Moluccas, which has become strikingly unhealthy since the earthquakes that occurred in it in 1835.

Among the numerous military enterprises into whose records malaria enters largely, may be mentioned the expedition against Carthagena (1741), the Walcheren expedition (1810), and the capture of Rangoon (1824). Recent enterprises in which malarial fever has been a great factor are the expedition against Achin by the Dutch (1873), the occupation of Cyprus by the English (1878), and the subjugation of Tunis by the French (1881). Schemes of colonization, such as the Darien scheme (1701), have sometimes been frustrated by malaria. Of historical personages, James I. and Cromwell died in London of malarial fever, the latter of a pernicious tertian.

There have been numerous historical epidemics of intermittent and remittent fever, from that of 1557-58 (which spread over all Europe) down to that of 1872, which prevailed simultaneously in Europe, North America, and southern India. The epidemic or pandemic prevalence of intermittent and remittent fever in certain years probably finds its explanation in the meteorology of those years, but no uniform law has been discovered. Whenever malaria has settled endemically in a new locality, there had been epidemics coming and going for some time previously.

Malarious Localities.—The most malarious localities are the deltas and estuaries of rivers (Ganges, Euphrates, Po, Mississippi, Orinoco), low-lying country that is apt to be inundated (Danubian states), tropical or subtropical forests in which there is a moist atmosphere, with stagnation of the air and rank vegetation (jungles), tracts of land that have been cleared of trees and have gone out of cultivation, being in more cases dry than wet (Roman Campagna, Tuscan Maremma, many parts of Persia, Asia Minor, and North Africa, including the sites of ruined cities), inland swamps and marshes (Pontine Marshes), and situations on the coast where the tidal and fresh water join to form brackish marshes (mangrove swamps of the West Indian, Central American, Brazilian, and West African coasts). The mangrove is associated with the most pestilential localities; it springs "like a miniature forest out of the greasy mud-banks, the bright green colour of the bushes reminding one of the rank grass in a churchyard" (C. Darwin). In all those localities there is a soil, usually wet but sometimes dry, rich in the products of vegetable decay; the soil has been either deposited by rivers and tides, or it has formed on the spot out of the undisturbed accumulation of decaying vegetation season after season over a long period. There is, however, a second great class of malarious localities, distinguished by characters that are to some extent the opposite of the foregoing. These are barren rocks (Ionian Islands, Hong Kong, parts of Baluchistan, De Los Islands near Sierra Leone); high table-lands more or less barren (Deccan, Mysore, Persia, New Castile); mountainous regions (Andes, Rocky Mountains); prairies of North America and savannas of Venezuela and Brazil; sandy plains (North Africa, Rajputana, Sindh). A somewhat exceptional locality for malaria is on board ship at sea; there are several well-authenticated instances of epidemic outbreaks at sea, in most cases referred to the putrid bilge-water, and in one case to a cargo of wet deals from the Baltic.

There are several localities whose exemption from malaria has been thought remarkable. Among these, Singapore has long been noted; other instances are the Amazon (as compared with its tributaries and with the Orinoco), the pampas of the La Plata and the Parana, marshy parts of Australia, New Zealand, and New Caledonia, and the marshy Bermudas. The explanation given of the exemption of Singapore, where many of the supposed malarial conditions are present, is that the range of temperature (diurnal and annual) is small; the explanation for the Amazon is that a wind constantly blows up the river from the sea (not reaching the side streams), which serves to equalize the day and night temperature and to obviate the nocturnal radiation of heat.

Malarious Seasons.—In temperate climates autumn is the season when malaria prevails most. "In the autumn, and after the harvest has been gathered, when the ground is covered with its debris, when the rain falls in torrents and when the solar heat has acquired its greatest intensity, all the conditions of greatest quantity of vegetable matter, of moisture, and of highest temperature are united, so that the season which realizes the hopes of the husbandman is the period of pestilence and of his greatest danger" (R. Williams). In the equatorial regions of the East Indies, Africa, and America, the rainy season (May to July or August) is most unhealthy, and especially the time of commencement of the rains and the time of cessation; on the west coast of Africa the months of February, March, and April, which are the hottest months of the year, are at the same time the most healthy. But while autumn and the time of the rains are the malarious season for those localities that are distinguished by wet soil, rank vegetation, &c., it is summer, or the time of extreme heat and drought, that is the unhealthy season for the localities distinguished by dryness of the soil and often by barrenness. The hill fever of the Deccan and Mysore is often most prevalent and most severe in the hottest and driest seasons; in Algeria there is most fever when the country is parched to a desert. The malarial season in the Tuscan Maremma is from June to the middle of September. In military experience it has frequently happened that malaria has attacked the troops in the hottest weather after camping in the dried-up water-courses of uplands, or in parched meadows and sandy levels that are apt to be flooded only in winter.

Conditions of Origin.—In all localities and at all seasons, it is at or after sunset that the malarial influence prevails, and it tells most when a cold night follows a hot day. Perhaps the most constant fact relating to malaria is that it goes with watery exhalations and with the fall of dew. On wet soils, and over marshes, swamps, and jungles, the aqueous vapour condenses as the air cools; while on dry surfaces the rapid radiation of heat causes a heavy dew-fall. The occurrence of malaria on bare rocks, parched uplands, and treeless tracts of dry fallow land may have several associated circumstances; but that which has been most uniformly observed in such localities is great diurnal range of temperature, with rapid radiation of heat after sunset, and copious fall of dew. The "hill fever" of Mysore occurs among bare rocks and stones and brown earth; at the hottest season (March to June) the diurnal range of the shade temperature may be 20° to 30°, while the rocks in the sun may show a surface temperature up to 220°, and undergo a rapid cooling after sunset. The most malarious locality at all times of the year on the Orinoco is around the great cataract, where the banks of the river for some distance are covered with bare black rocks piled to a considerable height; the rocky substance and the black surface combine to produce the greatest absorption of heat and the most rapid radiation, and the rocks there, as well as in other parts of South America and in India, are credited by the natives with giving off poisonous exhalations which cause the fever. Among the conditions of origin the predisposition of the human subject takes a prominent place. Those who have been habituated to extreme heat, and are on occasion exposed to cold and damp, are likely to acquire intermittent or remittent fever; and those who are poorly clad, housed, and fed are most likely. Fires at night in a malarious locality are a well-known protection from fever; the cover of trees (preventing the radiation of heat) is also a protection. Those who have had ague before are liable to have it again on exposure in a malarious locality, or to chill anywhere.

Diffusion of Malaria.—On the hypothesis that malaria is a poisonous substance, it is permissible to speak of its diffusion. It acts for the most part only within a few feet of the ground; in the East Indies the raising of dwellings on piles serves to keep off, or at least lessen, the liability to fever, and the Indians in South America escape it by sleeping in the branches of trees. Although it is not known to act beyond a few feet from the earth's surface, it may produce fever in localities situated at a height of 7000 to 9000 feet above the sea-level. It sometimes acts at a distance from its supposed place of origin. Thus, it it is said to have caused fever on board ships lying 2 or 3 miles off a malarious shore, although it is more usual for ships at even a short distance from the shore to escape. In West Indian experience it has been known to render the high limestone ridge more unhealthy than the swamp at its foot, and a similar experience has occurred on the Kentish shore of the Thames estuary, and at other parts of the English (Channel) coast. There are instances where it has, so to speak, travelled along a narrow valley from an unhealthy marsh to a salubrious situation. Although a still night is most favourable to its production, there is a popular opinion that it is carried by the wind. In many malarious localities there is a definite "ague line," beyond which the noxious influence is not felt. A belt of trees, or even a wall, will "keep it off." It clings to those surfaces that are most easily bedewed. Situations to windward of a malarious swamp are usually reckoned safe.

Hypothesis of Malaria.—Malaria is known only by its effects on the animal body; the effects, although they vary much in intensity, are uniform, definite, or specific, and are characterized by a truly remarkable periodicity. The oldest and most prevalent hypothesis of malaria is that it is a specific poison generated in the soil. Perhaps not every soil is capable under circumstances of causing malaria, but it is difficult to assign limits to its potential presence. There are seemingly well-authenticated cases of malarial disease appearing during the making of railway cuttings, canals, and other excavations in places where malaria had not previously been known; and there is sufficient evidence that malaria has appeared in the track of cultivation in the western States of America, and that it follows on the upturning of virgin soil, and even of soil that has been long fallow. Attempts have been made, without success, to separate a malarious poison from the gases generated by swamps, or from the air of malarious localities. Still more frequent and elaborate attempts have been made to discover the hypothetical poison among the numerous minute vegetable organisms that occur in the soil of malarious (and non-malarious) places; and these also have hitherto yielded no solid result. Another hypothesis is that malaria is a "telluric intoxication," generated by the vegetative power of the soil when that power is not duly exhausted by plant growth. Lastly, there is an hypothesis that malarial fevers are caused by the excessive and sudden abstraction of heat from the body under the influence of cold and damp, and that the specific effects of the nocturnal chill, amounting to intermittent and remittent fever, are most usual and most marked in hot climates because of the antecedent exposure of the body to great solar heat.

Remedies.—Cinchona or Peruvian bark (with its alkaloid quinine) is a remedy universally applied with good effect in the treatment of malarial fevers. The treatment is usually commenced during the first intermission or remission. There is no good evidence that the taking of quinine wards off the attack of malaria. The extent of cinchona planting in southern India, Ceylon, Jamaica, and elsewhere is the best measure of the value of quinine as a remedy, and more particularly as a remedy for ague. Arsenic has proved one of the most efficient substitutes for quinine. The dwellers in malarious localities have found in opium a palliative of the misery induced by the malarial cachexia.

Literature.—Hirsch, *Geographisch-historische Pathologie*, 2d ed., Stuttgart, 1881, pt. i. sec. 7 (the bibliographical references appended to Hirsch's chapter on malaria include upwards of eight hundred names); W. Ferguson, "On the Nature and History of the Marsh Poison," *Trans. Roy. Soc. Edin.*, ix., 1823 (omitted by Hirsch; was the first to dwell upon the fact that malaria is often associated with heat and drought, and elevated rocky localities); Macculloch, *Malaria, an Essay*, &c., London, 1827; Robert Williams, *Morbid Poisons*, London, 1836-41, vol. ii., chapter on "Paludal Diseases"; Colin, *Traité des fièvres intermittentes*, Paris, 1870 (expounds the theory of "intoxication tellurique"); C. F. Oldham, *What is Malaria? and Why is it most Intense in Hot Climates?* London, 1871 (a comprehensive review and acute criticism of established facts and current theories, with the motive of showing that there is no specific malarial poison); Morehead, *Clinical Researches on Disease in India*, London, 1856, vol. i. (for symptoms, diagnosis, and treatment of intermittent and remittent fevers); Fayrer, *Climate and Fevers of India*, London, 1882 (both general and clinical). (C. C.)

MALAṬIA, less correctly MALAṬÍYAH, the ancient Melitene of Cappadocia, a town of Kurdish Armenia in the vilayet of Diarbekir, about 8 miles to the south-west of the Euphrates below the confluence of the Tokhma-su, and about half way between Baghdad and Constantinople, on a route which for ages has been one of the most important in that part of Asia. Asbuzi or Aspuzi, a place about 5 miles distant, which was formerly inhabited by the people of Malatia during the summer only, has become the permanent residence of a large part of the population (about 20,000, including both), but Malatia proper remains the administrative centre of the sanjak. The remains of the ancient town are much dilapidated.

In the time of Strabo (xii. 537) there was no town in the district of Melitene. Under Titus the place became the permanent station of the 12th legion; Trajan raised it to a city. Lying in a very fertile country at the crossing-point of important routes, it grew in size and importance, and was the capital of Armenia Minor or Secunda. Justinian, who completed the walls commenced by Anastasius, made it the capital of Armenia Tertia; it was then a very great place (Procop., *De Æd.*, iii. 4). The town was burnt by Chosroes on his retreat after his great defeat there in 577. Taken by the Saracens, retaken and destroyed by Constantine Copronymus, it was presently recovered to Islam, and rebuilt under Mansúr (757-58 A.D.). It again changed hands more than once, being reckoned among the frontier towns of Syria (Istakhry, p. 55, 62). At length the Greeks recovered it in 934, and Nicephorus II., finding the district much wasted, encouraged the Jacobites to settle in it, which they did in great numbers. A convent of the Virgin, and the great church which bears his name, were erected by the bishop Ignatius (Isaac the Runner). From this time Malatia continued to be a great seat of the Jacobites, and it was the birthplace of their famous maphrian Barhebræus (or Abulfaragius). At the commencement of the 11th century the town was said to number 60,000 fighting men (Assem., *Bib. Or.*, ii. 149; comp. Barheb., *Chr. Eccl.*, i. 411, 423). At the time of the first crusade, the city, being hard pressed by the Turks under Ibn Danishmend, was relieved by Baldwin, after Bohemund had failed and lost his liberty in the attempt. But the Jacobites had no cause to love Byzantium, and the Greek governor Gabriel was so cruel and faithless that the townsmen were soon glad to open their gates to Ibn Danishmend (1102), and the city subsequently became part of the realm of Kilij Arslan, sultan of Iconium.

MALAY PENINSULA, MALACCA, or TÁNAH MALÁYU Plate V. ("Malay Land"), the southernmost region in Asia, attached to Further India by the isthmus of Krá, in 10° N. lat., whence it projects for about 600 miles, first south, then south-east parallel with Sumatra, to Cape Ramúnia (Romania) in 1° 23′ N., within 95 miles of the equator; it varies in width from 45 miles at the isthmus of Krá, and again at Talung in 7° 30′ N., to 210 at Perak in 5° N., and 150 at Selángor, 3° 20′ N. The area is about 70,000 square miles, with a population of at least 650,000.[1] The peninsula, which is washed on the west by the Bay of Bengal and Malacca Strait, on the east by the Gulf of Siam and China Sea, belongs geographically and ethnically rather to the eastern archipelago than to the Asiatic continent. Hence, whenever the proposed canalization[2] of the isthmus of Krá is carried

[1] A careful calculation made by T. J. Newbold in 1838 gave a total population of 375,000, since which date the British possessions have increased about fourfold, from 90,000 to 330,000. Hence, allowing for a slight increase elsewhere, the present population must be at least 650,000 (*Political and Statistical Account of the British Settlements in the Straits of Malacca*, London, 1839, vol. i. p. 418).

[2] The several projects of canalization are fully discussed by M. Léon Dru in *L'Exploration* for March 9 and 16, 1882. The most feasible, but not the shortest, follows the line of railway already projected in

MALAY PENINSULA.

out, this region will fall into its natural position as one of the great islands of Malaysia. In a wider sense the peninsular formation begins properly at the head of the Gulf of Siam, about the parallel of Bangkok. But this northern section between 10° and 13° 30′ N. being comprised within the limits of Siam proper and British Burmah, is not usually included in Malacca, whose political frontier towards the north-west is thus traced by the lower course of the river Pakshan, which there separates it from Tenasserim, the southernmost division of British Burmah. But east of that river there is no natural or political frontier towards Lower Siam, which embraces all the land as far south as the river Muda on the west coast in 5° 33′ N., and on the east side as far as the state of Pahang in 4° N. The seaboard, which is generally flat and overgrown with mangroves for 5 or 6 miles inland, is fringed with numerous islands and insular groups, of which the chief are Salanga (Junk Ceylon), Langkawi, and Pulo Penang on the west side; Singapore, Batang, and Bintang at the southern extremity; Tantalem and Bardia on the east coast. All these islands, which may have a total area of some 5000 square miles, seem to have originally formed part of the mainland, of which they may be regarded as scattered geological fragments.

Although known to Europeans since the beginning of the 16th century, and nowhere more than 100 miles from the sea, the interior still remains one of the least known lands in Asia. D'Souza's large map, prepared in 1879 for the British Government, is still in many places almost a complete blank; the mountain ranges are traced only for short distances, chiefly on the west side below Kedah; the river courses and political boundaries are often merely conjectured, while the elevation of some of the highest peaks is absolutely unknown. Accurate surveys, however, have since then been made, especially by H. S. Deane in the Perak and Selángor states, by D. D. Daly in most of the British native states,[1] by Dru in the extreme north, and by others in the extreme south about the Endau river basin and at several other points, from which a rough idea may be formed of the general orographic and geological features and hydrographic systems. The surface seems to be everywhere essentially mountainous, and considerably more elevated than had till recently been supposed. The land is traversed in its entire length by a somewhat irregular and ill-defined backbone, forming a southern continuation of the Arakan and Tenasserim ranges, but here falling to a mean elevation of perhaps 3000 feet, and constituting a distinct water-parting between the streams flowing east and west to the surrounding seas. The surface is further varied by numerous spurs and detached ridges running mainly north and south, besides isolated masses often vying in elevation with the central ranges. Little space is thus left for upland plateaus, broad valleys, or lowland alluvial plains of any extent, except about Tringgánu and Pahang on the east, and Selángor on the west side. The highest ascertained altitudes are the Titi Bangsa range (7000 feet), between Kedah and Perak; the Gunong Inas (5000) ascended in 1881 by Deane; the Gunong Bubu (5650), and Gunong Ulu Tumulang (6435), near the right and left banks of the Perak river; the Slim range (6000 to 7000) in south-east Perak; the Gunong Rajah (6500), in the main range; a peak (7000) in the Endau river basin, nearly double the height of Gunong Ledang, or Mount Ophir (3849), hitherto supposed to be the highest point in the extreme south. But an unexplored ridge towards the west frontier of Kelantan, with a probable elevation of 8500 or 9000 feet, is taken by Miklucho Maclay as the culminating land of the whole peninsula. These mountains are scarcely anywhere traversed by recognized beaten tracks, the natural passes between the eastern and western watersheds being still mostly overgrown by dense jungle. Deane, however, came upon a forest path across the main water-parting from Kedah to Patáni, and a route is said to lead from the Bernam river basin across the main axis to Pahang on the east side.

Owing to the formation of the land, the rivers, although numerous, are necessarily of short length, and, as their mouths are generally obstructed by bars and coral reefs, they are on the whole more useful for irrigation than as water highways. Nevertheless some are navigable by light craft for considerable distances, and in 1881 Deane steamed up the Bernam between Perak and Selángor to Kampong Chankat Bertiham, 76 miles from the coast. He proceeded by boat thence for 9 miles to Simpang, where the stream divides and shallows. For about 80 miles it is 10 to 17 feet deep, while the Perak, with its chief tributaries, the Plus, Kinta, and Batang Padang, presents a total navigable waterway of perhaps 200 miles. The Perak on the west and the Pahang on the east slope are by far the largest river basins in the peninsula, each draining an area of 5000 to 6000 square miles. The other chief streams are the Selángor and Klang on the south-west coast, the Johór facing Singapore, and on the east side the Endau, Kelantan, and Patáni.

As far as has been ascertained, the main geological formations would appear to be Lower Devonian sandstones and unfossilized clay slates, with a basis of grey stanniferous granite everywhere cropping out. Although no trace has been found of recent volcanic action, there are several isolated and unstratified limestone masses from 500 to 2000 feet high, of a highly crystallized character, with no fossils of any kind. Earthquakes also are frequent, while numerous hot springs attest the presence of still active igneous forces beneath the surface. In the south porphyry occurs, associated with granite and clay ironstone; and laterite, resembling that of the Malabar coast, abounds, especially along the west slope. The rich stanniferous granites forming the backbone of the peninsula render this region the most extensive storehouse of tin in the world. Vast deposits of tin ores, sometimes associated with gold and silver,[2] occur almost everywhere, and are continued in the neighbouring islands as far south as Banca on the Sumatra coast.[3] Gold, whence the land was known to the ancients as the *Aurea Chersonesus*, is also found in considerable quantities, either disseminated in quartz or in alluvial deposits, especially about Mount Ophir, in Pahang, Gomichi, Tringgánu, and Kemáman. The total yield has amounted in some years to 25,000 and 30,000 ounces. Iron ores abound especially in the south, and coal has recently been found in the isthmus of Krá conveniently situated for the future ship canal across the peninsula.

The climate, everywhere moist and hot, becomes

1861 by Fraser and Forlong across the neck of the isthmus in 10° 30′ between the estuaries of the rivers Pekshan and Champon. This scheme, which might be carried out for about £5,000,000, would shorten the sea route from India to China by four days, besides avoiding the dangerous navigation of the Straits.

[1] A detailed account of Mr Daly's surveys, which extended over the years 1875–82, appeared in the *Proceedings of the Royal Geographical Society* for July 1882. It is accompanied by a large map which fills up several gaps left in that of D'Souza. Yet the surveyor remarks that "there is a vast extent—more than half—of the Malayan Peninsula still unexplored," p. 409.

[2] Although the Perak river is named from the Malay word *perak*, "silver," the presence of this metal has been doubted. M. Alfred Marche, however, who recently visited the west coast, found it in Laroot, associated with the rich tin ores of that district (*Comptes Rendus* of the French Geol. Soc. for April 14, 1882, p. 165).

[3] "The alluvial tin deposits permeate the whole length of the Malayan Peninsula on the western side of the dividing range" (Daly).

oppressive and even malarious along the low muddy banks of the coast streams. Higher up, although cooler, it is not always more healthy, and the uplands, especially about Mount Ophir, have the reputation of being extremely dangerous to Europeans (Wallace). Yet the mean temperature, thanks to the general elevation of the land and the prevailing sea-breezes, is much lower than that of many Asiatic lands lying much farther from the equator. While the glass rises normally on the Makrán coast and in the Persian Gulf to 110°, 120°, and even 125° Fahr., the mean summer range in the peninsula scarcely exceeds 90°, while at an altitude of 2500 feet it is under 70° for the whole year. There is strictly speaking no winter, nor a distinctly marked rainy season, the alternate north-east and south-west monsoons distributing the moisture over the east and west slopes throughout most of the year. The average number of rainy days is about one hundred and ninety, and the mean rainfall from 100 to 130 inches. The west coast is exposed to sudden squalls of short duration, known as "Sumatras" from the direction whence they blow, while the opposite side is often visited by tornadoes during the monsoons.

Except in some limestone tracts, especially in Perak and Kedah, the soil is generally poor, and the country, which may be described as of comparatively recent formation slowly undergoing decomposition, is incapable of growing sufficient rice even for the local demand (D. D. Daly). The land, however, is almost everywhere clothed with a magnificent tropical vegetation, in which the most conspicuous and useful plants are the gutta-percha (here first discovered), the camphor tree, ebony, sapan, ratan, eagle wood, bamboo, nibung, and nipa palm. Unfortunately the work of reckless destruction has already commenced, and the Chinese miners have in many places cleared extensive tracts, cutting down the finest trees to serve as fuel for smelting the tin ores. Of fruits the most characteristic are the durian and mangosteen; and of cultivated plants the most common are rice, the sugar-cane, cotton, tobacco, yams, batata, cocoa and areca palms. Tea and coffee might be successfully cultivated along the slopes of the Perak and Selángor rivers (Deane). A species of climbing indigo and the wild nutmeg are indigenous, and the true nutmeg, cinnamon, and cloves have long been introduced, and thrive well (Newbold).

The fauna of the peninsula, which is unusually rich, is allied, like the flora and the inhabitants, rather to that of the Eastern Archipelago than the mainland. Here are the one-horned rhinoceros, Malay tapir (tánau), elephant, and hog, all of the same species as those of Sumatra. Here is also a small bear (bruangh), found elsewhere only in Borneo, as well as the Sunda ox of Java, besides two kinds of bison said to be peculiar to the peninsula (Crawfurd). On the other hand, the Asiatic tiger has extended his range throughout the whole region, even crossing over to Singapore and other adjacent islands. Of quadrumanes there are no less than nine species, including the chimpanzee (*Simia troglodytes*), the kukang (*Lemur tardigradus*), the black and white unka, but apparently not the orang-outan, although the word is in common use among the Malays, who often apply it in its natural sense to the Sakai and other wild tribes of the interior. Of birds perhaps the most characteristic are the rhinoceros hornbill (*Buceros*), the banga or Javanese stork, the argus and pencilled pheasants, birds of paradise (*Paradisea regia* and *P. gularis*), myna or grackle (*Gracula religiosa*), murei or dial bird (*Gracula saularis*), the humming bird, besides kingfishers, flycatchers, doves, and pigeons in endless variety. The islands are frequented by the *Hirundo esculenta*, or swallow that builds edible nests. The forests swarm with coleoptera, lepidoptrea, and other insects, including the magnificent butterfly *Ornithoptera Brookeana*, till recently supposed to be peculiar to Borneo (Deane). The surrounding waters are inhabited by the halicore, or "mermaid," a sirenian whose Malay name *duyong* has been corrupted to dugong in our natural history books.

Politically the peninsula is partly held directly by Siam and Great Britain, and partly divided among a number of petty Malay states, either tributary to or in treaty with those paramount powers. The Siamese territory and states embrace the whole of the northern section southwards to 5° 35′ N., and thence on the east side as far as the southern frontier of Tringgánu in 4° 35′ N. A line drawn from this parallel on the east coast across the peninsula north-westwards to Kedah on the west coast will thus mark the southern limits of all the land directly or indirectly subject to Siam. The rest of the peninsula is occupied by the British possessions grouped under the collective name of the STRAITS SETTLEMENTS (*q.v.*), and by the more or less independent Malay states proper, which may be regarded as forming part of the British system. Subjoined is a table of all the political divisions of the peninsula :—

Siamese Political System.

Ligor, Sengora. These two provinces of Lower Siam proper comprise the isthmus of Krá between 7° and 10° N., with a coast-line of 240 miles on the east and 260 on the west side; area perhaps 17,000 square miles; population, 50,000 (?).

Kedah, between Ligor and Perak, 7° to 5° 35′ N., with 120 miles on west coast; area, 3600 square miles; population, 30,000.

Patáni or Raman, between Sengora and Kelantan, 7° to 5° 30′ N., with coast-line on east side 50 miles; area, 5000 square miles; population, 30,000.

Kelantan, between Patáni and Tringgánu, 6° to 4° N., 60 miles coast on east side; area, 7000 square miles; population, 20,000.

Tringgánu with Kemáman, between Kelantan and Pahang, 5° 30′ to 4° N., with 80 miles coast-line on the east side; area, 6000 square miles; population 50,000 (?).

British Political System.

Perak, between Kedah and Selángor, 5° 30′ to 4° N., with 80 miles coast-line on west side; area, 6500 square miles; population, 30,000.

Selángor with Kalang, between Perak and Malacca territory, 4° to 3° N., with 120 miles coast-line on west side; population, 15,000.

Johór, southern extremity of the peninsula from 2° 40′ N. to Cape Romania; area, 10,000 square miles; population, 20,000.

Pahang, between Johór and Tringgánu, 3° to 5° N., 90 miles coast on east side; area, 3500 square miles; population, 20,000.

Jelébu, Sungei Ujong, Sri Menanti, Jumpól, Johól, Rambau, Jelai, Segámat or Moar. These inland states, lying between 2° and 4° N., formerly constituted with Naning (Malacca territory) the so-called Negri Sambilan, or "Nine Lands," governed by panghúlus or chiefs, feudatory first to the sultans of Malacca and then to those of Johór. It is now proposed again to consolidate them in one state under the suzerainty of or in alliance with Great Britain. They lie surrounding Malacca territory, between Johór on the east, Pahang on the north, and Selángor on the west and north-west. Total area probably not more than 5000 square miles; population, 50,000 (?). The more important are Rambau (Linggi river basin), Segámat (Moar river basin), Johól (north from Mount Ophir), and Sungei Ujong (Lángat river basin).

Straits Settlements: parts of Perak, Malacca, Pulo Penang, and Singapore; total area, 1445 square miles; population (1881), 314,000.

Excluding the Chinese, Klings, Bugis, and other more recent arrivals, the inhabitants of all these states belong to three distinct stocks—the Tai (Siamese), Malay, and Negrito. The Siamese of pure blood occupy the extreme north with scattered communities as far south as the town of Sengora (7° 10′ N.). A mixed Malayo-Siamese people, commonly known as Samsams, form the bulk of the population in the lower parts of Ligor and Sengora, and in the north of Kedah. Although entirely assimilated to the Siamese in speech, customs, and religion, these Samsams appear to be allied physically much more to the Malay than to the Tai stock. Yet their national sympathies seem to be altogether with the dominant race, and the people, especially of Ligor, have during the present century zealously co-operated with the Siamese in their persistent efforts to subdue the Malays of the neighbouring states.[1]

All the rest of the peninsula, from about 7° N. to Cape Romania, may be regarded as essentially "Malay land," as it is in fact called by the people themselves. But whether the Malays are here indigenous, or intruders from Sumatra, is a question still warmly discussed by ethnologists. Those, however, who support the latter view by appealing to the undoubted historic migrations of civilized Malays from Menangkabo or Palembang in the 12th century, or even to still earlier arrivals from Java, do not understand the point at issue. For the peninsula is occupied, not only by these civilized Orang Maláyu of cultured speech, Mohammedans and mostly no doubt originally from Sumatra, but also by the Orang Benua, that is, "men of the soil," or aborigines, of Malay stock and of rude Malay speech, nature worshippers, and settled here from prehistoric times. Similar uncultured Malay tribes, such as the Orang Kubu of Palembang, are no doubt also found in Sumatra. But it is unlikely that any of these people ever crossed the shallow intervening Straits of Malacca, which were probably dry land when the race was gradually diffused over the common area. Whether the migration proceeded eastwards or westwards is therefore a point which cannot be determined pending the settlement of the further and broader question of the origin and dispersion of the Malay race itself. If the Malays are a branch of the Mongol stock, as many hold, then the Orang Benua must have passed through the peninsula southwards to the archipelago at a time when most of it still formed part of the Asiatic mainland. But if they originated in the archipelago itself, as others maintain, then the stream of migration must have been reversed.

In any case the Orang Benua are not the only aborigines in the peninsula. For the most recent research has fully confirmed the somewhat vague statements of earlier writers regarding the presence in this region of a Negroid element differing fundamentally from the Malay type, and apparently to be affiliated to the Negrito of the Andaman Islands and Philippines. "Purely anthropological observations and considerations lead me to accept the supposition of a 'Melanesian' element (a remnant of the original race), which through intermixture with the Malays is being more and more supplanted. . . . . In the mountains of Pahang and Kelantan as far as Sengora and Ligor, I have discovered a Melanesian[2] population. This people undoubtedly belongs to the Melanesian stock" (Miklucho Maclay in *Ethnologische Excursion in Johor*).[3]

The Malay and Negrito aborigines are collectively known to the civilized Malays as Semang and Sakei[4] respectively, although much confusion seems to have arisen in the use of these terms, nor is this surprising, seeing that the two races themselves, who have been in contact for ages, have become largely intermingled and assimilated in customs, and even in speech. The original Negrito dialects, which Maclay has compared with those of the Philippines, are everywhere yielding to the Malay, which is spoken throughout the peninsula with little dialectic variety as far as 6° and 7° N., where it is replaced by Siamese. The aborigines, who are said not to number altogether more than some 10,000, are divided into a great many tribes, of which the best known are the Jakuns, widespread in the south, the Udai, Básisi, Sabimba, Mintira (Mantra), and Hala. All are in a very low state of culture, holding aloof from the settled populations, living entirely on the chase, and pursuing the game with poisoned arrows. It is noteworthy that even the more or less civilized Malays, especially of Rambau and other inland states, still hold to the tribal organization, the very names of many of their tribes, such as the Anak Achi ("children of Achín") and Sri Lummah Menangkabau, betraying their comparatively recent migration from Sumatra.

Other ethnical elements in the peninsula are the Bugis from Celébes, formerly powerful on the west coast; the "Moors" (Arabs), now mostly absorbed by the civilized Malays; the Klings[5] from India, chiefly traders in the seaports; the Topas (Topazio), half-caste Portuguese Christians, still numerous especially in Malacca territory, a few Europeans, Battas, and African slaves; and, lastly, the Chinese, by far the most numerous of all, who are gradually converting the Malay peninsula into a second China. They have already monopolized the mining and agricultural industries, as well as the retail trade and local shipping.

Although vaguely known to the ancients as the Aurea Chersonesus, and even by them already described as a "Regio Latronum," or piratical land, the Malay peninsula possesses no historic traditions earlier than the 13th century. According to the native writers the first settlement was made at Singa-pura, or the "Lion City," about 1250 by emigrants from the banks of a river Maláyu in Sumatra. Expelled from Singapore by the Javanese king Majapáhit, the colonists founded the city of Malacca on the south-west coast of the mainland in 1253. From this point the cultured and Mohammedan Malays of Sumatra are supposed to have rapidly spread over the whole peninsula, where they had already established a number of petty piratical states, when the Portuguese under Albuquerque reached Malaysia and reduced Malacca in 1511. Being thus, so to say, taken on the flank by the Europeans, while their progress northwards was barred by the Siamese continually pressing forward from Indo-China, the Malays of the peninsula, ever prone to piracy and lawlessness, have remained in a more or less unsettled state almost down to the present time. The Portuguese held Malacca for one hundred and thirty years, when they were supplanted in 1641 by the Dutch, who yielded in 1795 to the English, and finally in 1824 surrendered all their possessions on the mainland to Great Britain in exchange for Bencoolen in Java. Penang and Singapore had already been occupied by the British, who, by the suppression of piracy and the old monopolies, the proclamation of free trade principles, the example of a wise administration and treaties with the surrounding states, have gradually laid a solid foundation for the future prosperity of this distracted land. (A. H. K.)

MALAYS (Orang Maláyu, "Malay Men"), the dominant people in Malacca and the Eastern Archipelago (hence often called Malaysia), where they are diversely intermingled with other races, and where they have represented the local cultured element for over two thousand years. The Malays proper, that is, those who call themselves by this name,[6] who speak the standard Malay language, and who possess a common sentiment of racial unity, are found in compact masses chiefly in the Malay peninsula as far north as 8° or 9° N. lat., in the adjacent islands of Penang, Bintang, Lingen, &c., and in Sumatra, of which they occupy fully one half, mainly in the south, along the east coast, and on parts of the west coast. In these lands

[1] The horrors attending the reduction of Kedah in 1821 were caused chiefly by the ferocity of the Samsams of Ligor in the Siamese service.

[2] This writer applies the term "Melanesian" to all the dark races of the Oceanic area, and not merely to the natives of the Melanesian Archipelago.

[3] See also the *Field*, April 23, 1878; *Journal of the Straits Branch of the Roy. As. Soc.* for 1878–81, *passim*; and the paper of Mr Daly, who says, "The true Orang Sakei is a Negrito, and reminds one of the Papuans of New Guinea, whom I have seen in Torres Straits," p. 409.

[4] The aborigines of the neighbouring island of Billiton are also collectively known as *Sakah* (*Annales de l'Extrême Orient*, 1879, p. 130).

[5] The term *Kling*, a corrupt form of Telinga (Telugu), is applied throughout Malaysia to all the natives of India settled in that region.

[6] The origin of this word has given rise to much controversy. Its derivation from the Javanese *ma-layu*, to run or flee, must be rejected as grammatically impossible, for this is a true *verbal* form, whereas the national name is strictly *adjectival*, hence always accompanied by a noun. Valentyn points out (*Beschryvinge van Sumatra*, p. 13) that the name is specially applied in Sumatra to the great Súngei-págú-Maláyu tribe of the Súngei-págú auriferous district, and it seems on the whole most probable that it was originally the name of some local tribe, which rose to pre-eminence.

alone they are really indigenous, and regard themselves as the aboriginal population. Elsewhere they are met in scattered communities chiefly round the coast of Borneo, in the Sulu Archipelago, in Tidor, Ternate, and some other members of the Molucca group, where they are held to be intruders or immigrants from Sumatra.

Long considered as an independent division of mankind, the Malays are now more generally affiliated to the Mongol stock, of which A. R. Wallace, De Quatrefages, and other eminent naturalists regard them as a simple variety more or less modified by mixture with other elements. "The Malayan race, as a whole, undoubtedly very closely resembles the East-Asian populations from Siam to Manchuria. I was much struck with this when in the island of Bali I saw Chinese traders who had adopted the costume of that country, and who could then hardly be distinguished from Malays; and, on the other hand, I have seen natives of Java who, as far as physiognomy was concerned, would pass very well for Chinese."[1] In fact, the typical Malay can scarcely be distinguished anthropologically from the typical Mongolian. He is described as of low stature, averaging little over 5 feet,[2] of olive-yellow complexion inclining to light brown or cinnamon, brachycephalous, with somewhat flat features, high cheek bones, black and slightly oblique eyes, small but not flat nose, dilated nostrils, mouth wide but not projecting, hands and feet small and delicate, legs very thin and weak, coarse black hair, always lank and round in section, scant or no beard.[3]

The departure from this description so frequently noticed in the archipelago must be attributed to intermixture with the black Papúan stock in the east, and with a distinct pre-Malay Caucasic element in the west. The presence of this "Indonesian" element, as it is called by Dr Hamy, may now be regarded as an ascertained fact, the recognition of which will help to remove many of the difficulties hitherto associated with the natural history of the Malay race. It at once explains, for instance, the apparent discrepancy between the foregoing description of the ordinary Malay and that of the Battas, Orang Kabu, and many other Sumatran and Bornean peoples described as tall and robust, with regular features, symmetrical figure, light complexion, brown and wavy hair, and general European appearance.[4]

These considerations also enable us to fix the true centre of dispersion of the Malay race rather in Malacca than in Sumatra, contrary to the generally received opinion. If they are to be physically allied to the Mongol stock, it is obvious that the earliest migration must have been from High Asia southwards to the peninsula, and thence to Sumatra, possibly at a time when the island still formed part of the mainland. The national traditions of a dispersion from Menangkabo or Palembang in South Sumatra must accordingly be understood to refer to later movements, and more especially to the diffusion of the civilized Malay peoples, who first acquired a really national development in Sumatra in comparatively recent times. From this point they spread to the peninsula, to Borneo, Sulu, and other parts of Malaysia, apparently since their conversion to Islam, although there is reason to believe that other waves of migration must have reached Further India and especially Camboja, if not from the same region at all events from Java, at much earlier dates. The impulse to these earlier movements must be attributed to the introduction of Indian culture through the Hindu and Buddhist missionaries, perhaps two or three centuries before the Christian era. During still more remote prehistoric times various sections of the Malay and Indonesian stocks were diffused westwards to Madagascar, where the Hovas, of undoubted Malay descent, still hold the political supremacy, and eastwards to the Philippines, Formosa, Micronesia, and Polynesia. This astonishing expansion of the Malaysian peoples throughout the Oceanic area is sufficiently attested by the diffusion of a common Malayo-Polynesian speech from Madagascar to Easter Island, and from Hawaii to New Zealand. See POLYNESIA.

The Malays proper have long been divided socially into three distinct groups,—the *Orang Benúa*, or "Men of the Soil," that is, the uncivilized wild tribes; the *Orang-laut*, or "Men of the Sea," that is, the semi-civilized floating population; and the *Orang Maláyu*, or "Malay Men," that is, the civilized Malays with a culture, a literature, and a religion. The Orang Benúa, called also *Orang Gunung*, or "Highlanders," and sometimes even *Orang-utan*, or "Wild Men," constitute the aboriginal Malay element, the "raw material," so to say, of the race, which has hitherto remained wholly unaffected by foreign influences, and which is still grouped in small tribes at a very low stage of culture, living nearly exclusively by the chase, and almost destitute of all social organization. They are found chiefly in the more inaccessible wooded uplands of Malacca and Sumatra, in the former region more or less intimately associated for ages with the Negrito tribes, and in the latter island apparently the sole occupiers of the land from the first. Intermediate between the Orang Benúa and Orang Maláyu are the Orang-laut, the "Sea Gipsies" of English writers, who still occupy the same low social position that they held when the Portuguese first reached Malaysia. They were then described by De Barros under the name of Cellates, or "people of the Straits," as "a vile people dwelling more on the sea than on the land," and "living by fishing and robbing"; and this description is still largely applicable, although piracy is now all but suppressed in the Eastern waters. The Bajau and Millanau of the Sulu Archipelago and neighbouring coast lands also belong to this class of sea nomads. Lastly, the Orang Maláyu are that section of the race which, under the influence first of the Hindus and then of the Arabs, has developed a national life and culture, and which has founded more or less powerful political states in various parts of the archipelago. But here again it is necessary to distinguish between the civilized Malays proper, and the other civilized branches of the race, to whom the term Malay is never applied, and who speak languages which, while belonging to the common Malay linguistic family, differ greatly from the standard Malay speech. The chief divisions of all these civilized communities are as under:—

Orang Maláyu: Menangkabo, Palembang, and Lampong in Sumatra; petty states of the Malay Peninsula; Borneo; Tidor; Ternate.
Sumatran group: Achinese, Rejangs, Passumahs.
Javanese group: Javanese proper, Sundanese, Madurese, Balinese.
Celebes group: Bugis, Mangkassara, and others.
Philippine group: Tagalas, Bisayans, Bicol, Sulu, and others.
Outlying groups: Hovas of Madagascar, Formosan Islanders.

In all these the distinctly Malay physical type decidedly predominates, whereas elsewhere in the archipelago the so-called Malays are often rather "Indonesians," in whom the distinctly Caucasic physical type predominates. Such especially are the Battas and Orang Kubu of Sumatra, the Nias and Mentawey islanders, the Kayans, and many of the Dyak tribes of Borneo.[5]

In their temperament no less than in their features the Malays still betray their Asiatic origin. They are described as of a taciturn, undemonstrative disposition, little given to outward manifestations of joy or sorrow, yet extremely courteous towards each other, and as a rule kind to their women, children, and domestic animals. Slow and deliberate in speech, neither elated by good nor depressed by bad fortune, normally impassive and indolent, they are nevertheless capable of the greatest excesses when their passions are roused. Under the influence of religious excitement, losses at gambling, jealousy or other domestic troubles, they are often seized by the so-called "amok" fever, when they will rush wildly through the crowded streets armed with their sharp krisses, cutting down all who cross their path with incredible fury and without the least discrimination. Amongst the practices and propensities which connect them with the Mongoloid inhabitants of Indo-China the most striking are pile-building, especially in Java and Borneo; cock-fighting, universal throughout the archipelago; a pronounced taste for putrescent fish, with a corresponding dislike of milk; head-hunting (Borneo and Celebes); large ear-ornaments, greatly distending the lobe; husband entering the wife's family, and father

exchanging his own for his child's name; counting by numeral auxiliaries, such as pebble, chief, log, mountain, feather, &c., according to the nature of the object.[1]

The race is on the whole of a sluggish intellect, inferior in natural intelligence even to the surrounding Papúan populations. Dr Montano tells us that in the girls' school at Malacca, conducted by the Roman Catholic sisters, the Chinese children take the first, the Mantras (aborigines) the second, and the Malays the last place in order of capacity.[2] Unaided by foreign influences they never attained a higher culture than that of the "Sea Gipsies"; and for their letters, most of their arts, and their religions they are indebted either to the Hindus or the Arabs. (A. H. K.)

Malay Language and Literature.

The Malay language is a member of the Malayan section of the Malayo-Polynesian class of languages, but it is by no means a representative type of the section which has taken its name from it. The area over which it is spoken comprises the peninsula of Malacca with the adjacent islands (the Rhio-Lingga Archipelago), the greater part of the coast districts of Sumatra and Borneo, the seaports of Java, the Sunda and Banda Islands. It is the general medium of communication throughout the archipelago from Sumatra to the Philippine Islands, and it was so upwards of three hundred and fifty years ago when the Portuguese first appeared in those parts.

There are no Malay manuscripts extant, no monumental records with inscriptions in Malay, dating from before the spreading of Islam in the archipelago, about the end of the 13th century. By some it has been argued from this fact that the Malays possessed no kind of writing prior to the introduction of the Arabic alphabet (W. Robinson, J. J. de Hollander); whereas others have maintained, with greater show of probability, that the Malays were in possession of an ancient alphabet, and that it was the same as the Rechang (Marsden, Friederich), as the Kawi (Van der Tuuk), or most like the Lampong (Kern),—all of which alphabets, with the Battak, Bugi, and Macassar, are ultimately traceable to the ancient Cambojan characters. With the Mohammedan conquest the Perso-Arabic alphabet was introduced among the Malays; it has continued ever since to be in use for literary, religious, and business purposes. Where Javanese is the principal language, Malay is sometimes found written with Javanese characters; and in Palembang, in the Mĕnangkabo country of Middle Sumatra, the Rechang or Renchong characters are in general use, so called from the sharp and pointed knife with which they are cut on the smooth side of bamboo staves. It is only since the Dutch have established their supremacy in the archipelago that the Roman character has come to be largely used in writing and printing Malay. This is also the case in the Straits Settlements.

By the simplicity of its phonetic elements, the regularity of its grammatical structure, and the copiousness of its nautical vocabulary, the Malay language is singularly well-fitted to be the *lingua franca* throughout the Indian archipelago. It possesses the five vowels *a*, *i*, *u*, *e*, *o*, both short and long, and one pure diphthong *au*. Its consonants are *k*, *g*, *ng*, *ch*, *j*, *ñ*, *t*, *d*, *n*, *p*, *b*, *m*, *y*, *r*, *l*, *w*, *s*, *h*. Long vowels can only occur in open syllables. The only possible consonantal nexus in purely Malay words is that of a nasal and mute, a liquid and mute and vice versa, and a liquid and nasal. Final *k* and *h* are all but suppressed in the utterance. Purely Arabic letters are only used in Arabic words, a great number of which have been received into the Malay vocabulary. But the Arabic character is even less suited to Malay than to the other Eastern languages on which it has been foisted. As the short vowels are not marked, one would, in seeing, *e.g.*, the word *bntng*, think first of *bintang*, a star; but the word might also mean a large scar, to throw down, to spread, rigid, mutilated, enceinte, a kind of cucumber, a redoubt, according as it is pronounced *bantang*, *banting*, *bentang*, *buntang*, *buntung*, *bunting*, *bonteng*, *benteng*.

Malay is essentially, with few exceptions, a dissyllabic language, and the syllabic accent rests on the penultimate unless that syllable is open and short; *e.g.*, dātang, namāña, bĕsár, diumpatkaññālah. Nothing in the form of a root word indicates the grammatical category to which it belongs; thus, *kāsih*, kindness, affectionate, to love; *ganti*, a proxy, to exchange, instead of. It is only in derivative words that this vagueness is avoided. Derivation is effected by infixes, prefixes, affixes, and reduplication. Infixes occur more rarely in Malay than in the cognate tongues. Examples are—*gūruh*, a rumbling noise, *gumūruh*, to make such a noise; *tunjuk*, to point, *telunjuk*, the forefinger; *chūchuk*, to pierce, *cherūchuk*, a stockade. The import of the prefixes—mĕ (mĕng, mĕñ, mĕn, mĕm), pĕ (pĕng, pĕñ, pĕn, pĕm), bĕr (bĕl), pĕr, pĕl, ka, di, tĕr,—and affixes—an, kan, i, lah—will best appear from the following examples: root word *ājar*, to teach, to learn; *mĕngājar*, to instruct (expresses an action); *bĕlājar*, to study (state or condition); *mĕngajāri*, to instruct (some one, trans.); *mĕngājarkan*, to instruct (in something, causative); *pĕngājar*, the instructor; *pĕlājar*, the learner; *pĕngajāran*, the lesson taught, also the school; *pĕlajāran*, the lesson learnt; *diājar*, to be learnt; *tĕrājar*, learnt; *tĕrājarkan*, taught; *tĕrajāri*, instructed; [*pĕrāja* (from *rāja*, prince), to recognize as prince; *pĕrajākan*, to crown as prince; *karajāan*, royalty]; *ājarkanlah*, teach! Examples of reduplication are—*ājar-ājar*, a sainted person; *ājar-bĕrājar* (or *bĕlājar*), to be learning and teaching by turns; similarly there are forms like *ājar-mĕngājar*, *bĕrājar-ajāran*, *ājar-ajāri*, *mĕmpĕrājar*, *mĕmpĕrājarkan*, *mĕmpĕrajāri*, *tĕrbĕlājarkan*, *pĕrbĕlājarkan*, &c. Altogether there are upwards of a hundred possible derivative forms, in the idiomatic use of which the Malays exhibit much skill. See especially H. von Dewall, *De vormveranderingen der Maleische taal*, Batavia, 1864; and J. Pijnappel, *Maleisch-Hollandsch Woordenboek*, Amsterdam, 1875, "Inleiding." In every other respect the language is characterized by great simplicity and indefiniteness. There is no inflexion to distinguish number, gender, or case. Number is never indicated when the sense is obvious or can be gathered from the context; otherwise plurality is expressed by adjectives such as *sagāla*, all, and *bāñak*, many, more rarely by the repetition of the noun, and the indefinite singular by *sa* or *sātu*, one, with a class-word. Gender may, if necessary, be distinguished by the words *laki-lāki*, male, and *pĕrampūan*, female, in the case of persons, and of *jantan* and *bĕtīna* in the case of animals. The genitive case is generally indicated by the position of the word after its governing noun. Also adjectives and demonstrative pronouns have their places after the noun. Comparison is effected by the use of particles. Instead of the personal pronouns, both in their full and abbreviated forms, conventional nouns are in frequent use to indicate the social position or relation of the respective interlocutors, as, *e.g.*, *hamba tuan*, the master's slave, *i.e.*, I. These nouns vary according to the different localities. Another peculiarity of Malay (and likewise of Chinese, Shan, Talaing, Burmese, and Siamese) is the use of certain class-words or coefficients with numerals, such as *orang* (man), when speaking of persons, *ekor* (tail) of animals, *kĕping* (piece) of flat things, *bīji* (seed) of roundish things; *e.g.*, *līma bīji tĕlor*, five eggs. The number of these class-words is considerable. Malay verbs have neither person or number nor mood or tense. The last two are sometimes indicated by particles or auxiliary verbs; but these are generally dispensed with if the meaning is sufficiently plain without them. The Malays avoid the building up of long sentences. The two main rules by which the order of the words in a sentence is regulated are—subject, verb, object; and qualifying words follow those which they qualify. This is quite the reverse of what is the rule in Burmese.

The history of the Malays amply accounts for the number and variety of foreign ingredients in their language. Hindus appear to have settled in Sumatra and Java as early as the 4th century of our era, and to have continued to exercise sway over the native populations for many centuries. These received from them into their language a very large number of Sanskrit terms from which we can infer the nature of the civilizing influence imparted by the Hindu rulers. Not only in words concerning commerce and agriculture, but also in terms connected with social, religious, and administrative matters, that influence is traceable in Malay. See W. E. Maxwell, *Manual of the Malay Language*, 1882, pp. 5–34, where this subject is treated more fully than by previous writers. This Sanskrit element forms such an integral part of the Malay vocabulary that in spite of the subsequent infusion of Arabic and Persian words adopted in the usual course of Mohammedan conquest it has retained its ancient citizenship in the language. The number of Portuguese, English, Dutch, and Chinese words in Malay is not considerable; their presence is easily accounted for by political or commercial contact.

The Malay language abounds in idiomatic expressions, which constitute the chief difficulty in its acquisition. It is sparing in the use of personal pronouns, and prefers impersonal and elliptical diction. As it is rich in specific expressions for the various aspects of certain ideas, it is requisite to employ always the most appropriate term suited to the particular aspect. In Maxwell's *Manual*, pp. 120 *sq.*, no less than sixteen terms are given to express the different kinds of striking, as many for the different kinds of speaking, eighteen for the various modes of carrying, &c. An unnecessary distinction has been made between *High Malay* and *Low Malay*. The latter is no separate dialect at all, but a mere brogue or jargon, the medium of intercourse between illiterate natives and Europeans too indolent to apply themselves to the acquisition of the language of the people; its vocabulary is made up of Malay words, with a conventional admixture of words from other languages; and it varies, not only in different localities, but also in proportion to the individual speaker's acquaintance with Malay proper. The use is different as regards the term *Jāwī* as applied to the Malay language. This has its origin in the names Great Java and Lesser Java, by which the mediæval Java and Sumatra were called, and it accordingly means the language spoken along the coasts of the two great islands.

Malay is probably spoken with greatest purity in the Rhio-Lingga Archipelago and in the independent states of Perak and

[2] *Jour. d'Anthropologie* for March 1882.

Kedah, on the western coast of the peninsula of Malacca. In other states of the peninsula (Johor, Tringganu, Kelantan) dialectical divergencies both as to pronunciation and the use of words have been noted. The most important and the most interesting of all the Malay dialects is that of Menangkabo (Menangkarbau) in the residency of Padang and in Upper Jambi, in Central Sumatra. It abounds in diphthongs, and prefers vocalic to consonantal terminations, thus changing final *al* and *ar* into *a'*, *il* and *ir* into *iye*, *ul* and *ar* into *uwe*, *as* and *at* into *e'*, *us* into *uwi*; final *a* mostly passes into *ō*, so that for *sudāra* and *sudāgar* they say *sudĕrō*, *sudĕgō*; the emphatic *-lah* is turned into *-malah* or *malah há*; the prefixes *bĕr*, *pĕr*, *tĕr* are changed into *bă*, *pă*, *tă*, or *bără*, *pără*, *tără*. Among other changes in pronunciation may be noted *ūrang* for *orang*, *mungko* for *maka*, *lai* for *lāgi*; they use *nan* for *yang*, *na'* for *hendak*, *deh* for *oleh*, *ba'* for *bāgai*, *pai* for *pergi*, *ko'* for *jikalau*, &c. In some districts of Menangkabo (Palembang, Lebong) the Renchong character is in general use in writing this dialect, for which purpose it is far better suited than the Arabic. As early as 1822 a small tract on the customs and traditions of Moko-Moko, in this dialect, was printed with a translation at Bencoolen. But it is only in recent years that the Dutch have commenced to pay the dialect the attention it deserves, by publishing texts, with transliteration and translations, and supplying other materials for its investigation. See the *Transactions* and *Journal* of the Asiatic Societies of Batavia and the Hague, the *Indische Gids*, and more especially the philological portion, by A. L. van Hasselt, of *Midden-Sumatra*, iii. 1 (Leyden, 1880), where also the best and fullest account of the Renchong character is to be found. Of other Malay dialects in Sumatra, only the one spoken at Achih (Achin) deserves mention; in Java the Batavian dialect shows the most marked peculiarities. The numerous and greatly divergent dialects spoken in the Molucca Islands (valuable information on which has been supplied by F. S. A. de Clercq, G. W. W. C. van Hoevell, and A. van Ekris) and in Timor differ so materially from the Malay of the peninsula and of Menangkabo that they cannot be called Malay dialects at all; whereas the Malay spoken in some parts of the Minahassa (Celebes) scarcely differs from Malay proper.

There is no grammar of Malay by a native writer with the sole exception of a small tract of 70 pages, entitled *Bustānu 'lkātibīn*, by Rāja Ali Hajji of Rhio, which was lithographed in the island of Peñengal in 1857. A. Pigafetta, who accompanied Magellan in his first voyage round the globe, was the first European whose vocabulary of Malay words (450) has come down to us. Next in the field were the Dutch, who provided a medium of intercourse between their traders and the Malays. F. Houtman's *Vocabulary and Conversations, in Dutch, Malay, and Malagasy*, appeared at Amsterdam in 1603; and it may be noted that the Malay spoken in those days does not appear to have materially altered since. The same dialogues appeared in English and Malay in 1614. Since then numerous grammars, dictionaries, and conversation books have been brought out by English and Dutch writers. As the best helps at present available for the study of Malay may be recommended W. E. Maxwell's *Manual of the Malay Language*, London, 1882 (especially valuable for its full treatment of the idioms); P. Favre, *Grammaire de la langue Malaise*, Vienna and Paris, 1876; and *Dictionnaire Malais-Français, ib.*, 1875, 2 vols.; *Dictionnaire Français-Malais, ib.*, 1880, 2 vols.; J. J. de Hollander, *Handleiding bij de beoefening der Maleische taal en letterkunde*, Breda, 1882; J. Pijnappel, *Maleische Spraakkunst*, Hague, 1866; and *Maleisch-Hollandsch Woordenboek*, Amsterdam, 1875. The printing of Von Dewall's *Dictionary*, edited by H. N. van der Tuuk, is still in progress at Batavia.

Literature.—There are two kinds of Malay popular literature—the one in prose, the other in poetry. The former comprises the proverbs, the latter the "pantuns." "Agriculture, hunting, fishing, boating, and wood-craft are the occupations or accomplishments which furnish most of the illustrations, and the number of beasts, birds, fishes, and plants named in a collection of Malay proverbs will be found to be considerable" (W. E. Maxwell, *Malay Proverbs*). H. C. Klinkert published a collection in the *Bijdragen tot de taalkunde van N. I.* (Journal of the Asiatic Society of the Hague) for 1866, pp. 39-87. See also J. Habbema on the Menangkabo proverbs, in vols. xxv. and xxvi. of the Batavian *Tijdschrift*, and Favre's *Dictionnaire Malais-Français, passim.* The pantuns are improvised poems, generally (though not necessarily) of four lines, in which the first and third and the second and fourth rhyme. They are mostly love poems; and their chief peculiarity is that the meaning intended to be conveyed is expressed in the second couplet, whereas the first contains a simile or distant allusion to the second, or often has, beyond the rhyme, no connexion with the second at all. The Malays are fond of reciting such rhymes "in alternate contest for several hours, the preceding pantun furnishing the catchword to that which follows, until one of the parties be silenced or vanquished." See T. J. Newbold, *Account of the British Settlements in the Straits of Malacca*, vol. ii. 346; Klinkert in the *Bijdragen* for 1868, pp. 309-70; L. K. Harmsen in the *Tijdschrift*, vol. xxi. pp. 480-533 (Menangkabo). If the Malays have kept entirely aloof from the influences of Islam in this the most characteristic part of their literature, they have almost equally preserved their independence in the other departments. Not that this may be considered entirely to their credit; for, if they had endeavoured to infuse into their writings some of the spirit of Arabic and Persian historiography, poetry, and fiction, it could not but have benefited the character of their own literary productions. As it is, their histories and chronicles are a strange motley of truth and fiction; their poems and novels lack coherence and imagination, and are singularly monotonous and devoid of that spirit of chivalry which pervades the corresponding branches of literature among the leading nations of Islam. As Malay copyists are much given to making arbitrary changes, it happens that no two MSS. agree, and that of many a popular work different recensions exist, which, moreover, often go by different names. This circumstance greatly tends to increase the difficulties of editing Malay texts. Works on specially Mohammedan subjects (theology, law, ethics, mysticism) are of course only imitations of Arabic or Persian originals; there are also numerous novels and poems treating of purely Mohammedan legends. But not only is there traceable in many of these a slight undercurrent of Hinduism and even pre-Hinduism; the Malays possess also, and indiscriminately read along with their Mohammedan books, quite as many works of fiction of purely Hindu origin. The want, however, of political cohesion, and of a national spirit among tribes so scattered as the Malays are, which could have favoured the growth of a national epic or national songs, sufficiently accounts for the absence from their literature of any productions of this class, such as exist in Bugi and Macassar literature. The most popular of their poetical productions are the *Sha'ir Ken Jambūhan*, *Sha'ir Bidāsāri*, *Sha'ir Jauhar Mānikam* and *Sha'ir 'Abdu'lmulūk*, all of which have been printed. Among the prose works there are various collections of local laws and customs (*undang-undang*), chronicles (such as the *Sajarat malāyu*), books on ethics (the best are the *Makota sagāla raja-rāja*, and the *Bustānu'ssalātīn*, and a very large number of works of fiction and legendary lore, some of which possess much descriptive power. They all bear the title Hikāyat, and the following are the best-known: *H. Hang Tūah*, *H. Hamzah*, *H. Ismā Yatīm*, *H. Jumjumah*, *H. Bakhtiyār* (*Sādah Bakhtīn*, *Gholām*), *H. Sīmiskin*, *H. Sultān Ibrāhīm*, *H. Sri Rāma*, *H. Pandāwa līma.* Several of these and many other works not mentioned here have appeared in print (with or without translation) chiefly in Holland, Batavia, and Singapore, and extracts have been given in the various Malay chrestomathies by Dulaurier, De Hollander, Niemann, Van der Tuuk, Grashuis, and in Marsden's *Malay Grammar.* The best recent Malay writer was 'Abdullah ibn 'Abdelkādir Mūnshi of Singapore, who died, it is said of poison, at Mecca, some eight and twenty years ago. His autobiography, "journey to Kelantan," and "pilgrimage to Mecca" are patterns of Malay style, though the author's contact with educated Europeans is traceable in them, while his translation (from the Tamil version) of the *Panchatantra* is free from such influence.

Malay literature is fairly represented in England in the British Museum, the India Office, and the Royal Asiatic Society, and descriptive catalogues of the Malay MSS. in each of these libraries are available. See Niemann in the *Bijdragen*, iii. 6, p. 96-101; Van der Tuuk in *Tijdschrift voor Ned. Indië* for 1849, i. p. 385-400, and in the *Journal of the Royal Asiatic Society*, new series, ii. p. 85-135. An account of the Leyden collection, by J. Pijnappel, is given in the *Bijdragen*, iii. 5, p. 142-178. The finest collection of Malay MSS., upwards of 400 volumes, is in the library of the Asiatic Society of Batavia. See L. W. C. van den Berg, *Verslag van eene verzameling Maleische, &c., handschriften*, Batavia, 1877. If it had not been for the loss, by fire, on their passage from India, of three hundred Malay MSS., the property of the late Sir T. S. Raffles, England would now boast of the largest assemblage of Malay MSS. in the world. On Malay literature in general compare G. H. Werndly, *Maleische Spraakkunst*, Amsterdam, 1736, pp. 227-357; E. Jacquet in the *Nouveau Journal Asiatique*, vol. ix. (1832), pp. 97-132, and 222-253; T. J. Newbold, *British Settlements in the Straits of Malacca*, 1839, vol. ii. pp. 215-368; E. Dulaurier, *Mémoire, lettres, et rapports*, Paris, 1843; J. J. de Hollander, *Handleiding bij de beoefening der Maleische taal en letterkunde*, Breda, 1882, pp. 277-388; and G. K. Niemann, in *Bijdragen*, iii. 1 (1866), pp. 113-46, 333 *sq.* (R. R.)

MALCOLM, Sir John, G.C.B. (1769-1833), soldier, diplomatist, administrator, and author, was born at Burnfoot of Esk, near Langholm, Dumfriesshire, Scotland, on May 2, 1769. At the age of twelve he received a cadetship in the Indian army, and in April 1783 he landed at Madras, shortly afterwards joining his regiment at Vellore. In 1792, having for some time devoted himself to the study of Persian, he was appointed to the staff of Lord Cornwallis as Persian interpreter, but two years afterwards was compelled by ill-health to leave for

England. On his return to India in 1796 he became military secretary to Sir Alured Clarke, commander-in-chief at Madras, and afterwards to his successor General Harris; and in 1798 he was appointed by Lord Wellesley assistant to the resident at Hyderabad. In the last-mentioned capacity he highly distinguished himself by the manner in which he gave effect to the difficult measure of disbanding the French corps in the pay of the nizam. In 1799, under the walls of Seringapatam, began his intimacy with Colonel Arthur Wellesley, which in a short time ripened into a life-long friendship; in the course of the same year he acted as first secretary to the commission appointed to settle the Mysore government, and before its close he was appointed by Lord Wellesley to proceed as envoy to the court of Persia for the purpose of counteracting the policy of the French by inducing that country to form a British alliance. Arriving at Teheran in December 1800, he was successful in negotiating favourable treaties, both political and commercial, and returned to Bombay by way of Baghdad in May 1801. He now for some time held the interim post of private secretary to Lord Wellesley, and in 1803 was appointed to the Mysore residency. At the close of the Mahratta war, in 1804, and again in 1805, he negotiated important treaties with Sindhia and Holkar, and in 1806, besides seeing the arrangements arising out of these alliances carried out, he directed the difficult work of reducing the immense body of irregular native troops. In 1808 he was again sent on a mission to Persia, but circumstances prevented him from getting beyond Bushire; on his reappointment in 1810, he was successful indeed in procuring a favourable reception at court, but otherwise his embassy, if the information which he afterwards incorporated in his works on Persia be left out of account, was (through no fault of his) without any substantial result. He sailed for England in 1811, and shortly after his arrival in the following year was knighted. His intervals of leisure he devoted to literary work, and especially to the composition of a *History of Persia*, which was published in two quarto volumes in 1815. On his return to India in 1817 he was appointed by Lord Moira his political agent in the Deccan, with eligibility for military command; as brigadier-general under Sir T. Hislop he served against the Mahrattas and Pindharis, and took a distinguished part in the victory of Mehidpur (December 21, 1817), as also in the subsequent work of following up the fugitives, determining the conditions of peace, and settling the country. In 1821 he returned once more to England, where he remained until 1827, when he was appointed to the Bombay government. His influence in this office was directed to the promotion of various economical reforms and useful administrative measures. Leaving India for the last time in 1830, he shortly after his arrival in England entered parliament as member for Launceston, and was an active opponent of the Reform Bill. He died of paralysis on May 30, 1833.

Besides the work mentioned above, Sir John Malcolm published *Sketch of the Political History of India since . . .* 1784, in 1811 and 1826; *Sketch of the Sikhs*, 1812; *Observations on the Disturbances in the Madras Army in* 1809, 1812; *Persia, a Poem*, anonymous, 1814; *A Memoir of Central India*, 2 vols., 1823; and *Sketches of Persia*, anonymous, 1827. A posthumous work, *Life of Robert, Lord Clive*, appeared in 1836. See *Life and Correspondence of Major-General Sir John Malcolm, G.C.B.*, by J. W. Kaye, 2 vols., 1856.

MALDAH, a district in the lieutenant-governorship of Bengal, India, between 24° 29′ 50″ and 25° 32′ 30″ N. lat., and 87° 48′ and 88° 33′ 30″ E. long., the Ganges river forming the continuous west and south-west boundary. The administrative headquarters are at English Bázár. The district, of which the area is 1813 square miles, is divided into two almost equal parts by the Mahánandá river, flowing from north to south. The western tract between the Mahánandá and the main stream of the Ganges is a low-lying alluvial plain of sandy soil and great fertility. The eastern half is an elevated region broken by the deep valleys of the Tángan and Purnábhábá rivers and their small tributary streams. The soil of this district is a hard red clay; and the whole is overgrown with thorny tree jungle known as the *kátál*. Agricultural prosperity centres on the Mahánandá, where mango orchards and high raised plots of mulberry land extend continuously along both banks of the river. The Ganges nowhere intersects the district, but skirts it from its north-western corner to the extreme south. The Mahánandá flows in a deep well-defined channel through the centre of the district, and joins the Ganges at the southern corner. Its tributaries are the Kalindri on the right, and the Tángan and Purnábhába on the left bank.

The population in 1881 was 710,310 (347,055 males and 363,255 females). In 1872 the number of inhabitants was 671,974,—355,276 Hindus, 307,460 Mohammedans, 9195 aborigines, and 43 Christians. The male adult agriculturists numbered 134,358. Only two towns then contained upwards of 5000 inhabitants, viz., English Bázár or Angrazábád, 12,859, and Maldah, 5262. The most important centres of commerce are Haiatpur on the Ganges, and Rohanpur on the Purnábhábá, just above the confluence of that river with the Mahánandá. Rice constitutes the staple crop, and occupies about 53 per cent. of the total cultivated food crop area. The miscellaneous crops include indigo, mulberry, and mangoes. The average rate of rent may be put at over 4s. an acre. There is little that is peculiar in the land tenures of the district, except the existence of several large rent-free estates, granted as endowments to Mohammedan *fakírs*. Among cultivating tenures, the *hal hásilá* deserves notice, under which the annual rent varies according to the nature of the crop raised. This tenure is most common in the backward parts of the district, and one of its incidents is that it allows a certain proportion of the village lands to lie fallow. Maldah is liable to some extent to the calamities of flood and drought; but the means of communication by river are sufficiently ample to prevent scarcity from intensifying into acute distress. The two staple manufactures are silk and cotton. Brass ware of excellent quality is manufactured at Nawábganj, and paper in certain villages. The principal exports are rice, silk, indigo, brass ware, and mango fruit. The imports comprise cotton cloth, salt, sugar, spices, and betel-nuts. The net revenue of the district in 1880–81 amounted to £60,674, of which £37,998 was derived from the land tax, and £11,538 from excise. Education was afforded in 1872 by 170 schools, attended by 4207 pupils. The average annual rainfall of the district is returned at 54·56 inches. The chief epidemic diseases are malarious fever, cholera, and small-pox.

Maldah supplied two great capitals to the early Mohammedan kings of Bengal; and the sites of Gaur and Panduah exhibit the most interesting remains to be found in the lower Gangetic valley. See GAUR, vol. x. p. 112 *sq.* The connexion of the East India Company with Maldah dates from a very early period. As far back as 1686 there was a silk factory there. In 1770 English Bázár was fixed upon for a commercial residency, the buildings of which at the present day form both the public offices and private residence of the collector.

MALDEN, a city of the United States, in Middlesex county, Massachusetts, situated on the Malden river, 5 miles north of Boston. Malden was settled in 1634, being then known as the village of Mystic Side. It was incorporated as a town under the name of "Mauldon" in 1649, and became a city in 1882. It is a place of considerable industry, producing india-rubber boots and shoes, leather, lasts, sandpaper, &c. There are Turkey red dye-works; and the U. S. Government has a depôt where large quantities of saltpetre are stored. Judson, the apostle of Burmah, was born in the town in 1788. The population has increased from 7367 in 1870 to 12,017 in 1880.

MALDIVE ISLANDS, a remarkable archipelago in the Indian Ocean, the northern extremity of which is 7° west of Ceylon, and which extends in length from north to south, from 7° 7′ N. lat. to 0° 42′ S., a space of 540 British miles (or about as far as from Kirkwall in Orkney to Dover), and is limited in width by the meridians 72°

27′ and 73° 50′.[1] The strange appearance which this group assumes in the old maps of the 16th and 17th centuries (see fig. 2, from *Mappemonde*, cited on p. 329) is entirely inaccurate in detail, but hardly so singular as the reality exhibited by modern surveys.

The archipelago is in some respects one of the most distinctly typical examples of a great aggregation of coral islands; indeed the technical name adopted by modern science for the annular coral formation which they exhibit (viz., *atoll*) has been taken from the language of these islands.[2] For Mr Darwin's theory of such formations see vol. vi. p. 378. Objections to this have recently been raised by Mr John Murray, but these do not affect the description.[3]

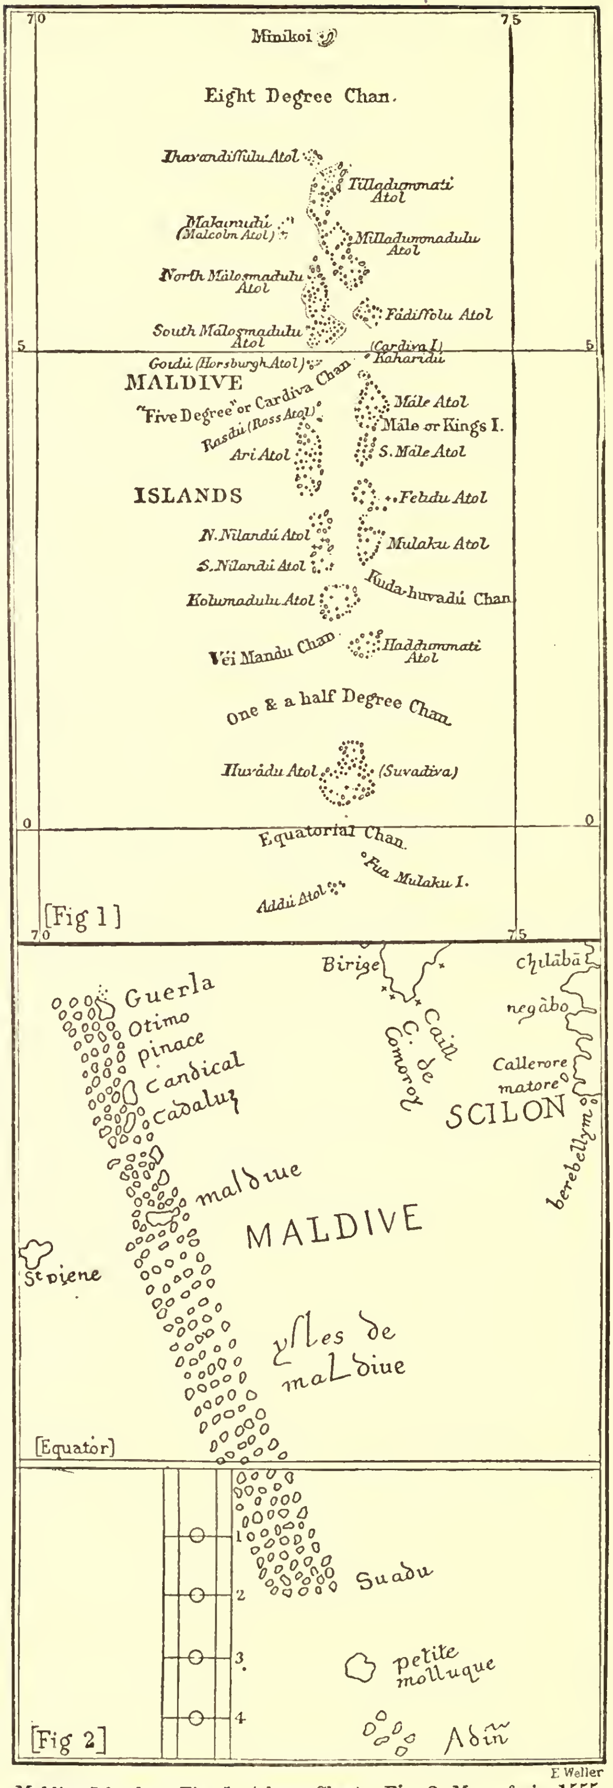
The Maldive archipelago in plan may be compared to a chain suspended from a peg, each link of which chain is an irregularly elliptical chaplet of islets, the greater axes of these quasi-ellipses varying from about 90 miles downwards. Taking separately any one of these chaplets (or *atolls*), we now know it to be the nearly level summit of a submarine table-mountain, rising abruptly from the unfathomable ocean, and approaching the surface within a distance which varies in different atolls from 20 to 45 fathoms. The quasi-elliptical margin of the atoll is fringed, and the central expanse of its area is more or less sparsely studded, "with oval basins of coral-rock just lipping the surface of the sea, and each containing a lake of clear water" (Darwin). These small oval basins, or ring-shaped reefs and islets, are in fact essentially miniatures of the atoll itself.

The general impression made by the Maldive atoll is vividly drawn by the French adventurer Pýrard de la Val (1602–7):

> "Each *atollon* is detached, and contains within it a great multitude of small islands. It is a marvel to see one of these *atollons*, compassed all round by a great bank of stone, insomuch that no art of man could so well enclose with walls an equal space of ground. . . . . Looking from the middle of an atollon you see all round you that great bank of stone encircling the isles and defending them against the violence of the sea. And it is a fearful thing even for the boldest to draw near this bank and see the waves come on and break furiously all round . . . . so that you see all round you as it were a whitened wall."

Though the barrier reef, or *banc de pierre*, of which Pyrard speaks, exists in most of the atolls, there is none in the most northerly of the great atolls (Tiladummati and Milladummadu, two divisions of one atoll). In this there are broad and safe navigable channels, from 1 to 2 miles wide, between all the islands forming the chaplet. A vessel can enter the atoll by any one of these channels, and steer within it in any direction, anchoring anywhere on a sandy bottom in 20 to 25 fathoms. In the more southerly atolls entrance channels are only found at occasional intervals, though in all they are pretty numerous. Thus in Suadiva, the most southerly of the large atolls (50 miles from north to south, 36 miles from east to west), which has a barrier reef on great part of its contour, there are forty-two channels by which a ship can enter the lagoon.

It is observed that in the double part of the chain of atolls the openings are most numerous on those sides which are in juxtaposition. Thus on the three atolls of



Maldive Islands. Fig. 1, Admy. Chart; Fig. 2, Map of *cir.* 1555

[1] The solitary island of Minucoy (*Minakai*), lying 70 miles north of the Maldives (med. lat. 8° 16′ 30″ N.; population 3000), pertains to these islands by the race and language of its people, but, as it has long belonged to the raja of Cannanore, it is usually classed with the Laccadives.

[2] Mald. *atolu*. The word *atollon* is already defined as a generic expression in Zeidler's *Universal Lexicon*, 1732 ("a name applied to such a place in the sea as exhibits a heap of little islands lying close together, and almost hanging on to each other"). *Atolu* is probably connected with the Singhalese prep. *etula*, "inside" (Bell).

[3] See *Proc. Roy. Soc. Edin.*, 1879–80, No. 107.

Ari and North and South Nilandu there are on the inner or eastern side seventy-three deep-water channels through the barrier, on the outer or western side only twenty-five; whilst on the atolls of South Mâlé, Felidû, and Mulaku, which lie facing the three former, there are on the inner or western side fifty-six deep-water openings, and on the outer or eastern side only thirty-seven. These differences are doubtless due to differences in the action of the sea caused by the juxtaposition of the two rows of atolls, and analogous facts are observed elsewhere in atolls exposed to trade-winds.

Immediately outside of the great chaplets or atolls the figures of the soundings rise suddenly. Thus at Ihavandiffulu (Heawandoo of charts), the most northerly atoll, close to the margin of the reef the line gave 50 and 60 fathoms, and at 300 yards distance there was no bottom with a 300-fathom line. And this sudden increase of depth applies to the deep channels between the atolls as much as to the ocean east and west of them.

We have spoken of the small reefs, which fringe the atolls and dot their area, as also ring-shaped. This is the type, but it is not universal. The charts show that where the channels or breaches through the marginal reef of the atoll are few or narrow there are no minor annular reefs (*e.g.*, in Suadiva); where the channels are somewhat broader, the intercepted portions of reef are annular, but not the reef in the central area; where the channels are broadest, almost every reef throughout the atoll is more or less perfectly annular. The depth of the lagoon within these rings is generally 5 to 7 fathoms, but sometimes, as in Ari atoll, it reaches 12 fathoms. The outer margin of the rings is bordered with living coral, within which is a flat surface of coral-rock. On this flat, sand partially indurated, and fragments of coral, &c., have accumulated, and been converted into islets clothed with vegetation. Such islets sometimes fill the whole ring of reef, and sometimes are mere strips occupying a segment of it. Obviously the whole aggregate of actual dry land in such an archipelago is infinitesimal compared with the area of the atolls. The highest part of the islands is generally about 6 feet above water. Moresby found the surface-sand usually about 3 feet thick, the upper part partially mixed with vegetable matter so as to form a light soil; below this a white compact sand, and then a soft sandstone 2 feet thick, below which it softened to sand again, and fresh-water appeared.

All the islands of any extent are well clothed with wood, including many fine large trees and the ordinary shrubs of the Ceylon coast-jungle; where the jungle has been cleared, grass grows luxuriantly. But the cocoa-palm is the characteristic tree; and, low as the islands are, being covered with these, they can be seen from a masthead at 15 miles. The appearance they present is that of a tuft or line of trees rising out of the water.

A good deal of vicissitude seems to go on in the formation of new islets and decay of old ones, of which our survey-officers met with various instances.

All the inhabited islands, and some besides, afford fresh water. But the quality of water varies; and it is not uncommon to see two wells within a few feet of each other, one brackish and the other excellent. None of the wells are more than 6 feet deep.

The whole archipelago has from the earliest reports of it formed a little kingdom. Physically the number of atolls may be reckoned as nineteen, besides some solitary islands; but administratively these are grouped into thirteen, and the term atoll has been transferred to this division. We give in the following table the list of these (political) atolls, in a second column the spelling of the marine charts, and in a third the list of atolls as given by Pyrard de la Val, in the beginning of the 17th century.

Names of Atolls.	As in Moresby's Charts, 1837.	As in Pyrard de la Val.
1. Tilladummatî.	Tilla Dou Matte.	Tilla dou matis.
2. Miladummadulu,[1] or Miladummadu.	Milla Dou Madou.	Milla doue madoue.
3. Fâdiffolu.	Paddipholo.	Padypolo.
4. Malosmadulu.	Mahlos Mahdou.	Malos madou.
5. Mâlé.	Mālé.	Malé Atollon.
6. Ari.	Ari.	Ariatollon.
7. Felidu.	Phah-Lee-doo.	Poulisdous.
8. Mulaku.	Moloque.	Molueque.
9. Nilandu.	Nillandoo.	Nillandous.
10. Kolumadulu, or Kolumandu.	Collomandoo.	Collomadous.
11. Haddummatî.	Adou Matte.	Adou matis.
12. Suvâdiva, or Huvâdu.	Suadiva, or Hooah-doo.	Souadou.
13. Addu, which includes the island of Fua Mulaku.	Addoo (and Phooa Moloku Island).	Addou and Poua Molueque.

The list from Pyrard shows that the division in the beginning of the 17th century was identical with what it now is. But we may gather that it is substantially of much greater antiquity, from the statement of Ibn-Batuta (*c.* 1343), who says the islands were divided into *aklîm* (κλίματα), each under a governor. He mentions eleven of these:—Bâlibûr, Kannalûs, Mahal, Tilâdîb, Karaîdû, Tîm, Tiladummati, Hiladummati, Barîdû, Kandakal, Mulûk,—of which indeed the names of only seven, viz., (1) Tiladummati, (2) Heladummati, (3) Bâlibûr, (5) Mahal, (7) Barîdû, (8) Mulûk, (12) Suweid, can be identified with those of the existing divisions. But another, Karaîdû, no doubt represents Karadîva, a well-known solitary island north of Mâlé atoll; Kandakal is an island of the Miladummadu atoll, called in the charts Condaicoll; Tîm appears near the north of Tilladummati as Oteim; and the three—Kannalûs, Kandakal, and Tîm—are presented prominently as the islands Camdalus, Camdicall, and Otimo in the *Mappemonde* made for Henry II. of France (*c.* 1555, see Jomard's *Facsimiles*, livr^n. vi., copied in fig. 2 *supra*; and compare *Portolano* of 1570, copied in Mr Birch's translation of Albuquerque's *Commentaries*). Possibly, therefore, the Moorish traveller had substituted true names of islands which he remembered for the names of atolls which he had forgotten.

The Maldives are inhabited by a people of old civilization, professing Islam, and ruled by a sultan of ancient lineage. What the number of islands may be we cannot say. They are popularly estimated at 12,000, as appears by the ancient style of the sultan as "king of 12,000 islands and 13 atolls." (See also *Marco Polo*, 2d ed., 1875, ii. 417–19.) Those marked with names in the British survey amount to 602, and the inhabited islands to 178. The men are of a darkish copper colour, short stature (5 feet 2 inches), and poor physique, but oval contour of face, pleasing expression, and large bright eyes, suggesting resemblance to both the Singhalese and Malabar people. The women are fairer than the men, with regular features and clean healthy aspect. A few of the people bear signs of African mixture, easily accounted for; and probably the blood of the small communities has been tinged by the occasional settlement of other foreigners. The people are decidedly unwarlike; and there is hardly any crime of violence among them. They are said to be lax in morals and conversation; but otherwise their character and disposition have favourably impressed visitors. Though suspicious of strangers, they are hospitable; and among themselves they are kindly, and affectionate to their kindred and in attendance on the sick. They are very cleanly in person

[1] The frequent termination *du* represents the Singh. *dúva*, *díva*, and Sansk. *dvípa*, "island." Bell takes *madulu* for Sansk. *maṇḍala*, "region." Qu. *mahâ-atoḷu*, "great atoll"?

and domestic habits. The population has been guessed in some books at 200,000; almost certainly one-tenth of that number would be an ample estimate. Moresby states the population of 98 islands, and the aggregate is 11,310. In the same proportion 178 islands would give 20,543; but the aggregate quoted includes the King's Island, which is much above the average in population.

The language is undoubtedly a dialect of Singhalese approaching the old *Elu*, but indicating a separation of ancient date, and it is more or less Mohammedanized. Nothing at present can be said of grammar. But Mr Albert Gray has drawn out in parallel columns the Maldivian words given by Pyrard with the modern Singhalese equivalents (see *Jour. Roy. As. Soc.*, quoted at end). A cursory analysis of the list (which contains 275 words) gives the following result:—

1.	Words evidently to be explained by Singhalese	58·0 per cent.
2.	,, less evidently ,, ,,	2·2 ,,
3.	Persian and Arabic	10·6 ,,
4.	Malay	1·9 ,,
5.	Tamil	1·1 ,,
6.	Portuguese	1·1 ,,
7.	Sanskrit or Pali, not Singhalese	0·8 ,,
8.	Undetermined	24·3 ,,

Combining 1, 2, and 7, we have 61 per cent. of words of Singhalese or Sanskrit origin. And an analysis by Mr Bell of one of the sultan's letters to the Ceylon Government gives 65 per cent. of such words.

The origin of the name *Mal-dîva* or *Mâldîva* is obscure. Dîva is a familiar word in the Indian *prakrits* (Sansk., *dvîpa*; Pali, *dîpo*) for an island. By a form of this word the people formerly designated themselves and their country, and this survives in letters of last century from the sultan to the Ceylon Government, in which he designates his kingdom as *Diveḥi Râjjé*, and his subjects as *Diveḥi mîhun*, "island people." There is a very old example of this use in Ammianus Marcellinus, who, in reference to the alleged excitement in the East at the accession of Julian, says that missions were prepared "*ab usque* Divis *et* Serendivis," from the people of the *Dîvas* and of *Serendîva* or Ceylon. And this is the name *Dîva* or *Dîba-jât* (Pers. plural form) by which these islands are described by the early Arabian geographers. The first literary use of the whole name is Ibn Batuta's *Dhîbat-al-Mahal* (14th century), an Arabized form, sometimes used (*Mahal-dîb*) by the people now, though the proper form seems to be *Malé*. *Malé-diva* may possibly, as Bishop Caldwell (comp. *Grammar*, 2d ed., Introd. p. 28) and others have suggested, have meant the "islands of Malé" or Malabar. On the other hand *Mâlâ* (Sansk.), "a chaplet" or "row," is not an impossible etymology considering how naturally the word "chaplet" occurs in the endeavour to describe an atoll. But these are conjectures. Under the sultan (who styles himself on coinage "Lord of Land and Sea") there used to be six recognized viziers or councillors (but this system is now obsolete), besides a chief of law and religion called *fandiari*. Over each of the thirteen atolls is a king's agent, called *atoḷu-veri*, who collects the revenue. This official is often one of the royal family, or a vizier's son, and often resides at Mâlé, employing a deputy. On each island is a headman called *rarḥu-veri*. There is also on each island containing forty inhabitants a *kâtibu* (Ar., *kâtib*, "scribe"), who acts as judge and minister, celebrating marriages, &c. Pyrard calls him the *curé*.

Some of the oldest accounts of these islands represent them as always governed by a woman,—a notion which probably arose among the Mohammedan visitors from finding that female heirs were not precluded from succession. Just the same notion was held about Achîn in the 17th century, because there chanced to reign there several female sovereigns in succession (see vol. i. p. 97). We do find females nominally reigning on the Maldives on two of the rare occasions when we have glimpses of their state, viz., in the time of Ibn Batuta, and again in the last century.

Islam is universally professed by the people, nor is there tradition of any other religion, though there are a variety of Pagan superstitions and some doubtful traces of Buddhism. Thus the *Bo-tree* (or pippal), so sacred among the Buddhists of Ceylon, is still cherished near mosques. Pyrard de la Val was informed that the conversion to Islam took place two centuries at most before his time, *i.e.*, about 1400. But, unless there was a decay and revival, we know this to be wrong, as the islanders were Mohammedan in the time of Ibn Batuta (1343). And this traveller tells that the father of one of his wives in the islands had for his grandfather (though the word used may mean "ancestor" only) the Sultan Dâûd, who was grandson of Ahmed Shanû-râza, the first king who adopted Islam. Accepting the meaning of "grandfather," this would carry the conversion back to about 1200, a probable epoch, for about that time there was a considerable outburst of missionary zeal in Islam, which led to the conversion of the coast states of Sumatra, &c. Ibn Batuta records an inscription on the Jami Mosque of the King's Island which ran:— "Sultan Ahmed Shanû-râzah embraced Islam at the hands of Abu 'l Baraḳât the Berber from the West"; but no date is given.

We have mentioned the occurrence of the name *Divi* in Ammianus. At an earlier date Ptolemy notices the numerous islands lying in front of Taprobane, alleged to number 1378. It is possible also that the *Maniolæ* of the same geographer may constitute a duplicate indication of the Maldives. For in the gossip of Palladius about India (see C. Müller's *Pseudo-Callisthenes*, p. 102) this name *Maniolæ* is applied to a group of islands, 1000 in number, that lay near Taprobane, and respecting which the old fable of the magnetic rock was current, which Ptolemy also connects with the *Maniolæ*.

Cosmas (*c.* 545) shows distinct knowledge of the Maldives (without naming them) as numerous close-set small islands round Sielediba or Taprobane, in all of which were found cocoa-nuts and fresh water. Passing next to the Arabian notices translated by Renaudot and Reinaud, which date from 851, and to the work of Mas'ûdi in the next century, we find tolerably correct accounts of the *Dîbas*, said to be 1900 in number. Al Birûni's account (*c.* 1030) of the islands is marked by his usual perspicacity and accuracy. The *Dîvas* are islets which form themselves in the sea, appearing like a ridge of sand, extending and uniting till they present a solid aspect. But also with time some decompose and melt away in the sea, whilst the inhabitants transfer their cocoa-trees and possessions to an island which is waxing instead of waning,—circumstances corroborated by modern observation.

All the old authors speak of coir (the fibre of the cocoa-nut husk) as one of the staple products of these islands, and the importance of this article for marine equipment led the Portuguese about 1518 to establish a factory on the Maldives. João Gomez, the head of the settlement, was at first well received, but his arrogant and violent conduct gave great offence to the Mohammedan traders from Cambay, who brought an armed flotilla against the Portuguese and put them all to death. The Portuguese several times renewed the attempt to establish themselves on the islands, and maintained a garrison for some time, but these endeavours had no permanent result. The islanders were also frequently subject to raids at the hands of the Mopla pirates of Malabar, and sometimes also, it would seem, to maltreatment from the crews of European vessels. The MS. diary of Mr (afterwards Sir William) Hedges, who passed through the Maldives in 1685, says: "We putt out a piece of a Red Ancient to appear like a Moor's Vessell: not judging it safe to be known to be English; Our Nation having lately gott an ill Name by abusing ye Inhabitants." Such circumstances probably led the islanders to place themselves in relation with the rulers of Ceylon; and in 1645 occurs the first record of the embassy from the sultan of the Maldives to the Dutch governor at Colombo, which has continued to the present day, under Dutch and English, to arrive annually, bringing some poor offering, as a vague token of homage and claim of protection. The last political trouble of which we have notice occurred in the middle of last century. In 1753 the chief minister conspired to hand over the islands to the Ali raja of Cannanore. A Mopla force occupied Mâlé, and carried off the sultan. The traitor himself was rewarded by being thrown into the sea. The oppression of these foreigners made the islanders rise and expel them. The sultan never returned, and a minister who had ruled on his behalf assumed the kingdom in 1760. In 1754 Dupleix occupied Mâlé with a small French detachment, which remained several years. In 1811 the sultan wrote to the governor-general (Lord Minto) to complain of the violent conduct of the officers of a ship under British colours which had been wrecked on the islands. Lord Minto sent back a courteous answer with presents. There have been no other events during the British rule in Ceylon, and the last sultan, Mohammed Moidin, reigned without dispute from 1835 to 1882.

We have only three substantial accounts of the Maldives from actual residence:—(1) that of the Moor Ibn Batuta, who lived upon them more than a year (1343-44), and filled the office of cadi; it contains much curious detail; (2) the narrative of François Pyrard de la Val, a French adventurer on board a ship of St Malo, which was wrecked on a reef of the Malosmadulu atoll in 1602, and who was detained five years on the islands,—a book of the greatest interest and accuracy, and by far the best account of these islands in existence; (3) a memoir by two officers of the Indian navy, Lieut. Young and Mr Christopher, who had been employed in the survey of the islands under Captain R. Moresby in 1834-35, and who volunteered to remain behind at Mâlé, in order to acquire a knowledge of the language, customs, &c., of the inhabitants,—a laudable effort, but the result of it was marred somewhat by the illness which prostrated both officers.

The sultan's residence and the capital of the kingdom is the island of Mâlé, which lies near the middle of the archipelago on the east side. It is about 1 mile long by ¾ mile wide, and contains a population approaching 2000. It has been at one time encompassed with walls and bastions, but these continue in repair only on the north and west. On the north too is an old fort, apparently of Portuguese construction, with a few old guns. On the north and west sides also advantage has been taken of the encircling reef as the base of a wall which has been built up so as to form the lagoon into a harbour for small craft, having a depth of 6 to 12 feet, and a width of 150 yards. The town is laid out in long regular streets at right angles, shaded with trees; the houses are in "compounds," with high fences excluding the street, and are surrounded with fruit trees and flowers. The sultan's palace, a large upper-roomed house, occupies with its appurtenances an area of ¼ square mile, enclosed by a shallow ditch now choked with vegetation. The houses generally are large cottages of about 28 feet by 12, formed of substantial wooden frame, with peaked roofs thatched with cocoa-leaves; the walls are matted with cocoa-leaves, but sometimes planked. There are several mosques, and at least one minaret, about 40 feet high, for the call to prayer. Stone-built houses, common in Pyrard's time, are so no longer; there is now but one. There are marked distinctions of rank among the people. At least six classes (we hardly know whether to call them castes) are recognized, of whom the two highest form a pure aristocracy. The sixth class, called *Kallo* ("black"?), consists of the common people generally, of whom the toddy-drawers are regarded as the lowest.

The employments of the common people are fishing, gathering cocoa-nuts and cowries, weaving, and toddy-drawing. Women beat the cocoa-fibre and twist it into yarn, make mats, prepare breadfruit by slicing and drying in the sun, spin and dye cotton thread, make sweetmeats of cocoa-nut and palm-sugar. Women are not secluded or veiled as in typical Moslem countries.

Rice, the staple of food, is imported. Other chief food is fish (chiefly dried bonito), breadfruit prepared in various ways, cocoa-nut, and a few fruits and vegetables. There are a few sheep and cattle on Mâlé island, which are occasionally slaughtered.

From the earliest notices the production of coir, the collection of cowries, and the weaving of excellent textures on these islands have been noted. This last, and that of fine mats are the only manufactures in which skill is shown. The mats seem to be now produced only in Suadiva atoll; the cloth chiefly, but not solely, in Malosmadulu atoll.

The chief exports of the islands, besides coir and cowries (a decreasing trade), are cocoa-nuts, *copra* (*i.e.*, cocoa-nut husk), tortoise-shell, and dried bonito-fish. An enormous amount of this last was formerly carried to Ceylon and Sumatra, the latter being supplied by traders who came from Chittagong. It has been known over the East from time immemorial as *koboli-mâs*, a corruption apparently of the Maldivian *kalû-bili-mâs*, "black bonito fish," sometimes further corrupted to *gomulmutch*.

Native vessels of 80 to 200 tons burthen make annual trips to Calcutta towards the end of the south-west monsoon, returning with the north-east monsoon in December. After leaving the Maldives they sight no land till Jagannâth. They carry thither the articles named above, and bring back rice, cotton stuffs, and sundries. These long voyages are not confined to the craft of the capital. Moresby, in 1834-35, found that a small island in the North Nilandu atoll sent annually to Bengal five or six boats of 80 to 100 tons each. On the same island there was a kind of navigation school, and the natives made and repaired some kind of nautical instruments. The old cash of the Maldives was the curious *lârîn* or "fish-hook money" made of a bent rod of silver. This has been long replaced by coins of base metal bearing the same name. The Anglo-Indian rupee is current for larger payments, and cowries are still used to some extent.

Two alphabets are known on the islands (besides the Arabic, which appears on tombstones and in other inscriptions). The first is an ancient alphabet, known as *Divehi Hakura*, "island letters." This in 1835 still survived in the southern atolls, and orders for these were written in it. It is written, like all the Indian alphabets, from left to right, and is evidently (by comparison with plate xvii. in Dr Burnell's *Elements of South Indian Palæography*) a form (with additional letters) of the old Tamil character (700 to 1300 A.D.) called in Malabar *Vatteluttu*, or "round hand."[1] The modern Maldive writing, called *Gabali Tana*, is usually[2] written from right to left, like Arabic. It is said to have been introduced in the 16th century, and has gone through several variations. Some of the letters are modified from the Arabic character, and nine of them are the Arabic numeral digits. On the other hand numerals are represented by letters of the alphabet. The former system of reckoning was duodecimal, but this is dying out.

Nothing is accurately known of the flora of the islands, and Kew possesses no illustration of it. Among larger trees are mentioned the banyan, pippal, breadfruit, tamarind, and a large tree called *kandu*, affording a very light wood used for rafts, floats, &c.; also species of pandanus. The castor-oil tree is abundant, though not used. The cocoa-nut of the islands, though of fine quality, is very small, not much larger than an orange. The tree itself furnishes the only indigenous wood used for boat-building. The *dumbari* (*Calophyllum inophyllum*) and *kuradi* (*Pemphis acidula*) are used in minor wood-work. A tuber, grated and steeped in water to remove its acridity, is made into flour,—perhaps a *Colocasia*, which Ibn Batuta mentions (*al-kalakâs*) as used to make a kind of vermicelli. They have also sweet potatoes, pine-apples, pomegranates (bearing fruit throughout the year), plantains, and most of the other tropical or subtropical Indian fruits, chillies, a few areca trees, &c. The double cocoa-nut of the Seychelles Islands (fruit of *Lodoicea Sechellarum*) used to be cast up on the islands, and was believed to be a submarine pro-

[1] The resemblance to this is much closer than to the old Singhalese with which it is compared in Mr Albert Gray's valuable paper already referred to.

[2] "Usually"; but a Maldivian skipper who gave James Prinsep information wrote it from left to right (see *Jour. As. Soc. Bengal*, v. 794).

duction,—hence called the sea cocoa-nut. It was valued for imaginary qualities, and exported to India. The Portuguese long believed it to be a product of these islands, and called it the Maldive cocoa-nut.

Animals are few. Those named are rats, numerous and destructive, which climb the cocoa-trees and devour the kernels; the large bat called in India "flying-fox," also said to destroy many small cocoa-nuts; tortoises; a small snake said to be harmless, &c. Domestic animals are rare; a few goats and cattle are reared on Mâlé.

The climate is not oppressive or disagreeable, but is very unhealthy for strangers, whether Asiatic or European. Ibn Batuta says every visitor was attacked by violent fever; Pyrard says the same; and this was substantially the experience of the survey officers and crews in 1834–35. The native crews also suffered much from the disease called *beri-beri* (which has dropsical symptoms, and is often fatal) and from violent bowel-complaints.

A complete report on the Maldives has recently been prepared by Mr H. C. P. Bell of the Ceylon civil service, who has visited the islands, and this is now being printed at Colombo. Mr Bell kindly enabled the present writer to see a copy before this article went to press, and many valuable facts have been added from it. Other materials used have been—Darwin, *The Structure and Distribution of Coral Reefs*, 1842; *Voyage de François Pyrard de la Val*, Paris, 1679 (previous editions 1611, 1615–16, 1619); *Voyages d'Ibn Batoutah*, trans. of Defrémery and Sanguinetti, tom. iv., Paris, 1858; Hamilton, *Desc. of Hindostan*, ii. 299; Moresby, *Naut. Directions for the Maldiva Islands*, &c., 1840; Young and Christopher, in *Trans. Bomb. Geog. Soc.*, vol. i. pp. 54–86; also see *ibid.* p. 102 and p. 313; *Trans. Roy. Geog. Soc.*, vol. ii. pp. 72–93; also vol. v. p. 398; *Jour. As. Soc. Bengal*, vol. v. p. 794; *Jour. Roy. As. Soc.*, vol. vi. pp. 42–76; *ibid.*, new series, vol. x. pp. 173–209 (paper by Mr Albert Gray), &c. (H. Y.)

MALDON, a municipal and parliamentary borough and seaport town of Essex, England, is situated on an acclivity rising from the south side of the Blackwater, 44 miles east-north-east of London and 16 south-west from Colchester. It consists principally of one main street with several cross streets at right angles. The church of All Saints, dating from 1056, is a spacious edifice consisting of chancel, nave, and aisles, with a triangular tower at the west end surmounted by an hexagonal spire. The church was restored in 1867, and new windows were added in 1877. St Mary's Church is also of very early origin, and was restored in the 17th century. The other public buildings are the grammar school, founded in 1547; the town-hall, formerly D'Arcy's tower, built in the reign of Henry VI.; and the public-hall, 1859. There are manufactures of crystallized salt, as well as breweries, iron foundries, and some shipping. The population of the municipal borough (3508 acres) in 1871 was 5586, and in 1881 it was 5476. That of the parliamentary borough (5177 acres) in the same years was 7151 and 7128.

Maldon, which is a very ancient town, is supposed to have received its name, meaning "cross hill," from a cross at one time erected on the eminence. From remains found in the neighbourhood there is no doubt that the place was of some importance in the time of the Romans, but the supposition that it was *Camulodunum* is not sufficiently established. On the western side of the town there are also traces of a large camp, but whether the work is of Roman, Saxon, or Danish origin it is impossible to say. The oldest historical mention of the town is in 913, when Edward the Elder encamped near it to impede the progress of the Danes. The town received its first charter from Henry II., and in 1553 it was incorporated by Queen Mary. From the time of Edward III. it returned two members to parliament, but since 1867 only one member.

MALEBRANCHE, Nicolas (1638–1715), a well-known disciple of Descartes, was the youngest child of Nicolas Malebranche, secretary to Louis XIII., and Catherine de Lauzon, sister of a viceroy of Canada, and was born at Paris on August 6, 1638. Of an extremely feeble constitution and somewhat deformed habit of body, he received his elementary education in Latin and Greek from a domestic tutor, and only left home when sufficiently advanced to enter upon a course of philosophy at the Collége de la Marche, and subsequently to study theology at the Sorbonne. He had resolved to enter the church, but his retiring and studious disposition led him to decline a stall in Notre Dame, and in 1660 he joined the Congregation of the Oratory. Both his ecclesiastical superiors and himself appear to have experienced considerable difficulty for some time in ascertaining what his special talents were, if they existed at all. He was first advised by Père Lecomte to devote himself to ecclesiastical history, and he accordingly set about a laborious perusal of the works of Eusebius, Socrates, Sozomen, and Theodoret, but it was found that "the facts refused to arrange themselves in his mind, and mutually effaced one another." Afterwards Richard Simon undertook to teach him Hebrew and Biblical criticism, but with no better success. At last having accidentally, in 1664, fallen upon one of the works of Descartes (the *Traité de l'Homme*), Malebranche was forthwith alive to his true vocation. So overpowered was he by the novelty and luminousness of the ideas, and by the solidity and coherence of the principles of his author, that (it is said) he was repeatedly compelled by violent palpitations of the heart to lay aside his reading. Malebranche was from that hour consecrated to philosophy, and especially to that of Descartes; and after ten years' study of the works of his master he produced, in 1674, the famous *Recherche de la Vérité*, which was followed at intervals by other works, both speculative and controversial, the titles of which are given below. Like most of the great metaphysicians of the 17th century, Malebranche interested himself also in questions of mathematics and natural philosophy, and in 1699 he was admitted an honorary member of the Academy of Sciences. During his later years his society was much courted, and he received many visits from foreigners of distinction. His death took place on October 13, 1715; according to Stock, the biographer of Berkeley, it was hastened by an excited metaphysical argument into which he had been drawn in the course of an interview sought by that philosopher. For a critical account of Malebranche's place in the history of philosophy, see Cartesianism (vol. v. p. 148 *sq.*).

The following is a list of his principal works:—*De la Recherche de la Vérité, ou l'on traite de la nature de l'esprit de l'homme, et de l'usage qu'il en doit faire pour éviter l'erreur dans les sciences* (1674, 6th ed. 1712; Latin translation by J. Lenfant at Geneva in 1685; two English translations, the second by Taylor in 1712; translations also into German, Dutch, and modern Greek); *Conversations Chrétiennes, dans lesquelles on justifie la Vérité de la Religion et de la Morale de Jesus Christ* (1676, and frequently); *Traité de la Nature et de la Grace*, 1680; *Méditations Chrétiennes et Métaphysiques*, 1683; *Traité de la Morale*, 1684; several polemical works against Arnauld from 1684 to 1688; *Entretiens sur la Métaphysique et la Religion*, 1688; *Traité de l'Amour de Dieu*, 1697; *Entretien d'un Philosophe Chrétien et d'un Philosophe Chinois sur l'existence et la nature de Dieu*, 1708; *Réflexions sur la Prémotion Physique*, 1715. A convenient edition of the *Œuvres choisies de Malebranche*, in two volumes, with an introduction, was published by Jules Simon in 1846.

MÁLER KOTLA, a native state in the Punjab, India, situated between 30° 24′ and 30° 41′ N. lat., and between 75° 42′ and 75° 59′ 15″ E. long., with an estimated area of 165 square miles, and an estimated population of 91,560. The chief products are cotton, sugar, opium, aniseed, tobacco, garlic, and grain. The gross revenue is £25,893. The nawáb exercises complete jurisdiction, and receives a compensation of £250 per annum in perpetuity from the British Government, on account of loss of revenue caused by the abolition of customs duties. Máler Kotla town is situated 30 miles south of Ludhiána.

The nawáb or chief is of Afghán descent; his family originally came from Cabul, and occupied positions of trust in Sirhind under the Mughal emperors. They gradually became independent as the Mughal empire sank into decay in the course of the 18th century.

In General Lake's campaign against Holkar in 1805 the nawáb of Máler Kotla sided with the British. After the subjugation and flight of Holkar, the English Government succeeded to the power of the Mahrattas in the districts between the Sutlej and the Jumna; and in 1809 its protection was formally extended to Máler Kotla, as to the other cis-Sutlej states against the formidable encroachments of Ranjít Sinh. In the campaigns of 1806, 1807, and 1808 Ranjít Sinh had made considerable conquests across the Sutlej; in 1808 he marched on Máler Kotla, and demanded a ransom of £10,000 from the nawáb. This led to the interference of the British, who addressed an ultimatum to Ranjít Sinh, declaring the cis-Sutlej states to be under British protection. Finally the rájá of Lahore submitted, and the nawáb was reinstated in February 1809.

MALESHERBES, Chrétien Guillaume de Lamoignon de (1721–1794), minister and afterwards counsel for the defence of Louis XVI., came of a famous legal family, and was born at Paris on December 6, 1721. He too was destined for the legal profession, much to the surprise of Marcel, the famous dancing master, who declared that his pupil would never be able to dance well enough to be a soldier or a lawyer, and must therefore be a priest. The young lawyer soon proved his intellectual capacity, when he was appointed president of the *cour des aides* in the parlement of Paris in 1750 on the promotion of his father to be chancellor. One of the chancellor's duties was to control the press, and this duty was entrusted to Malesherbes by his father during his eighteen years of office, and brought him into connexion with the public far more than his judicial functions. To carry it out efficiently he kept in communication with the literary leaders of Paris, and especially with Diderot, and Grimm even goes so far as to say that "without the assistance of Malesherbes the *Encyclopédie* would probably never have been published." Though he met with abuse from all sides, there can be no doubt that it was the eminently judicious manner in which he carried out his objectionable duties which laid the foundation of his subsequent popularity. In 1771 he was called upon to mix in politics; the parlements of France had been dissolved, and a new method of administering justice devised by Maupeou, which was in itself commendable as tending to the better and quicker administration of justice, but pernicious as exhibiting a tendency to over-centralization, and as abolishing the hereditary "nobility of the robe," which, with all its faults, had from its nature preserved some independence, and been a check on the royal power. Malesherbes presented a strong remonstrance against the new system, and was at once banished to his country seat at St Lucie, to be recalled, however, with the old parlement on the accession of Louis XVI., and to be made minister of the *maison du roi* in 1775. He only held office nine months, during which, however, he directed his attention to the police of the kingdom, which came under his department, and did much to check the odious practice of issuing *lettres de cachet*. On retiring from the ministry with Turgot in 1776, he betook himself entirely to a happy country and domestic life. He had always been an enthusiastic botanist; his avenue at St Lucie was world famous; he had written against Buffon on behalf of the botanists whom Buffon had attacked, and had been elected a member of the Académie des Sciences as far back as 1750. He was now elected a member of the Académie Française, and everything seemed to promise a quiet and peaceful old age spent in the bosom of his family and occupied with scientific and literary pursuits, when the king in his difficulties wished for the support of his name, and summoned him back to the ministry in 1787. Again he held office but a short time, but returned to his country life this time with a feeling of insecurity and disquiet, and, as the troubles increased, retired to Switzerland. Nevertheless, in December 1792, in spite of the fair excuse his old age and long retirement would have given him, he voluntarily left his asylum and undertook with Tronchet and Desèze the defence of the king before the convention, and it was his painful task to break the news of his condemnation to the king. After this effort he returned once more to the country, but in December 1793 he was arrested with his daughter, his son-in-law M. de Rosambô, and his grandchildren, and on April 23, 1794, he was guillotined, after having seen all whom he loved in the world executed before his eyes for their relationship to him. Malesherbes is one of the sweetest characters of the 18th century; though no man of action, hardly a man of the world, by his charity and unfeigned goodness he became one of the most popular men in France, and it was an act of truest self-devotion in him to sacrifice himself for a king who had done little or nothing for him. With reason does his statue stand in the hall of justice at Paris, for he is the greatest representative of that noble independence which should prevent any thought of self when a counsel is pleading his client's cause, however perilous such advocacy might be.

There are in print several scientific works of Malesherbes of varying value, of which the most interesting is his *Observations sur Buffon et Daubenton*, written when he was very young, and published with a notice by Abeille in 1798. There exist also his *Mémoire pour Louis XVI.*, his *Mémoire sur la liberté de la presse*, published 1809, and extracts from his remonstrances, published as *Œuvres choisies de Malesherbes* in 1809. For his life should be read the *Notice historique* of Dubois, the *Éloge historique* of Gaillard, and the interesting *Essai*, in 2 vols., 1818, of Boissy d'Anglas. There are also many *éloges* on him in print, of which the best-known is that of M. Dupin, which is interestingly reviewed with much light on Malesherbes's control of the press by Sainte-Beuve in the second volume of the *Causeries du Lundi*.

MALHERBE, François de (1555–1628), poet, critic, and translator, was born at Caen in 1555. His family was of some position, though it seems not to have been able to establish to the satisfaction of heralds the claims which it made to nobility older than the 16th century. The poet was the eldest son of another François de Malherbe, *conseiller du roi* in the magistracy of Caen. He himself was elaborately educated at Caen, at Paris, at Heidelberg, and at Basel. At the age of twenty-one he entered the household of Henri d'Angoulême, grand prior of France, the natural son of Henry II. He served this prince as secretary in Provence, and married there in 1581. It seems that he wrote verses at this period, but, to judge from a quotation of Tallemant des Réaux, they must have been very bad ones. His patron died when Malherbe was on a visit in his native province, and for a time he had no particular employment, though by some servile verses he obtained a considerable gift of money from Henry III., whom he afterwards libelled. He lived partly in Provence and partly in Normandy for many years after this event; but very little is known of his life during this period. It was in the year parting the two centuries (1600) that he presented to Marie de' Medici the first of his remarkable poems. But four or five years more passed before his fortune, which had hitherto been indifferent, turned. He was presented by his countryman, the cardinal Du Perron, to Henry IV.; and, though that economical prince did not at first show any great eagerness to entertain the poet, he was at last summoned to court and endowed after one fashion or another. His father died in 1606, and he came into his inheritance. From this time forward he lived at court, corresponding affectionately with his wife, but seeing her only twice in some twenty years. His old age was saddened by a great misfortune. His son, Marc Antoine, a young man of promise, perished in one of the frivolous but desperate duels which, common at all periods of French history, were never more frivolous or more desperate than in the 16th and the early 17th centuries. Marc Antoine de Malherbe fell in 1626. His father used his utmost influence to have the guilty parties (for more than one were concerned, and there are grounds for thinking that it was not a fair duel) brought to justice. But he died before the suit was decided (it is said in consequence of disease caught at the camp of La Rochelle, whither he had gone to petition the king), at Paris, on the 16th of October 1628, at the age of seventy-three.

The personal character of Malherbe was far from amiable. He was an obstinate solicitor of favours from the great, a morose and bearish companion to his equals, a loose liver at a time of life when loose living is especially unbecoming if not especially blameable, a jealous and unfair critic; but he exercised a great and enduring effect upon French literature, though by no means a wholly beneficial one. The lines of Boileau beginning *Enfin Malherbe vint* are rendered only partially applicable by the extraordinary ignorance of older French poetry which distinguished that peremptory critic. But the good as well as bad side of Malherbe's theory and practice is excellently described by his contemporary and superior Regnier, who was animated against him, not merely by reason of his own devotion to Ronsard, but because of a brutal act of discourtesy of which Malherbe had been guilty towards Regnier's uncle Desportes. These are the lines:—

> "Cependant leur savoir ne s'étend nullement
> Qu'a régratter un mot douteuse au jugement,
> Prendre garde qu'un *qui* ne heurte une diphthongue,
> Épier si des vers la rime est brève ou longue,
> Ou bien si la voyelle à l'autre s'unissant
> Ne rend point à l'oreille un vers trop languissant.
> . . . .
> C'est proser de la rime et rimer de la prose."

This is perfectly true, and from the time of Malherbe dates that great and deplorable falling off of French poetry in its more poetic qualities, which was not made good till 1830. Nevertheless the critical and restraining tendency of Malherbe was not ill in place after the luxuriant importation and innovation of the *Pléiade*; and if he had confined himself to preaching greater technical perfection, instead of superciliously striking his pen through the great works of his predecessors, he would have deserved wholly well. As it was his reforms helped to elaborate the kind of verse necessary for the classical tragedy, and that is the most that can be said for him. His own poetical work is scanty in amount, and for the most part frigid and devoid of inspiration. The beautiful *Consolation à Du Perrier*, in which occurs the famous line—

> Et, rose, elle a vécu ce que vivent les roses—

the odes to Marie de' Medici and to Louis XIII., and a few other pieces comprise all that is really worth remembering of him. His prose work is much more abundant, not less remarkable for care as to style and expression, and of greater positive value. It consists of some translations of Livy and Seneca, and of a very large number of interesting and admirably written letters, many of which are addressed to Peiresc, the man of science of whom Gassendi has left a delightful Latin life. It contains also a most curious commentary on Desportes, in which Malherbe's minute and carping style of verbal criticism is displayed on the great scale.

The chief authorities for the biography of Malherbe are the *Vie de Malherbe* of his friend and pupil Racan, and the long *Historiette* which Tallemant des Réaux has devoted to him. The standard edition is the admirable one of M. Ludovic Lalanne, 5 vols., Paris, 1862–69. Of the poems only, there is an excellent and handsome little issue in the *Nouvelle Collection Jannet*, Paris, 1874. (G. SA.)

MALINES. See MECHLIN.

MALLANWÁN, a town in Hardoi district, Oudh, India, situated on the Hardoi and Unas road, in 27° 2′ 10″ N. lat. and 80° 11′ 30″ E. long., with a population in 1869 of 11,670. Under native rule the town possessed considerable political importance, and upon the British annexation of Oudh it was selected as the civil head-quarters of the district, but was abandoned in favour of Hardoi town on the reoccupation of the province after the mutiny. The town has now but little trade, and a deserted indigo factory occupies the site of the old fort. Saltpetre and brass utensils are manufactured.

MALLEMUCK, from the German rendering of the Dutch *Mallemugge* (which originally meant small flies or midges that madly whirl round a light), a name given by the early Dutch Arctic voyagers to the FULMAR (vol. ix. p. 817 [1]), of which the English form is nowadays most commonly applied by our sailors to the smaller Albatroses, of about the size of a Goose, met with in the Southern Ocean—corrupted into "Molly Mawk," or otherwise modified. There is some difference of opinion as to the number of species of small Albatroses, and it is unfortunate that the results of the voyage of the "Challenger" do not clear up the doubts that have been expressed. Three species have been described and figured, the *Diomedea melanophrys* and *D. chlororhynchus* for a long while, while the third, *D. culminata*, was discriminated by Gould (*Proc. Zool. Society*, 1843, p. 107), who has stated that the difference between it and the second is so apparent that he had no difficulty in distinguishing them on the wing. Captain Hutton, on the other hand (*Ibis*, 1865, p. 283), considers all three to be specifically identical. Others, as appears by the *Report on the Birds* of the "Challenger" voyage (pp. 148, 149), while regarding *D. melanophrys* as distinct, would seem to unite *D. culminata* with *D. chlororhynchus*. The first of these birds, says Gould, is the commonest species of Albatros inhabiting the Southern Ocean, and its gregarious habits and familiar disposition make it well known to every voyager to or from Australia, for it is equally common in the Atlantic as well as the Pacific. The back, wings, and tail are of a blackish-grey, but all the rest of the plumage is white, except a dusky superciliary streak, whence its name of Black-browed Albatros, as also its scientific epithet, are taken. The bill of the adult is of an ochreous-yellow, while that of the young is dark. This species (supposing it to be one) is said to breed on the Falkland Islands and on Tristan da Cunha, but the latter locality seems questionable, for, according to Carmichael (*Trans. Linn. Soc.*, xii. p. 490), *D. chlororhynchus* is the bird of this group there found; while Professor Moseley (*Notes of a Naturalist*, p. 130) calls it *D. culminata.*[2] Whatever it may be, the excellent observer just named describes it as making a cylindrical nest of grass, sedge, and clay, with a shallow basin atop and an overhanging rim—the whole being about 14 inches in diameter and 10 in height. The bird lays a single white egg, which is held in a sort of pouch formed by the skin of the abdomen, while she is incubating. A few other details are given by him, but his visit was too hurried to enable him to ascertain the more important and interesting points in the economy of this Albatros which were neglected by his predecessor, Carmichael, during his four months' sojourn in 1816–17. *D. culminata* is said by Gould to be more plentiful in the Australian seas than elsewhere, numbers coming under his notice between Launceston and

[1] It was there erroneously stated that *Mallemuck* was a Dutch word, which it is not; and the correct German form, as given by Friderich Martens (*Spitzbergische oder Groenlandische Reise Beschreibung*, Hamburg, 1675, 4to, p. 68), is *Mallemucke*. The anonymous translation of this voyage, under the title of *An Account of several late Voyages and Discoveries to the South and North*, published in London in 1694 (p. 93), was probably the means of the name becoming known to Ray, in whose *Synopsis methodica Avium*, published in 1713, it appears (p. 130) as *Mallemuck*, and thereafter kept its place in English ornithological works.

[2] Mr Sclater with commendable caution assigns no specific name to the eggs of the *Diomedea* found breeding on this island and its neighbour (*Report, &c., ut supra*, p. 151).

Adelaide, and being also frequently observed by him between Sydney and the northern extremity of New Zealand, as well as in the same latitude of the Indian Ocean. He describes its bill as having the greyish-yellow ridge broad and flat, while that of *D. chlororhynchus* is laterally compressed and the ridge round. All these birds seem to have much the same habits. (A. N.)

MALLET, PAUL HENRI (1730–1807), born in Geneva in 1730, and educated there, became tutor in the family of the count of Calenberg in Saxony. In 1752 he was appointed professor of belles lettres to the academy at Copenhagen, but as the French language was then little known in Denmark he had but few students. He was naturally attracted to the study of the ancient literature and history of his adopted country, and in 1755 he published the first fruits of his researches, under the title —*Introduction à l'histoire de Danemarck où l'on traite de la religion, des mœurs, des lois, et des usages des anciens Danois.* A second part was issued in 1756, more particularly relating to the ancient literature of the country, and bearing the title—*Monuments de la mythologie et de la poesie des Celtes, et particulièrement des anciens Scandinaves.* In the same year a translation of the work appeared in Danish. This is the work by which the author is best known in Britain. Though intended only as a preliminary dissertation to the formal history of Denmark, by which it was followed, it has all the merits of an independent work, complete in itself, and presenting a general view of the civilization and culture, religion and customs, of the Scandinavian nations. A translation into English, with notes and preface, by Bishop Percy, was issued in 1770 under the title of *Northern Antiquities* (republished with additions in 1847). It had a wide circulation, and attracted much attention on account of its being the first (though a very defective) translation into French of the *Edda.* Mallet's dissertations and notes are vitiated by untenable theories as to the racial affinities of the early inhabitants of Scandinavia; but, judged by the standards of its time, his work was of great merit and usefulness. Its publication attracted the notice of the king to its author, and he was chosen as preceptor of the prince of Denmark. In 1760 he returned to Geneva, and became professor of history in his native city. While there he was requested by the czarina to undertake the education of the heir-apparent of Russia (afterwards the Czar Paul I.), but declined the honour. An invitation more congenial to his tastes led to his accompanying Lord Mountstuart in his travels through Italy and thence to England, where he was presented at court and commissioned to write the history of the house of Brunswick. He had previously received a similar commission from the landgrave of Hesse-Cassel for the preparation of a history of the house of Hesse, and both works were completed in 1785. The quietude of a literary life was rudely broken by the shock of the Revolution, to which he was openly hostile. His leanings to the unpopular side were so obnoxious to his fellow-citizens that he was obliged to quit his native country in 1792, and remained in exile till 1801. He died at Geneva, 8th February 1807.

A memoir of his life and writings by Simonde Sismondi was published at Geneva in 1807. Besides the *Introduction to the History of Denmark*, his principal works are—*Histoire de Danemarck*, 3 vols., Copenhagen, 1758–77; *Histoire de la maison de Hesse*, 4 vols., 1767–85; *Histoire de la maison de Brunswick*, 4 vols., 1767–85; *Histoire de la maison et des états de Mecklenbourg*, 1796; *Histoire des Suisses ou Helvétiens*, 4 vols., Geneva, 1803; *Histoire de la Ligue Hanséatique*, 1805.

MALLOW, botanically *Malva*, the typical genus of *Malvaceæ*, embracing about sixteen species of annual and perennial herbaceous plants, widely distributed throughout the northern hemisphere. The mallows possess the reniform one-celled anthers which distinguish the *Malvaceæ* from all other dichlamydeous exogens. The petals also are united by their base to the tube formed by the coalesced filaments of the stamens. The special characters which separate the genus *Malva* from others most nearly allied to it are the involucre, consisting of a row of three separate bracts attached to the lower part of the true calyx, and the numerous single-seeded carpels disposed in a circle around a central axis, from which they become detached when ripe. The flowers are mostly white or pinkish, never yellow, the leaves radiate-veined, and more or less lobed or cut. Three species are natives of Britain. The musk mallow (*Malva moschata*) is a perennial herb with five-partite, deeply-cut leaves, and large rose-coloured flowers clustered together at the ends of the branched stems, and is found growing along hedges and borders of fields, blossoming in July and August. It owes its name to a slight musky odour diffused by the plant in warm dry weather when it is kept in a confined situation. The round-leaved mallow (*Malva rotundifolia*) is a creeping annual, growing in waste sandy places, with roundish serrate leaves and small pinkish-white flowers produced in the axils of the leaves from June to September. It is common throughout Europe and the north of Africa, extending to western Asia. The common mallow (*Malva sylvestris*), the *mauve* of the French, is an erect biennial plant with long-stalked roundish-angular serrate leaves, and conspicuous axillary reddish-purple flowers, blossoming from May to September. Like most plants of the order it abounds in mucilage, and hence forms a favourite domestic remedy for colds and various other complaints affecting the mucous membrane. The aniline dye called mauve derives its name from its resemblance to the colour of this plant.

The marsh mallow (*Althæa officinalis*), the *guimauve* of the French, belongs to another genus having an involucre of numerous bracts. It is a native of marshy ground near the sea or in the neighbourhood of saline springs. It is an erect perennial herb, with somewhat woody stems, velvety, ovate, acute, unequally serrate leaves, and delicate pink showy flowers blooming from July to September. The flowers are said to yield a good deal of honey to bees. The root is used in medicine as a demulcent, on account of its containing more mucilage than the common mallow. It is supposed to form a chief ingredient in the well-known *pâte de guimauve* lozenges. The marsh mallow is remarkable for containing asparagin, $C_4H_8N_2O_3,H_2O$, which, if the root be long kept in a damp place, disappears, butyric acid being developed. The root also contains about 25 per cent. of starch and the same quantity of mucilage, which differs from that of gum arabic in containing one molecule less of water and in being precipitated by neutral acetate of lead. The marsh mallow is far more largely used on the Continent than in England.

The mallow of Scripture, Job xxx. 4, has been sometimes identified with Jew's mallow (*Corchorus olitorius*), but more plausibly (the word מַלּוּחַ implying a saline plant) with *Atriplex Halimus*, or sea orache. In Syria the *Halimus* was still known by the name *Mallûḥ* in the time of Ibn Beitar. See Bochart, *Hieroz.*, iii. 16.

MALLOW, a municipal and parliamentary borough, market-town, and watering-place in the county of Cork, Ireland, is situated on the Blackwater, 150 miles south-west from Dublin, and 20 north from Cork. The town owes its prosperity to its beautiful situation in a fine valley surrounded by mountains, and to its tepid mineral spring, which is very efficacious for general debility and for scorbutic and consumptive complaints. A spa-house with pump-room and baths was erected in 1828. Besides the parish church in the Later English style, erected in 1818, the principal buildings of the town are the court-house, the work-house and infirmary, and the bridewell. There are a manufactory of mineral water, a condensed-milk manufactory, corn-mills, and tanneries. Mallow received a charter of incorporation from James I. The population of the borough in 1871 was 4165, and in 1881 it was 4437.

MALMESBURY, a parliamentary borough and market-town of Wilts, England, is finely situated on an eminence almost surrounded by the Lower Avon, and on a branch of the Great Western Railway, 92 miles west of London. Of the Benedictine house which was founded in the 7th century, and in the reign of Edward III. rose to the dignity of a mitred abbey, little more than the nave and side aisles of the conventual church now remain; this at the dissolution was changed into a parish church, instead of the old church of St Paul's. There are a town-hall, national and endowed schools, and several almshouses. In the market-place there is a richly ornamented octagonal cross supposed to date from the reign of Henry VIII. The industries include the manufacture of ribbons and pillow lace, brewing, and tanning. The population of the town in 1871 was 3142, and of the parliamentary borough (which comprises an area of 21,772 acres, mostly rural) 6879. In 1881 the numbers were 3133 and 6866.

Malmesbury is supposed to have been a British town, and also a Roman settlement. A castle is known to have existed there as early as the 7th century, at which time the monastery was also founded. It received its first charter from Edward the Elder, which was confirmed by Athelstan. The charter granted to it by Charles I. has undergone various modifications, and at present it is governed by a high steward, an alderman, and twelve capital burgesses. From the reign of Edward I. the town sent two members to parliament; since the Reform Act of 1832 it has returned only one. During the civil war it was twice captured by the parliamentarians and once by the royalists. Malmesbury is the birthplace of the philosopher Hobbes. Athelstan was buried at Malmesbury, but the Gothic canopy in the church called his tomb dates from the 16th century.

MALMESBURY, JAMES HARRIS, EARL OF (1746–1820), the best-known English diplomatist of the latter half of the 18th century, was born at Salisbury on April 21, 1746. He was the son of JAMES HARRIS (*q.v.*), the author of *Hermes*, and, what was important for his son's future success, M.P. for Christchurch, a lord of the treasury under George Grenville (1763–65), and comptroller to the queen (1774–80). Educated at Winchester, Oxford, and Leyden, the younger Harris was intended for diplomacy. In 1768 he became secretary to the British embassy at Madrid, and in 1770 he was left as *chargé d'affaires* at that court on the departure of Sir James Gray until the arrival of George Pitt, afterwards Lord Rivers. This interval gave him his opportunity; he discovered the intention of Spain to attack the Falkland Islands, and was instrumental in thwarting it by putting on a bold countenance. As a reward he was appointed minister *ad interim* at Madrid, and in January 1772 minister plenipotentiary to the court of Prussia. His success was marked, and in 1776 he was transferred to the court of Russia. At St Petersburg he made his reputation, for he managed to get on with Catherine in spite of her predilections for France, and steered adroitly through the accumulated difficulties of the first Armed Neutrality. In 1782 Sir James Harris (he was now a Knight of the Bath) returned home from ill-health, and was appointed by his friend Fox minister at the Hague, an appointment confirmed after some delay by Pitt, which he took up in July 1784. He did very great service in furthering Pitt's policy of maintaining England's influence on the Continent by the arms of her allies, and held the threads of the diplomacy which ended in the king of Prussia's overthrowing the republican party in Holland, which was inclined to France, and re-establishing the prince of Orange. He was in recognition of his services created Lord Malmesbury of Malmesbury in the county of Wilts, and permitted by the king of Prussia to bear the Prussian eagle on his arms, and by the prince of Orange to use his motto "je maintiendrai." In 1789 he returned to England, and took an anxious interest in politics, which ended in his seceding from the Whig party with the duke of Portland in 1793, in which year he was sent, but in vain, to try to keep Prussia true to the first coalition against France. In 1794 he was sent to Brunswick to solicit the hand of the unfortunate Princess Caroline for the prince of Wales, to marry her as proxy, and conduct her to her husband in England. In 1796 and 1797 he was at Paris and Lille vainly negotiating with the French Directory. After 1797 he became partially deaf, and quitted diplomacy altogether; but for his long and eminent services he was in 1800 created earl of Malmesbury, and Viscount Fitzharris, of Heron Court in the county of Hants. He now became a sort of political Nestor, consulted on foreign policy by successive foreign ministers, trusted by men of the most different ideas in political crises, and above all was the confidant, and for a short time after Pitt's death almost the political director, of Canning. Younger men were also wont to go to him for advice, and Lord Palmerston particularly, who was his ward, was tenderly attached to him, and owed many of his ideas on foreign policy directly to his teaching. His later years were free from politics, and till his death in 1820 he lived very quietly and almost forgotten. As a statesman, Malmesbury had an influence among his contemporaries which is scarcely to be understood from his writings, but which must have owed much to personal charm of manner and persuasiveness of tongue; as a diplomatist, he seems to have deserved his reputation, and shares with Macartney, Auckland, and Whitworth the credit of raising diplomacy from a profession in which only great nobles won the prizes to a career opening the path of honour to ability.

Malmesbury did not publish anything himself, except an account of the Dutch revolution, and an edition of his father's works, but his grandson the third earl published four volumes of his diaries and correspondence from 1768–1807, and afterwards two volumes of letters to and from his family and friends.

MALMESBURY, WILLIAM OF, an historical writer of the 12th century, the date of whose birth is usually assigned to the year 1095, but may with more probability be placed some twenty years earlier. It may reasonably be conjectured from his own statement ("utriusque gentis sanguinem traho") that he was the son of a Norman father and an English mother; he undoubtedly represents the fusion of the two races, although his sympathies as a writer are unmistakably on the side of the conquerors. He received his early education at the ancient Benedictine abbey at Malmesbury, and he speaks of Aldhelm, bishop of Sherborne, the great benefactor and second founder of that house, who died in 709, as his "lord and patron," to whom he was indebted both for his life and his learning (*Gesta Pont.*, sec. 273). The earliest known incident in his personal history is the fact, which he himself records, that he assisted the abbot Godefrey in collecting books to form the first library of the abbey. William himself subsequently became the librarian, and was also precentor of the abbey; in 1140 he received the offer of the abbacy, an honour which he declined, probably from a desire to secure as much leisure as possible for study. In his later life he was honoured by the particular friendship of Robert, earl of Gloucester, a natural son of Henry I., and a distinguished patron of learned men and letters. In politics he was a warm partisan of the empress Matilda against Stephen, and he was present at the council of Winchester convened by her supporters in 1141. His death is supposed to have occurred in or after 1142.

Printed Works.—William's earliest important work was the *Gesta Regum Anglorum*, which he dedicated to his patron, the earl of Gloucester. It was originally completed in 1120, but subsequently brought down to 1128. It extends from 449 A.D. to the twenty-eighth year of the reign of Henry I., and is a record of the highest value, preserving from unknown sources numerous facts which would otherwise be lost to us. In 1125 William completed his *Gesta Pontificum Anglorum*. He himself tells us that the production of this work cost him especial pains, but that the material for its composition was neither so abundant nor so easily reducible to consistency as that for the *Gesta Regum.* The work may be regarded as the main source for our early ecclesiastical history, and constitutes the basis of later productions relating to the same subject at the same period. It is divided into five books, the bishops being grouped under their respective sees, and the chief monasteries under their jurisdiction being also noticed, sometimes at considerable length. The fifth book is mainly occupied by the life of St Aldhelm, and includes numerous details of interest not given in the earlier life by Faricius. The *Gesta Pontificum* is likewise brought by further additions down to the year 1140. William's last work was a continuation of the *Gesta Regum* under the title of *Historia Novella.* It concludes abruptly with the escape of Matilda from Oxford when besieged there by Stephen in 1142, and the manner of its termination suggests that the narrative was broken off by the death of the writer. Like the *Gesta Regum,* the *Historia* is dedicated to the duke of Gloucester, whose doings in behalf of his sister Matilda are described in such a way as to make him in a great measure the central figure of the narrative. Other printed writings of William are an account of the church of Glastonbury (included along with the life of St Aldhelm in Gale's *Scriptores XV.*), and a life of St Wulstan, of which a considerable portion is given in the second volume of Wharton's *Anglia Sacra.* The best text of the *Gesta Regum* and the *Historia Novella* is that given by Sir T. D. Hardy in the edition published by the English Historical Society in 1840; the text in Savile's *Scriptores* is faulty in the extreme. The *Gesta Pontificum* was edited for the Rolls Series, in 1870, by Mr N. E. S. A. Hamilton, from a manuscript which he was the first to identify as the autograph of William himself.

Extant Works Unprinted.—Among these are *Miracles of the Virgin Mary*; *Miracles of St Andrew*; *Life of St Dunstan*; a compend of the commentary on the book of Jeremiah attributed to Paschasius Radbertus; an abridgment of the treatise by Amalarius on *Sacred Offices*; *Lives of the English Saints*; and an epitome of the *History of Haymo of Fleury,* together with other abridgments or transcripts of historical and legal writers,—this last being an autograph preserved in the Bodleian, where, or at the British Museum, the other manuscripts are also to be found.

Lost Works.—Among these are a *Life of St Patrick*; a metrical *Life of St Ælfgiva*; the *Miracles of St Benignus*; and the *Little Chronicle,* in three books (of which a supposed fragment is preserved at the British Museum, Lansdowne MS. No. 436). The work which we have probably most cause to regret is the *Itinerarium Johannis Abbatis,* or account of the journey of John, abbot of Malmesbury, to Rome in 1140. This was written by William from the oral account which he received from Peter Baldwin, John's companion. A few extracts are given by Leland in his *Collectanea,* iii. 272.

Malmesbury's merits as an historian are of a very high order. He labours, it is true, under the defect of being but imperfectly acquainted with English institutions, and having but little sympathy with the English race, while he occasionally evinces a Norman contempt for the English language. His habitual carelessness in chronology is also at times extremely perplexing, and his narrative of facts is alloyed with romantic details which serve to excite distrust with respect to his general credibility. But, notwithstanding these faults, he is entitled to rank as an authority (in relation to the period of which he treats) with Bede and Matthew Paris. He is again the first of our historical writers in whom the critical faculty is to any extent discernible, and the comparisons which he occasionally institutes between two different and discrepant accounts of the same events form a noteworthy feature in his mode of treatment. The pains and judgment which he employs in the arrangement of his materials are also often no less conspicuous than his industry in collecting them.

MALMÖ, a seaport town of Sweden, inferior only to Stockholm and Gothenburg in importance, is the capital of the län or province of Malmöhus, and stands on the eastern shore of the Sound, opposite Copenhagen, from which it is 16 miles distant. The town, which is built on a level plain, formerly had strong fortifications, of which all that now remains is the citadel, where the earl of Bothwell was imprisoned for some time after 1573; it is at present used as a house of correction. In the large central square (Stortorg), which is planted with trees, stands the town-hall, a brick and sandstone structure in the Renaissance style; it contains the handsome Knutssal, or former council chamber of the guild of Canute. The principal ecclesiastical buildings are the church of St Peter (Petrikyrka), begun in 1319, and the German church (Tyskakyrka). The harbour in the north-west has recently been deepened, and admits vessels drawing 18 feet of water; there is daily communication by steamer with Copenhagen, and also at regular intervals with Stockholm, Gothenburg, Lübeck, &c. The trade of the port is considerable, the exports including timber, iron, tar, oil-cake, and bones, while the imports consist chiefly of wine, salt-fish, salt, and coal. There are a number of manufactures, that of gloves being the specialty. Malmö is connected with Stockholm by rail. Population in 1878, 35,626.

Malmö (Malmhauge, Malmey, Malmöye, Malmoughe), sometimes called "Ancona Scanorum" or "Ellenbogen," first appears in history about the middle of the 13th century. During the Hanseatic period it was the most important commercial town on the Sound, but in the 16th and 17th centuries greatly lost ground owing to the decay of its herring fisheries and the rise of its rival Copenhagen. Its modern prosperity is largely due to the enterprise of Frans Suell, one of its merchants, who first constructed the harbour, which has more than once been enlarged subsequently.

MALORY, Sir Thomas, the author or compiler of the *Morte Darthur,* was born most probably about the year 1430. From his own words he is known to have been a knight, and his description of himself as "a servant of Jesu both day and night" has led to the inference that he was also a priest. On the authority of Leland the antiquary he is believed to have been a Welshman. The name appears in a variety of forms, including those of Maillorie and Maleore. In the preface to the first edition of the *Morte Darthur* Caxton speaks of the work as printed by himself "after a copy unto me delivered, which copy Sir Thomas Malorye did take out of certain books of French, and reduced it into English." Malory himself tells us that he finished the book in the ninth year of Edward IV. (*c.* 1470). For the place of the *Morte Darthur* in the literary history of the Arthurian legend, see Arthur, Geoffrey of Monmouth, Grail (Holy), &c.

MALPIGHI, Marcello (1628–1694), of Bologna, was one of the first to apply the microscope to the study of animal and vegetable structure; his discoveries are so numerous and important that he may be considered to be the founder of microscopic anatomy. Shortly before his death, he drew up a long account of his academical and scientific labours, correspondence, and controversies, and committed it to the charge of the Royal Society of London, a body with which he had been in intimate relations for more than twenty years. The autobiography, along with some other posthumous writings, was published in London in 1696, at the cost of the Society. The personal details left by Malpighi are few and dry. His narrative is mainly occupied with a summary of his scientific contributions and an account of his relations to contemporary anatomists, and is entirely without graces of style or elements of ordinary human interest. He was born in the country, about 20 miles to the north of Bologna, on the 10th of March 1628. At the age of seventeen he began the study of the Aristotelian philosophy, and continued it for four years; it appears from another statement that he was in the habit of amusing himself with the microscope during this period. Owing to domestic circumstances, it became necessary for him, in 1649, to choose a profession, and he elected to study medicine; after four years study at Bologna he graduated there as doctor. He at once applied to be admitted to lecture in the university, but it was not till after three years (1656) that his request was granted. A few months later he was appointed to the chair of theoretical medicine at Pisa, where he enjoyed the friendship and countenance of Borelli. At the end of four years he left Pisa, on the ground of ill-health, and returned to Bologna. A call to be professor primarius at Messina (procured for him through Borelli, who had in the meantime become professor there) induced him to leave Bologna in 1662. His engagement at Messina was for a term of four years, at an annual stipend of 1000 scudi. An attempt was made to retain him at Messina beyond that period, but his services were secured for his native university, and he spent the next twenty-five years there. In 1691, being then in his sixty-fourth year, and in failing health, he removed to Rome to become private physician to Pope Innocent XII., and he died there of apoplexy three years later. In the portrait prefixed to his autobiography, the features are those of the phlegmatic type. His addiction to the microscope brought him into conflict with the respectabilities of the medical profession, including two of his colleagues at Bologna, whose names have been preserved from oblivion; it was felt by those who affected to watch over the future welfare of medicine that the study of microscopic anatomy was adverse to the true interests of medical practice, and that feeling is said to have found expression in a duel that was fought between the brother of Malpighi and a near relative of one of his conservative colleagues, in which the latter combatant was killed. Amid such incidents was the fruitful microscopic era of medical and biological science ushered in.

The compound microscope (invented in the Netherlands) had been used in Italy (Rome) to study the parts and organs of the bee as early as 1625, and it was employed by Malpighi and by his contemporaries Hooke (botanist) and Leeuwenhoek; the illumination of the objects was always direct, the mirror being a much later addition, and the tube was of unwieldy length. Owing to the inability to overcome spherical and chromatic aberration in compound lenses, the simple microscope came again into common use, and continued to be the chief instrument in the study of minute anatomy until the introduction of flint-and-crown glass lenses by English opticians about a century later. It was Malpighi's practice to open animals alive, and some of his most striking discoveries were made under those circumstances. Although Harvey had correctly inferred the existence of the capillary circulation, he had never seen it; it was reserved for Malpighi in 1661 (four years after Harvey's death) to see for the first time the marvellous spectacle of the blood coursing through a network of small tubes on the surface of the lung and of the distended urinary bladder of the frog. We are enabled to measure the difficulties of microscopic observation at the time by the fact that it took Malpighi four years longer to reach a clear understanding of the corpuscles in the frog's blood, although they are the parts of the blood by which its movement in the capillaries is made visible. His discovery of the capillary circulation was given to the world in the form of two letters *De Pulmonibus*, addressed to Borelli, published at Bologna in 1661 and reprinted at Leyden and other places in the years following; the letters to Borelli contained also the first account of the vesicular structure of the human lung, and they made a theory of respiration for the first time possible. The achievement that comes next both in importance and in order of time was a demonstration of the plan of structure of secreting glands; against the current opinion (revived by Ruysch forty years later) that the glandular structure was essentially that of a closed vascular coil from which the secretion exuded, he maintained that the secretion was formed in terminal acini standing in open communication with the ducts. The name of Malpighi is still associated with his discovery of the soft or mucous character of the lower stratum of the epidermis, of the vascular coils in the cortex of the kidney, and of the follicular bodies in the spleen. He was the first to attempt the finer anatomy of the brain, and his descriptions of the distribution of grey matter and of the fibre-tracts in the cord, with their extensions to the cerebrum and cerebellum, are distinguished by accuracy; but his microscopic study of the grey matter conducted him to the opinion that it was of glandular structure and that it secreted the "vital spirits." At an early period he applied himself to vegetable histology as an introduction to the more difficult study of the animal tissues, and he was acquainted with the spiral vessels of plants in 1662. It was not till 1671 that he wrote his *Anatome Plantarum* and sent it to the Royal Society, who published it in the following year. An English work under a similar title (*Anatomy of Vegetables*) had been published in London a few months earlier, by Nehemiah Grew; so that Malpighi's priority as a vegetable histologist is not so incontestable as it is in animal histology. The *Anatome Plantarum* contained an appendix, *Observationes de ovo incubato*, which gave an account (with good plates) of the development of the chick (especially of the later stages) in many points more complete than that of Harvey, although the observations were needlessly lessened in value by being joined to the metaphysical notion of "prædelineation" in the undeveloped ovum. His works are—*De pulmonibus: Epistolæ duæ ad Borellium*, Bologna, 1661 (went through several editions); *Epistolæ anatomicæ Marc. Malpighii et Car. Fracassati*, Amsterdam, 1662 (on the tongue, brain, skin, omentum, &c.); *De Viscerum Structura: exercitatio anatomica*, London, 1669; *Anatome Plantarum, cum appendice observationes de ovo incubato continente*, London, 1672 (other editions in 1675 and 1679); *De Structura Glandularum conglobatarum*, London, 1689; *Opera posthuma, et vita a seipso scripta*, London, 1697 (another edition, with preface and additions, was published at Amsterdam in 1700). An edition containing all his works except the last two was published in London in 1687, in 2 vols. folio, with portrait and plates.

MALSTATT-BURBACH, a town in the district of Treves, Prussia, is situated on the right bank of the Saar (Sarre), almost contiguous with the town of St Johann, and separated from Saarbrücken by the river. It lies in the midst of an important coal-mining and industrial district, and is itself little more than a long and narrow row of manufactories and workmen's houses. The largest factories are engaged in the production of iron, steel, and cement, one iron-work employing nearly 2000 men, and producing 285,000 tons of raw and manufactured metal annually. There is a large wharf on the river for the export of coal. At the census of 1880 Malstatt-Burbach contained 13,158 inhabitants.

Malstatt is of very ancient origin, and received municipal rights in 1321. These, however, were afterwards resigned to the newer town of Saarbrücken, and in 1818 Malstatt and Burbach were two small villages with a joint population of only 822. About the middle of the century the population began to increase rapidly, in consequence of the development of the mining industry of the district and the extension of the railway system, and in 1875 the two villages were united to form a town. In 1870 Malstatt-Burbach was cannonaded by French troops under the command of Napoleon III.

MALT is the grain of any cereal artificially germinated so as to induce certain changes in the constitution of the seed, specially a conversion of a portion of the starch into sugar. The varieties of grain usually employed for malting are barley and bere or bigg, and the processes of preparing the substance are fully explained under BREWING (vol. iv. p. 266).

The specific effect of the malting of grain is to transform by the process of germination a proportion of the starch into soluble sugar and dextrin. These changes are effected by the agency of a peculiar nitrogenous ferment, diastase, which exists in the grain, but which is increased in amount during the germination. The precise sequence of changes, and the exact nature of the new chemical compounds evolved, are still matters of some doubt. It is clearly established that the ferment of barley is incapable of transforming the starch on which it operates entirely into sugar, the ultimate products of the action being partly dextrin and partly sugar. The relative proportions of these bodies evolved by fermentation from starch have been matter of dispute, some holding that from three molecules of starch there are evolved two molecules of dextrin and one of sugar, while others affirm that the yield is two of sugar and one of dextrin, and a third party hold that for each molecule of sugar there is one of dextrin produced, thus :—

$$\underset{\text{Starch.}}{2C_6H_{10}O_5} + H_2O = \underset{\text{Sugar.}}{C_6H_{12}O_6} + \underset{\text{Dextrin.}}{C_6H_{10}O_5}.$$

These statements, however, are based on the assumption that the sugar which results from the fermentation of germinating barley is ordinary grape sugar or dextrose, $C_6H_{12}O_6$; but it has been demonstrated, first by O'Sullivan, that it is a form of sugar possessed of peculiar properties to which the name maltose has been given. Maltose, according to O'Sullivan, is isomeric with cane sugar, $C_{12}H_{22}O_{11}$, but Märcker considers that its constitution should be represented by $C_{18}H_{34}O_{17}$, and that the equation is as follows :—

$$\underset{\text{Starch.}}{4C_6H_{10}O_5} + 2H_2O = \underset{\text{Maltose.}}{C_{18}H_{34}O_{17}} + \underset{\text{Dextrin.}}{C_6H_{10}O_5}.$$

Maltose possesses the power of reducing Fehling's solution (cupric oxide) only to the extent of 63 per cent. as compared with dextrose, but its power of right-handed polarization is three times as great = +154°. According to Dubrunfaut the efficient ferment in barley is maltin, a much more richly nitrogenous and active body than diastase, which he considers to be only a product of the decomposition of maltin.

By the processes of malting 100 parts by weight of barley yield about 80 of kiln-dried malt and 2 to 3 of dried radicle and plumule called "malt dust." The progressive modification in composition is shown in the accompanying table of analyses extracted from the report presented by Mr (now Sir) J. B. Lawes to the Board of Trade "On the Relative Value of Unmalted and Malted Barley as Food for Stock, 1866,"—an inquiry which resulted in showing that the advantages claimed for malt as a feeding material were largely illusory:—

	Barley.	Barley after Steeping.	4¼ Days on the Floor.	8 Days on the Floor.	12¼ Days on the Floor.	14¼ Days on the Floor.	Screened Malt.	Malt Dust.

Since the article BREWING was written the malt tax then in force in the United Kingdom has been repealed, and in its place, under the provisions of the Inland Revenue Act 1880 (43 & 44 Vict. cap. 20), an equivalent duty on beer has been substituted. By that enactment numerous modifications have been made practicable in the use of malt for feeding and other industrial purposes, and much greater latitude has been given to brewers in the selection and use of raw materials for the manufacture of the beverages hitherto known as malt liquors. Taking as the unit of measurement the bushel of malt, which is defined by statute as equivalent to 42 lb of malt or corn of any description, or to 28 lb of sugar, the malt duty, which under the provisions of the repealed statutes amounted to 2s. 7d., with 5 per cent. additional, has been transformed into a beer duty of 6s. 3d. charged upon every 36 gallons of wort of a specific gravity of 1057; and every brewer is deemed to have brewed 36 gallons of worts of that gravity who has used 2 bushels of malt in brewing. In the case of brewers for sale, should the quantity of worts produced and the specific gravity of such worts exceed by more than 4 per cent. the quantity and gravity above specified, the duty is charged for the excess over and above such 4 per cent. Brewers for domestic use and for the use of their own farm labourers are exempt from duty when the annual value of the house occupied by the brewer is not more than £10, and all brewers for domestic use who occupy houses exceeding in value that amount, and who consequently are subject to the beer tax, must brew their beer on their own premises only.

The malt tax, which in reality was a duty on raw grain, had long been regarded as a grievous impost, and its repeal was systematically agitated for by the agricultural interest. The tax, it was alleged, operated injuriously on the cultivators of barley, and prevented stockholders from freely using malt for the feeding of cattle and of ewes at the lambing season, &c. On the part of brewers it was maintained that the operation of the tax restricted them to the use of the heaviest and most expensive classes of barley alone; and that they were consequently precluded from using many varieties of grain and saccharine materials which under other conditions they might employ with advantage both to themselves and to the consumers of beer. No sooner, however, was it proposed by the Government to effect the change so long clamoured for—not indeed the entire abolition of taxation on malt liquors, but the freeing of a raw material from fiscal impost—than the agricultural community discovered they had made a mistake, and that, while it was really the beer drinker who paid the malt tax, its operation had rather tended to give the British barley-grower a monopoly of the trade in that raw material, and to artificially enhance the value of the heavier qualities of the grain. Further it was found that the idea of using malt for feeding purposes to any considerable extent, a right which stockholders already possessed under the provisions of the "Gladstone Act" (27 & 28 Vict. cap. 9) was entirely illusory; and as a matter of fact no demand has arisen for malt for such purposes. On the other hand, the freedom of choice as to raw materials which the Inland Revenue Act 1880 has given to brewers has not been without influence on the industry, although the modifications have up to this time been by no means so numerous and important as had been anticipated. Barley continues to be the principal, and, supplemented by sugar, almost the only, raw material of wort; but brewers no longer have any interest in confining themselves to the heaviest and plumpest growths, and consequently much light foreign-grown barley is now used. It was also expected that raw grain, and particularly maize, would be largely used with malt in the mashings, especially as a method had been devised and patented by Mr R. Blair Robertson of Glasgow for removing the germ of that grain, which contains a peculiar acrid oil, and which communicates a bitter unpleasant flavour to the wort in which it may be infused. To a limited extent a "maize beer," in which one-third part of Robertson's patent prepared maize is mashed with two-thirds of malt, is being brewed with quite satisfactory results, but the mixture does not appear to have commended itself generally to the trade either on the score of quality or of cheapness.

Malt is also the raw material from which the whisky of Scotland and Ireland is principally distilled, and it is the source of the greater part of the best qualities of table and pickling vinegar. Chiefly on account of the great solvent power over starch possessed by the diastase or maltin it contains, malt is extensively used as a combination in prepared farinaceous food for infants, and in the form of a malt extract it possesses considerable reputation in pharmacy.

MALTA is the chief island of the Maltese group, consisting of Malta, 35° 50′ N. lat. and 14° 30′ E. long., Gozo, 36° 5′ N. lat. and 14° 10′ E. long., Comino, which lies between them, and the two islets Cominotto and Filfla, a crown colony, and one of the Mediterranean possessions of Great Britain. Malta is 17¼ miles long by 9¼ broad, containing an area of about 95 square miles (about two-thirds the size of the Isle of Wight), and Gozo is 9 miles long by 5 wide, with an area of 20 square miles. The islands lie directly south of Sicily, distant from 55 to 60 miles, near the centre of the Mediterranean basin, where they appear as the remains of an ancient chain of islands, much worn and still wearing away by the sea. Gozo, which has the same general character as Malta, possesses more moisture and richer soil, and therefore more verdure. A cluster of single hills, remarkable for their steeply conical shape, on one of which stands Rabato, the principal village, is near the middle of the island. Along the northern and eastern shores of Malta the coast-line is frequently broken by deep indentations and bays (St Paul's, St George's, and St Julian's Bays); on the peninsulas in and round the most remarkable of these Valetta and its fortifications are built. The geological formation is late Eocene, the prevailing rocks being white, grey, reddish, or yellow sandstone, with

Plate III.

some beds of marl and coral limestone, in many parts abounding in fossils. The surface of the country is diversified by valleys and steep hills; there is little water, and no river, brook, or lake exists on any of the islands. The highest point of Malta is near Casal Dingli, about 750 feet above the sea to the south; a little farther north lies the ancient capital, Citta Vecchia, upon another steep height; west of these lies the range of Bingemma Hills running north-east to south-west; from this higher ground the island slopes somewhat towards the north-west. On the west and south the cliffs rise sheer from the sea to a height of 300 or 400 feet; on the north the rock in many places shelves to the water's edge, though the harbours of Valetta and the rocks where the apostle Paul was wrecked are an exception to this. At the east end is the large harbour Marsa Scirocco, into which the south-east sirocco blows with full force. The general appearance of the land is bare, owing to the want of woodland, and also to the use of stone walls as enclosures for the fields, which in the east of the island are smaller than in the west. The dark foliage of the carob and the singular masses of the prickly pear are, however, very marked in the landscape, which with its contrasts of blue sea running into the brown and yellow land, heightened by whatever of green may be, is of fascinating beauty under the effects of morning light and setting sun. The land is closely cultivated; often the soil is terraced on the sides of the hills as a safeguard against the winter rains. The soil is in many places extremely thin; it is, however, so fertile that it produces two and sometimes three crops in a year. Large quantities of early potatoes grown for the English market, corn sufficient to supply the island for four months of the year, cotton, principally for home use, and a fine red-flowering clover, called *sulla*, are the chief crops; excellent honey is obtained from Gozo; oranges and figs come to great perfection. Goats abound, but few cows are kept; the mules and asses are fine; cattle and sheep for butcher meat are imported from Barbary. Fish is good and abundant. The flowers of Malta are famous; Cicero mentions the cushions stuffed with roses used by Verres, and many a lovely garden is hidden behind the high stone walls. The interesting flora of the islands approaches that of Africa (to which continent the old geographers considered them to belong, as the French do still), including the palm, cactus, and other sub-tropical plants. The scanty fauna is for the most part European; the Maltese dog is mentioned by Strabo and other old writers; a few still remain, though not wild. Of birds there are about ten or twelve indigenous species, but a large number of migratory birds pass or rest here. The marine plants and animals also offer a rich fund of material to the student.

The winter climate is temperate and healthy, the thermometer ranging from 51° to 71° Fahr. between October and May. In the summer months the heat is almost tropical; from July to the end of October it ranges between 80° and 90°. Snow is unknown, but hail occurs in winter, and much rain usually falls between December and February. The northerly winds are bracing, but the south-east wind, called the sirocco, which brings the warm air from the African deserts, and then takes up the salt sea mists, is very deleterious; it occurs suddenly, chiefly in August and September, occasionally in the spring, and fortunately lasts usually but a few hours. The "gregale" ("eurokylon" of Acts xxvii. 14) is a strong north-east wind which occasionally blows in the winter months with great fury and force for two or three days together, especially in November and February, rendering it dangerous to cross the harbour, sometimes tearing up stone walls and landing-steps, and otherwise doing much damage.

The Maltese are a strong well-formed race, the men dark, handsome, and lithe, the women with black eyes and fine hair and an easy carriage; as in other Eastern nations, the working classes grow old at a comparatively early age. They are a cheerful, good-humoured, and industrious people, sober and abstemious, though quick-tempered and addicted to the use of the knife. Bread or pasta, with a few olives, a little oil, or milk cheese, forms the chief support of the poor, who seldom or never eat meat, and drink but little of the light wine of the country. The gentry have a large admixture of Spanish, Italian, and French, but among the people in general the Arab race and character predominate, influenced by contact with Sicily. Of the native language 70 per cent. consists of Arabic words, the rest being chiefly a corrupt Italian; that spoken in Gozo is the purest Maltese. The festivals and ceremonials of the Roman Church are kept up to an extraordinary degree, together with a few that seem to be derived from the Greek Church. The perpetual ringing of monotonous church bells, and the peculiar method of striking time, are relics of South Italian customs.

Malta is divided into twenty-six casals or village districts, Gozo into nine; some of the villages are large and populous, each having its church, often large and handsome. Near the middle of the island, on sharply rising ground, stands the ancient capital, called Civitas Melita by the Romans and oldest writers, Medina (*i.e.*, the city) by the Saracens, Notabile ("jocale notabile, et insigne coronæ regiæ," as it is called in a charter by Alphonso, 1428) under the Sicilian rule, and Citta Vecchia (old city) by the knights. The cathedral, overthrown by an earthquake in 1693, but rebuilt, stands on the reputed site of the house of Publius, Paul's friend; many Maltese gentry live in this town, and the English utilize some of the buildings. The Roman remains and catacombs of Citta Vecchia must not be forgotten. Since 1570 the chief town has been Valetta,—a city built on a ridge of rock (Mount Sceberras) which runs like a tongue into the middle of a bay, which it thus divides into two great harbours, subdivided again by three other peninsulas into creeks. On two of these peninsulas, and at their base, are built the aggregate of towns called the Three Cities, part of which (grown up under the old Fort St Angelo) is much older than the coming of the knights, and is called Vittoriosa in commemoration of the siege of 1565. Valetta, including the suburb Florian, is about 2 miles long and $\frac{3}{4}$ mile wide; Fort St Elmo, with a lighthouse, stands on the point; the summer suburb Sliema lies on the point which encloses the west or Marsamusceit harbour; Fort Ricasoli on the opposite point enclosing the east or grand harbour. The streets of Valetta, paved with stone, run along and across the ridge, and end on each side towards the water in steep flights of steps. Many of the houses, which are of stone throughout, with flat roofs, are large and luxuriously built; wooden covered balconies project from the windows and give a peculiar aspect to the streets. There are several fine public buildings, as the governor's palace, the new opera-house, the public library, the *auberges* or lodges of the knights, especially the Auberge de Castile, the English church built by Queen Adelaide and others. Roman Catholic churches in Valetta are very numerous: the cathedral of St John is famous for its rich inlaid marbles, its Brussels tapestries, its roof painted by Matteo Preti (1661–99), and the picture by Caravaggio, the Decollation of John the Baptist. The hospital of the knights contains one of the longest rooms in Europe, 503 feet in length, without a central support. The extensive bagnios under the rock, formerly occupied by the slaves of the knights, are now used for naval stores. The knights strengthened Valetta and its harbours by bastions, curtain-walls, lines, and forts, towards the sea, towards the land, and on every available point, taking advantage in every particular of the natural rock and of the marvellous advantages of situation, rendering it then almost impregnable. The work of fortifying the place with modern armament is carried on by the British Government, which possesses there the finest naval hospital in Europe, a military prison, and other necessary institutions, including immense subterranean stores of grain. New sanitary and water works and dwellings for the over-crowded poor have lately been undertaken by the local authorities. The city is clean and well-regulated, gay with the motley throng of all nations that continually come and go, and presenting many features common to the East; the influx of winter visitors attracted by the mild climate and social gaieties has of late years proved a source of wealth to the inhabitants. A railroad from Valetta to Citta Vecchia, the first in the island, is now nearly completed.

The importance of Malta lies, as of old, in its harbours, which render it a splendid port of call, repair, or refuge, as well as a fine naval station, in its capabilities as a depôt for coals and stores, in its hospitals, and in its strength as a military station. Its position in the Mediterranean is of the utmost value towards keeping a clear highway to the East and to India. During the eighty-two years of British occupation the population, trade, and produce have largely increased. The government, created by royal letters patent of 11th May 1849, consists of a council of eighteen members, eight elected by the Maltese (about two thousand three hundred electors), nine chosen by the crown, and the governor, with a salary of £5000, who is usually a military officer. To these were added by letters patent of May 1881 an executive council of three members to advise and assist the governor. The council have powers to make laws and to vote money; this last was restricted by the British Government in 1875, leading to a protest in the following year by the elected eight. The government of the islands presents peculiarities owing to the combination of military and civil duties. Several recent inquiries on taxation, education, &c., have led to important changes during the last two years. The consolidated revenue is at the disposal of the crown through the governor and council; Malta is self-supporting, costing the imperial exchequer little beyond the military and naval establishments, and even contributing £5000 annually towards the former. The revenue arises chiefly from import duties (of which a large proportion accrues from a tax of 10s. a quarter upon grain) and tonnage dues.

	Revenue.	Expenditure.
1879	£183,794	£185,946
1880	190,661	169,318

The tonnage of vessels entering and clearing equals that at Gibraltar; in 1878 it amounted to 6,503,859 (5,669,046 of which was for British vessels), and in 1880 it was 6,147,234. In 1879 the value of imports actually landed was £794,565, and of exports £216,050,—a value of about £18,700,000 merely touching at the port. The figures fluctuate; in the following year they fell considerably. In 1837 the revenue was but £95,600, while but one steamship, of 137 tons, entered the harbour; in 1879 2894 steamers, with a tonnage of 2,781,806 entered. In the naval yard numerous vessels are repaired yearly; in 1876–77 these amounted to 39 ironclad and other ships and 43 smaller vessels. One arm of the harbour is devoted to a coaling station, where enormous quantities of coal are annually imported and sold (384,272 tons in 1880). The British Mediterranean fleet is stationed there for six months of the year, the strength of the naval forces being usually about 5000 men. The strength of the military in the island is usually about 6500, the largest garrison in any British colony.

The population, which in 1837 was 115,570, was 154,892 in 1880, exclusive of British troops and their families, about 24,000 being English and foreigners; it is rapidly increasing, and is unequally distributed, the greater part being settled in the large casals or villages on the eastern half of Malta, including the densely populated Valetta; large tracts to the west are bare and but sparsely inhabited; about one-third of the island is rocky and uncultivated. Malta has now 1510 inhabitants to the square mile, Gozo 962. In 1879 there were 9868 children (about two-fifths of these at school age) attending elementary schools, including 768 students at the university and two lyceums; in 1880 the total was 9595. All the casals of Malta and Gozo (with but one or two exceptions), besides Valetta and the Cities, have schools, which are now placed on the same system as the board schools in England; great efforts are being made to extend the acquisition of the English language, which till recently was neglected in favour of Italian. The director of public education, besides the elementary, has under his care several secondary schools, two lyceums in Vittoriosa and in Valetta, and the university (founded by the knights in 1768), with faculties of philosophy and arts, law, medicine, and theology. In Valetta is a large public library founded by the knights in 1760, containing 48,000 volumes, open free daily; in Gozo is a smaller one.

History and Antiquities.—Malta (*Melita*), with its sister Gozo (*Gaulus* or *Gaudus*), has from time immemorial been a place of importance to whatever race wished to hold the highway of the Mediterranean, whether Phœnician, Punic, Roman, or Arab. Thus even the stories of Homer have a semblance of truth, for the Ogygian isle where Ulysses took refuge has been supposed to be Malta or Gozo, in both of which tradition (born of the poem) yet points out the grottoes of Calypso. The earliest inhabitants of whose presence we have any actual trace are the Phœnicians, from whom we have several important inscriptions which tell of them and their temples, several curious images believed to belong to their worship, and many specimens of their pottery and glass, chiefly found in tombs, some bearing Phœnician characters and potters' marks. Sepulchral caves and clusters of rock-hewn tombs, especially those in the hills of Bingemma, in several of which terra cotta sarcophagi have been found, are referred with reason to a Phœnician or a Punic origin; Caruana's *Report* gives a list of these in eight places, distinguishing them from numerous Greek and Christian catacombs which also exist in the islands. The most remarkable remains are three rough stone erections, one in Gozo (Torre dei Giganti), and two in Malta, about a mile apart (Hagiar Kim and Mnaidra), which mainly consist of several apsidal chambers side by side, the walls of which are built of enormous horizontal and upright stones. In Malta the ruins show evidence of much skill in stone-cutting; the entrances to the chambers consist of three large slabs of stone in place of doorpost, each smaller than and at a little distance from the one outside it; several have well-shaped holes for ropes or other fastening; other slabs have sharply-squared holes and shelves cut in the solid stone; others again are ornamented with "pit-markings" or little depressions cut evenly all over the surface of the stone. A table or altar is also found in some of the rooms, a massive slab of stone supported on an upright formed like the trunk of a tree; in one case the two ends of the slab are carefully mortised into the walls at each side, the chamber being very small, and apparently intended specially for its reception. Hagiar Kim was excavated by the Government in 1840, when considerable traces of the action of fire were found on some of the walls, as well as buried ashes. In other rooms were found quantities of bones, many fragments of pottery, lamps, bowls, &c., nine images, and a small ornamented altar (*Archæol.*, vol. xxix. p. 227). The ruins in Gozo were excavated about 1827 (*Archæol.*, vol. xxii. p. 294). All these buildings stand on commanding positions, high on the side or the shoulder of steep hills. They have been usually considered Phœnician temples; and, on comparison of them with what is known of the great temple of Melkart at the south-east corner of Malta, the presumption is strong that these too were built by the same race, at some very early period. The bilingual inscription found there belongs to a later age, the Græco-Punic time, to which Greek coins found in both islands and a few other remains bear evidence. It is probable that the islands shared in some degree the varying fortunes that followed on the wars in Sicily, which took place as Greek drove out Phœnician, as Carthaginian drove out Greek and tried to regain the ancient possession of the mother-land, as finally Rome conquered all. During the First Punic War (264–241 B.C.) Malta seems to have been conquered and reconquered more than once (Orosius, iv. c. 8). In the Second Punic War the Carthaginians, under Hamilcar, son of Gisco, gave it up to Titus Sempronius, 218 B.C. (Livy, xxi. 51).

In the pursuit of manufactures and commerce Malta had attained a high degree of prosperity under the Phœnicians, which still existed under the Romans of the Augustan age. It was especially famous for its textile fabrics (probably of cotton, which is grown and spun there to this day); the Sicilian prætor Verres sent there for women's woven garments. The inhabitants were rich, and there were many artificers of all kinds. Ovid speaks of it as a fertile island (*Fast.*, iii. 567). The remains formerly existed (unfortunately now for the most part dispersed or destroyed) of several fine Græco-Roman temples, such as the temple of Juno spoken of by Cicero and Valerius Maximus, whose ornaments and fine ivories and carved figures of Victory tempted more than one sacrilegious robber; the temple of Proserpine, which we learn from an inscription was repaired by Chrestion, a freedman of Augustus, procurator of Malta; and the temple of Apollo at the chief town Melita, which with a theatre shared the munificence of a wealthy Maltese under the Antonine rule; these and the ruins of a princely Roman dwelling with mosaics, system of water supply, &c., at the same place, are but a few signs of the luxury enjoyed in the islands. Diodorus noticed the beauty and adornment of the houses in Malta in his time, a few years after the shipwreck of St Paul. One of the islanders was a friend of Cicero, who had thoughts of retiring there himself. A mole and important harbour works, discovered a few years ago, show that the Romans were not behind in strengthening the natural advantages of the islands for shelter. Inscriptions recording municipal institutions there date from the time of Hadrian; how much earlier they possessed them is unknown. Before then we hear of Chrestion the procurator mentioned above, and a Roman governor under Augustus, Lucius Castricius, styled *πρῶτος Μελιταίων*, "chief man of the Maltese" (Caruana, 1882, p. 134; 1881, pp. 20, 21), just as, half a century later, Publius was *πρῶτος τῆς νήσου*, "chief man of the island" (Acts xxviii. 7); all these were probably concerned in the local government. The Romans retained the Maltese group for many centuries. At the division of the empire in 337 A.D. it passed with Italy, Illyria, and Africa to Constans; after the reunion, and the final division after the death of Theodosius in 395, Malta, as one of the isles of the Mediterranean, remained with the empire of the East. History has but little to mention regarding it during those early times, except that event of ever-living interest, the shipwreck of St Paul, 58 A.D., which it is now well-ascertained took place in a bay on the north side of Malta. The alleged conversion of the Maltese to Christianity following the three months' stay of the apostle and his companions may be a fact; Chrysostom refers to it (*Hom.* 54 on Acts). Many Christian monograms and inscriptions have been found, ranging from the 2d to the 9th century; and the tombs and subterranean cemeteries near Citta Vecchia are said to be arranged like the Christian cemeteries of subterranean Rome (Caruana, 1881, p. 18). Tradition says these were used as hiding-places in times of persecution; it is certain that Ptolemy at the end of the 2d century notes the famous temples of Hercules and Juno as still in existence; the old religion and the new must have gone on side by side for a long time. After a time Malta was made a bishopric; according to R. Pirrus (*Sicilia Sacra*, Melitensis Eccl. Not. vii., *s.v.* "Lucillo") it was, though considered part of Africa, subject to the bishop of Palermo (in 6th century primate of Africa); we find Gregory the Great dealing with a contumacious bishop of Malta and directing the bishop of Syracuse and others to depose him, and to aid the successor appointed in his place (Greg., *Epist.*, ii. 44; ix. 63; x. 1).

The Saracens did not gain possession of Malta without a struggle of many years; they invaded it three times, in 828, 836 (when it appears to have been chiefly Gozo that suffered), and finally in 870, when the inhabitants of Melita, having massacred the Greek (Byzantine) garrison of 3000, opened their gates to the invaders. The Arabs are said to have destroyed part of the city so as to bring the fortifications within smaller compass, rendering it more easy to defend, and to have changed its name to Medina (great or chief city). In a suburb just outside the present walls there was discovered in 1881 a burial-place containing numerous Arab coffins, overlying the remains of the Roman palace mentioned above, which was thus finally ruined and concealed by the conquerors. It is known that they built a fortress in 973, at the point of Mount Sceberras where Fort St Elmo now stands. A few coins are preserved, but otherwise very little record remains of the Arab dominion, which lasted about two hundred and twenty years; no more Christian bishops are known until after that time, but tradition asserts, not without probability, that some of the original natives remained in certain villages and some Greeks in the capital, among whom were Christians.

The Norman knights, who brought their conquering arms into Apulia, Calabria, and Sicily, and even sent ships to Byzantium, were probably the first to bring a Teutonic race and influence into Malta. Through somewhat uncertain dates it appears that Roger I. (youngest son of Tancred, and brother of Guiscard) about 1090 landed in the island and levied tribute, and that about 1127 Roger II., this not being paid, set sail with a fleet, took Medina, then governed by a *gaito*, Maimono, and after setting free all the Christians and exacting a large sum in money, mules, and horses, completed the conquest of Malta and Gozo. Walter, bishop of Malta, whose name is found as witness to a document of 1090, is believed to have been now appointed by Roger I., and consecrated by the pope. A succession of Christian bishops, endowments and buildings made, tithes granted, &c., testify to the restoration of the church in the islands, while they shared with Sicily the feudal laws and administration newly established under the Norman rule. In 1193 Malta as a county gave a title to Margarito Brundusio, grand-admiral of Sicily, and three successive counts of Malta followed. After the Norman princes had possessed the islands about a century, the kingdom of the Two Sicilies, and the Maltese islands with it, passed in 1194 to the emperor Henry VI., in professed right of his wife Constance, daughter and heiress of Roger II. In 1223 a Maltese named Henry or Arrigo is stated to have been grand-admiral of Sicily (Pirrus, p. 906; Miège, ii. 38). He is probably the same as the distinguished Henry, count of Malta, who with three hundred Maltese youths in 1205 earned the favours of the Genoese by brilliantly taking two forts in Tripoli (Caffarus, *Ann. Genuenses*, in Muratori, t. vi.), and who took part also in the fourth crusade. No traces of the crusades, however, have been found in these islands, although it is probable that their leaders would not neglect the advantages of Maltese ports and sailors.

Henceforward Malta, as a fief of Sicily, followed the fortunes of that country. The Maltese seem to have taken no part in the Sicilian Vespers (1282), but to have held out for Charles of Anjou until Peter of Aragon, crowned king of Sicily, August 1282, won a battle at sea against the French, attacked Notabile and the forts, and thus obtained possession of the islands. For nearly two hundred and fifty years the Spanish house, through fourteen kings of Aragon, bore rule over Sicily and Malta. In 1391 the countship was erected into a marquisate, which lasted two years only. In 1427 a swarm of Moors (18,000) ravaged Malta and Gozo, but were not able to take the city Notabile; yet the people, though afflicted by the plague in 1431—as not unfrequently at other times—were able to sally forth to conquer Gerbi on the coast of Africa in the following year. The king at this time (1432) authorized the demolition of the old castle at Notabile, built three hundred and fifty years before, and gave the ground on which it stood to the town; but the fortifications of the island were strengthened (1466), the chief stronghold in the 15th century being the fortress of St Angelo. The inhabitants, addicted to fighting at sea, were forbidden from 1448 to 1494 to send out armed corsair ships, in order it is said to retain those capable of defence in the islands, the population of which was at the beginning of that period very scant. The Jews were expelled from Malta by the same edict of Ferdinand, in 1492, which turned them out of Spain. By 1514 the population of Malta had doubled; the two islands together contained 22,000 inhabitants (Miège, ii. 81). They frequently attacked the Moors on the mainland, and suffered reprisals themselves as late as 1526. Their last king of the Spanish house, the emperor Charles V., in 1530 granted Malta and Gozo (with the city of Tripoli) as a noble and free fief to the knights of St John of Jerusalem, still retaining, however, the suzerainty, by the homage of a falcon annually to be given by the knights.

Malta thus during many centuries occupied the position of a feudal fief of Sicily; her laws and her church date from the times of the Normans, and both developed as in other feudal governments. The progress of her political independence in the 15th century, especially under Alphonso I. and John I., has been shown by the historian Miège; the history of the relations between Malta and the monarchs of Sicily affords an interesting example of feudal obligations with their attendant difficulties. That these fostered a spirit of liberty and independence in the people, and must have tended largely to the prosperity of the islands, is shown by numerous diplomas of the Aragonese suzerains preserved in the archives at Malta (Eton's *Authentic Materials*, 1803, p. 108 *sq.*), where it is seen that the inhabitants acquired many privileges and were also able to pay on emergency considerable sums of money to increase and preserve their privileges. Thus in 1428, only a century before the knights came, they paid 30,000 florins of gold to King Alphonso in order to secure their tenure by the crown of Sicily without any middle-lords, being the second time they thus bought back their island rights (Eton, p. 84). These things are to be noticed, because, as has been complained, the knights unjustly depreciated the value and advantages of the islands, in order the more readily to obtain the grant from Charles V. Under the kings of Sicily, Notabile was a *università* or commune, with its popular council and jurats, a captain-justiciar representing the rights of the crown; in other words, Malta was a republic governed by its own laws; the principal magistrate was named by the king out of three persons proposed by the *consilio popolare*, and was liable to dismissal on complaint by the people. The king protected the island, and in return the Maltese took a share in his wars. When the knights took possession the Maltese stipulated that each grand master on entering office should take oath to maintain their ancient rights and liberties (Eton, pp. 38, 85, 101). The knights began by deceiving the Maltese candidates for admission into their ranks. Their rule, at first conciliatory, soon became despotic; in time the overshadowing power of a rich military organization encroached upon the constitutional government, corruption brought the officials under the control of the knights, and the people lost their liberties, though the material prosperity of the islands was in many ways heightened.

For the history of the order of St John see St John (Knights of). Twenty-eight successive grand masters, from Lisle d'Adam to Hompesch (1530 to 1798), held the islands. Lisle d'Adam established his convent and hospital in the Borgo, a city that had grown up on the coast near the castle St Angelo, opposite the ancient fort St Elmo. In 1541 was made the first survey for the fortification of Valetta. Ten years later the Turks, led by their famous naval commander Dragut, ravaged Gozo, and made an attempt upon Malta which failed. The knights, already famous for their power at sea, were soon engaged in much skirmishing warfare against the pirates and Turks, winning success and riches, and the gratitude of Christian nations. In 1565, after eight years of threatening preparations, during which the knights had been strengthening and fortifying their island, the Turks besieged them with an immense force; they defended themselves with such valour that it took a month to reduce Fort St Elmo, and in rather over two months more the Turks, whose further advance was successfully resisted, were forced to retire, leaving the knights free to build their new city Valetta and its fortifications. The admiration and gratitude of Catholic countries for this service to Christendom showed itself in liberal donations towards these works; large sums were also raised from the possessions of the order; and Valetta, the first stone of which was laid on 26th March 1566, in four years rose upon the ridge of rock, "a city built by gentlemen for gentlemen," as it has been well described,—the original design of which, the cutting down the rock to a level platform, had only suffered from the continual fear of molestation by the Turks while building.

The order, now firmly established in their island, continued to carry out their mission, that of keeping the Mediterranean clear from Turkish and Moorish pirates, and of protecting Christendom against the infidels. Numerous sea-fights took place during the 16th and 17th centuries, many of them undertaken more to make up for the neglect of some of the grand masters to supply the islands with corn, by seizing upon Turkish stores, than for any better reason. Valetta became in consequence "a vast slave mart." In 1614, under G. M. Vignacourt, an aqueduct was constructed at a cost of £13,000 to bring water to Valetta from springs near Citta Vecchia, a work of immense value, and still in use. But the work of fortifying Malta occupied a large share of money and attention, and was carried on without relaxation by many of the grand masters, down as late as the building of Fort Tigné in 1793. Besides the great lines and forts in and round Valetta, the knights have left their mark all over the islands: they made good roads, improved Citta Vecchia, built watch-towers round the coasts, and erected towers, country palaces, and gardens. They also established and continually carried on, at Notabile and Valetta, their hospitals for the sick and wounded. In 1768 the Jesuits, having given much trouble, were expelled and their property confiscated. Danger from rebellion twice threatened the knights—in 1722, when the slaves were believed to be in communication with the Turks, and from 1773 to 1775, when both people and priests were wrought upon by oppression and misgovernment, which, only mitigated for a time by the better measures of G. M. Rohan, led to the weak and disorganized condition of the order that ended in its overthrow. In June 1798, the possessions of the order in France having already been seized by the republicans, Bonaparte on his way to Egypt landed with a large force in a bay behind Valetta; no resistance was made, and in a few hours the French were in possession of the whole of Gozo and Malta except the town of Valetta and one little fort. In four days more, without bombardment, the order had surrendered Valetta and practically ceased to exist. Bonaparte stayed six days, laying down laws and regulations with a high hand, and collecting plunder from churches, &c. He left Vaubois in charge, but in less than three months the Maltese had revolted from the tyranny of their new masters, and Vaubois inside Valetta with 6000 men sustained a siege and blockade lasting two years, during which time Portuguese, Neapolitans, and a small force of English assisted the Maltese. Sir Alexander Ball commanded in the name of the Sicilian king, and was put at the head of their National Council by the Maltese. On 4th September 1800 Vaubois surrendered, and the Maltese (who lost 20,000 men) put themselves and their islands under the protection of the English,—reunion to the crown of Sicily, which they had sought, being no longer thought of. The treaty of Amiens (1802) provided that the islands should be restored to the order of St John, obviously to the advantage of France, but repugnant to the Maltese. War breaking out again, the islands remained in the hands of England till in 1814 they were secured to her by the treaty of Paris (Art. 7), under which she still holds them.

Forbes, Captain Spratt, Dr G. Gulia, C. A. Wright, and Wood's *Tourist's Flora*. (L. T. S.)

MALTE-BRUN, Conrad, a distinguished geographer, was born August 12, 1755, at Thysted in Denmark, and died at Paris, December 14, 1826. His real name was Malte Conrad Bruun, and it was not till he settled in France that he became known by the more familiar form. While a student at Copenhagen, he made himself famous partly by his verses, but much more by the violence of his political pamphleteering; and at length, in 1800, the legal actions which the Government authorities had from time to time instituted against him culminated in a sentence of perpetual banishment. The principles which he had advocated were those of the French Revolution, and, though he at first sought asylum in Sweden, before long he found his way to Paris. There he looked forward to a political career; but, when Napoleon's personal ambition began to unfold itself, Malte Brun was bold enough to protest, and to turn elsewhere for employment and advancement. He was associated with Mentelle and Herbin in the compilation of their *Géographie mathématique . . de toutes les parties du Monde* (Paris, 1803–7, 16 vols.), and before many years he was recognized as one of the best geographers of France. He is remembered, not only as the author of six volumes of the learned *Précis de géographie universelle*, continued after his death by other hands, but also as the originator of the *Annales des Voyages* (1808), and the principal founder of the Geographical Society of Paris.

MALTHUS, Thomas Robert (1766–1834), the scientific expounder of the principle of population, was born in 1766 at the Rookery, a small estate owned by his father in the county of Surrey. His father was a gentleman of good family and independent fortune,—a man of considerable culture both in literature and philosophy, the friend and correspondent of Rousseau, and one of his executors, one, too, who showed no little interest in those social problems in which his son was to be an original inquirer. Young Malthus was never sent to a public school, but received his education from private tutors, who were themselves men of some distinction. In 1784 he was sent to Cambridge, where he was ninth wrangler, and became fellow of his own college (Jesus) in 1797. The same year he received orders, and undertook the charge of a small parish in Surrey, still, however, retaining his fellowship. In the following year he published the first edition of his great work, *An Essay on the Principle of Population as it affects the Future Improvement of Society, with remarks on the speculations of Mr Godwin, M. Condorcet, and other writers.* The work excited a good deal of surprise as well as attention; and with characteristic thoroughness and love of truth the author went abroad to collect materials for the verification and more exhaustive treatment of his views. As Britain was then at war with France, only the northern countries of Europe were quite open to his research at that time; but during the brief peace of Amiens Malthus continued his investigations in France and Switzerland. The result of these praiseworthy labours appeared in the greatly enlarged and more mature edition of his work, which was published in 1803. In 1805 Malthus married happily, and not long after was appointed professor of modern history and political economy in the East India Company's College at Haileybury. This situation he retained till his death in 1834. Malthus was one of the most amiable, candid, and cultured of men. In all his private relations he was not only without reproach, but distinguished for the beauty of his character. He bore the popular abuse and misrepresentation without the slightest murmur or sourness of temper. The aim of his inquiries was to promote the happiness of mankind, which could be better accomplished by pointing out the real possibilities of progress than by indulging in vague dreams of perfectibility apart from the actual facts which condition human life.

Malthus's *Essay on Population* grew out of some discussions which he had with his father respecting the perfectibility of society. His father shared the theories on that subject of Condorcet and Godwin; and his son combated them on the ground that the realization of a happy society will always be hindered by the miseries consequent on the tendency of population to increase faster than the means of subsistence. His father was struck by the weight and originality of his views, asked him to put them in writing, and then recommended the publication of the manuscript. It was in this way the *Essay* saw the light. Thus it will be seen that both historically and philosophically the doctrine of Malthus was a corrective reaction against the superficial optimism diffused by the school of Rousseau. It was the same optimism, with its easy methods of regenerating society and its fatal blindness to the real conditions that circumscribe human life, that was responsible for the wild theories of the French Revolution and many of its consequent excesses.

The *Essay on the Principle of Population* will best be considered under two heads :—(1) the principle itself, with the arguments and illustrations by which it is supported; and (2) remarks on its origin and its applications.

I. The principle itself. The idea with which Malthus starts is the improvement of society. In an inquiry concerning the improvement of society there are two things to be done,—(1) to investigate the causes that have hitherto impeded the progress of mankind to happiness, and (2) to examine the probability of the total or partial removal of these causes in future. Waiving the consideration of such an immense field of thought, Malthus restricts himself to the examination of one great cause intimately connected with human nature and its effects on society, which, though operating since the commencement of society, has been little noticed by writers. This cause is the constant tendency in all animated life to increase beyond the nourishment prepared for it. Throughout both the animal and vegetable kingdoms, nature has scattered the seeds of life abroad with the most profuse and liberal hand. Life on this planet is so prolific that, if allowed free room to develop itself, it would fill millions of worlds in the course of a few thousand years. There is only one limit to the indefinite increase, and that is necessity. In plants and irrational animals, which are impelled by blind instinct untroubled by doubts about providing for their offspring, the problem is simple; in their case increase is checked only by want of room and nourishment. As regards man, whose equally powerful instinct is controlled by reason, the question is more complicated. In his case, increase must either be checked by preventive restraint, which too frequently produces vice ; or a constant check, from the difficulty of acquiring food, must be in operation.

That population tends to increase beyond the means of subsistence is obvious in two ways,—(1) from a comparison of the natural increase of population, if left to exert itself with perfect freedom, with the available increase of subsistence under the most favourable conditions, and (2) from a review of the different states of society in which man has existed. Under the first head, Malthus considers it a safe calculation that population, when unchecked, goes on doubling itself every twenty-five years. It has even been calculated that it may double itself in about thirteen years ; that proportion has actually occurred for short periods in more countries than one. Malthus, however, contents himself with the more moderate rate, namely, that population, when unchecked, doubles itself every twenty-five years, or increases in a geometrical ratio. If so, how is the rate of increase of the means of subsistence to be estimated ? If we take a limited area, no improvement in developing the resources of the soil will keep pace with the unchecked increase of population. We may allow that, through the great improvements of agriculture in Great Britain, the average produce of the island could be doubled in the first twenty-five years ; but in the next twenty-five it is impossible to suppose that the produce could be quadrupled. The utmost we can allow is that the produce might be increased every twenty-five years by a quantity equal to what it at present yields. If we apply this supposition to the whole earth, we shall assume an increase much greater than any possible exertions of mankind could effect. On the whole, then, in the present average state of the earth, the means of subsistence could not be made to increase faster than in an arithmetical ratio. With such a disproportion between the ratio of increase of population and of the means of subsistence, population can be kept down to the level of the means of subsistence only by the strong law of necessity operating as a check on the greater power. In fact, the ultimate check to population is the want of food ; but this ultimate check is never the immediate check, except in cases of actual famine. The immediate check consists of all those customs and all those diseases which are generated by a scarcity of food, and all the causes independent of the scarcity which tend to weaken and destroy the human frame. These checks are either preventive or positive ; and the former consist either of moral restraint or of vice, always so pernicious to society. The positive checks are extremely various, including everything that contributes to shorten the natural duration of human life. "Under this head may be enumerated all unwholesome occupations, severe labour and exposure to the seasons, extreme poverty, bad nursing of children, large towns, excesses of all kinds, the whole train of common diseases and epidemics, wars, plague, and famine." The checks of all kinds may be reduced to three heads—moral restraint, vice, and misery. This theoretical exposition of the checks to population Malthus supports and illustrates by an exhaustive examination of the checks which have operated or still operate in the various countries and states of society from the brutal and revolting practices prevalent among the savages of Tierra del Fuego and Australia to the moral self-control of the highest nations. It is not a pleasant picture, but it is merely a presentation of historical and statistical facts for which Malthus is in no way responsible. Throughout his entire exposition he does not theorize, but seeks only to systematize and elucidate facts which cannot be controverted, belonging as they do to the history of the world. The only notable exception is his attempt to express in mathematical language the possible increase of the means of subsistence. The conditions determining such increase are too vague and various to be calculated in such a way. On this point Malthus is not followed by subsequent economists, and it is not essential to his principle. At the same time, in spite of its unsoundness, it does help us to realize the disproportion between the possible increase of population and the means of subsistence.

II. What remains to be said of the *Essay on the Principle of Population* may be embraced in the following notes. (1) Origin of the principle. The population question has always had a great influence on the development of mankind. In the most barbarous nations the problem of preserving the balance between food and population must always have been a pressing one, and has led to some of their cruellest and most immoral customs. The more theoretic consideration of the question has a large place in the political treatises of Plato and Aristotle. Just before Malthus's time it had been touched by such writers as Benjamin Franklin (*Observations concerning the Increase of Mankind*), Hume (*Populousness of the Ancient Nations*), Wallace (*On the Numbers of Mankind in Ancient and Modern Times*), Townshend (*Travels in Spain*), not to mention many other modern writers of less recent date. (2) The remedy for over-population usually proposed is emigration. No doubt there are immense fertile areas yet unpeopled. But the difficulty of transferring the surplus population, and especially of conveying surplus capital to these regions, and of co-ordinating the two, is a point that must not be overlooked. In spite of the great development of steam as a means of emigration, it remains a fact that population tends to excess in many of the most important centres of the world. Besides, emigration is only a postponing of the difficulty. In another century even the Mississippi valley will be well stocked. (3) Relation of Malthus to Darwin. In his book *Animals and Plants under Domestication*, vol. i. p. 10, Darwin expressly acknowledges his indebtedness to Malthus in thinking out his cardinal principle of natural selection. After the study of domestic productions had given him a just idea of the power of selection, he saw, "on reading Malthus *On Population*, that natural selection was the inevitable result of the rapid increase of all organic beings." (4) Poor-law reform. The reformed poor law of 1834 was a real triumph of Malthus's teaching. The effect of the old poor law was to encourage population by relieving the labouring classes of the due responsibility of supporting themselves and their families. By discouraging foresight, self-control, and the spirit of self-reliant independence, it demoralized the working man. The great aim of the new poor law was to emphasize the duty of self-support and the responsibilities of parentage. (5) Relation to modern politics. Some of the greatest difficulties in contemporary politics can be correctly understood only in the light of the principle of population. The most striking example of this is India, where, under the good government of England, the old and unhappy checks to population, such as war, famine, pestilence, and religious self-immolation, have been removed. As there has been no proportionate improvement in agriculture, and in the ethical development of the people, population has increased beyond the means of subsistence, and there prevails a tendency to chronic poverty, a very low standard of living, a general misery, and an unsatisfactory social *morale*, which correspond badly with the high European civilization under which such a state of things is maintained. (6) It is only due to the memory of a good man, who was a sincere lover of truth and of the progress of humanity, that we should emphasize the fact that Malthus is in no way responsible for the immoral theories popularly connected with his name. Apart from such increase in the means of subsistence as may be attained by emigration and improved agriculture, Malthus approved of only one method of solving the population question, namely, moral self-restraint. His single precept is "Do not marry till you have a fair prospect of supporting a family." The greatest and highest moral result of his principle is that it clearly and emphatically teaches the responsibility of parentage, and declares the sin of those who bring human beings into the world for whose physical, intellectual, and moral wellbeing no satisfactory provision is made.

Besides his great work, Malthus wrote *Observations on the Effect of the Corn Laws*; *An Inquiry into the Nature and Progress of Rent*; *Principles of Political Economy*; and *Definitions in Political Economy*. His views on rent were of real importance. For his life see *Memoir* by his friend Dr Otter, bishop of Chichester (prefixed to 2d edition, 1836, of the *Principles of Political Economy*). (T. K.)

MALTON, a parliamentary borough of Yorkshire, England, which includes Old Malton and New Malton in the North Riding, and the parish of Norton in the East Riding. New Malton is situated on an eminence on the right bank of the Derwent, 22 miles north-east of York and 213 north of London. Old Malton lies about a mile to the north-east, and a bridge across the river connects New Malton with Norton. New Malton, which is a market-town, consists of several well-built streets radiating from the market-place. The church of St Michael is a fine building in the Late Norman style; the church of St Leonard, of mixed architecture, with square tower and spire, has three Norman arches and a Norman font; the west doorway of the church of St Mary at Old Malton is one of the finest specimens of Norman in England. In Old Malton there is a grammar school founded in 1547, and also the remains of a priory of Gilbertine canons, founded in 1150. New Malton possesses a town-hall and a corn exchange. The town has some shipping trade, and also iron and brass foundries, agricultural implement works, corn mills, tanneries, and breweries. In the neighbourhood there are lime and whinstone quarries. The population of the parliamentary borough (area 6855 acres) in 1871 was 8168, and in 1881 it was 8750.

Malton was a Roman station, and various Roman remains have been found in the neighbourhood. The old castle, built by the De Vescis in the time of the Normans, was demolished by Henry II. In the reign of Stephen the town, while occupied by the Scots, was burned down by Thurston, archbishop of York, and on being rebuilt it was named New Malton. The borough sent members to parliament as early as the reign of Edward I., but for some years previous to 1640 the privilege was in abeyance. Since 1868 only one member has been returned.

MALTZAN, Heinrich K. E. H. Freiherr [Baron] von (1826–1874), African and Oriental traveller, was born in the vicinity of Dresden, and studied law at Jena, but on account of ill-health spent much of his time from 1850 in travel. Succeeding to his father's property in 1852, he extended the range of his journeys to Morocco and other parts of the Maghrib, and before his return home in 1854 had also visited Egypt, Palestine, and other countries of the Levant. In 1856–57 he was again in Algeria; in 1858 he reached the city of Morocco; and in 1860 he succeeded in performing the pilgrimage to Mecca, which he afterwards described in his book *Meine Wallfahrt nach Mecca*, but had to flee for his life to Jeddah without visiting Medina. He then visited Aden and Bombay, and after some two years of study in Europe again began to wander through the coasts and islands of the Mediterranean, repeatedly visiting Algeria. His first book of travel, *Three Years in the North-West of Africa*, appeared in 1863, and was followed by a variety of works and essays, popular and scientific, till a little before his death at Pisa in 1874, when he put an end with his own hand to neuralgic pains which had tortured him for years.

Maltzan's last book, *Reise in Arabien* (1873), is one of his most useful contributions. It contains, like his other works, some lively description, but is chiefly valuable as a digest of much information about little-known parts of South Arabia collected from natives during a residence at Aden in 1870–71. Among his other services to science must be noticed his collection of Punic inscriptions (*Reise in Tunis und Tripolis*, 3 vols., Leipsic, 1870), various collections on Arabic dialects (*Z. D. M. G.*, various dates), and the editing of Von Wrede's remarkable journey in Ḥadramaut (1873).

MALUS, Étienne Louis (1775–1812), the discoverer of the laws of the polarization of light by reflexion, born at Paris on the 23d of June 1775, was the son of Anne Louis Malus du Mitry, and of Louisa Charlotte Desboves, his wife. His father, who had a place in the treasury of France, gave him at home an excellent education in mathematics and in the fine arts, as well as in classical literature, and he then studied with distinction in the school of military engineers; but, being regarded as a suspected person, probably on account of the situation held by his father, he was dismissed from the school without receiving a commission, and obliged to enter the army as a private soldier. Being employed upon the fortifications of Dunkirk, he was soon distinguished by M. Lepère, the director of the works, as superior to his accidental situation, and was selected as a member of the École Polytechnique then to be established under Monge, who immediately chose him as one of the twenty who were to be instructors of the rest. In this institution, which at that moment was the only refuge of the sciences in France, he passed three years, giving special attention to the mathematical theory of optics. From the École he was admitted into the corps of engineers, and served in the army of the Sambre and Meuse; he was present at the passage of the Rhine in 1797, and at the affairs of Ukratz and Altenkirch. In Germany he fell in love with the daughter of Koch, the chancellor of the university of Giessen; and he was on the point of marrying her when he was obliged to join the Egyptian expedition. He remained in the East, and saw much service till the capitulation with the English, when he returned to France (October 1801), and hastened to Germany to fulfil his engagement. His fidelity was rewarded, during the eleven years that he survived, by the most constant and affectionate attention on the part of his wife.

Though his health was much broken by the eastern campaign, Malus was still able to combine the pursuit of his favourite sciences with his official duties in superintending the construction of works at Antwerp and at Strasburg; and upon occasion of a prize question proposed by the Institute he undertook the investigation of the extraordinary refraction of Iceland crystal, which the experiments of Dr Wollaston had previously shown to agree very accurately with the laws laid down by Huygens; and, besides completely confirming all Wollaston's results, he had the good fortune greatly to extend the Huygenian discovery of the peculiar modification of light produced by the action of such crystals, which Newton had distinguished by the name "polarity," and which Malus now found to be produced in a variety of circumstances, independently of the action of crystallized bodies. It seems natural to suppose that the investigation of the laws of the internal reflexion of light at the second surface of the crystals must have led him to the discovery of the effects of oblique reflexion in other circumstances; but, according to Biot, Malus's first observation of polarization by reflexion was due to the accident that he chanced to look through a quartz crystal at the image of the sun reflected from the windows of the Luxembourg. The value of his discovery was acknowledged by his election as a member of the Institute, by the award of the Rumford medal of the Royal Society of London, and by military promotion. Malus died on the 24th of February 1812, universally regretted by the lovers of science in all countries, and deeply lamented by his colleagues, who said of him, as Newton did of Cotes, that if his life had been prolonged we should at last "have known something" of the laws of nature.

Malus's first publication appears to have been a paper "On an unknown Branch of the Nile," in the first volume of the *Décade Égyptienne*. A mathematical "Traité d'Optique," presented to the Institute before the completion of his experiments on double refraction, was published in the *Mémoires pr. à l'Institut*, vol. ii., Paris, 1810. His more important discoveries were first made known in the second volume of the *Mémoires d'Arcueil*, Paris, 1809, 8vo; and again, in the "Theory of Double Refraction," *Mém. pr. à l'Inst.*, vol. ii., a paper which obtained a prize on the 2d of January 1810. See Delambre, *M. Inst.*, 1816, p. xxvii.; Biot, in *Biographie Universelle*, xxvi., Paris 1820.

MALVASIA (from the Greek *Monembasia*, *i.e.*, the city of the single approach or entrance; the Italian *Napoli di Malvasia*, the Turkish *Mengeshe* or *Beneshe*), one of the principal fortresses and commercial centres of the Levant during the Middle Ages, still represented by a considerable mass of ruins and a town of about 1000 inhabitants, stood on the east coast of the Morea, contiguous to the site of the ancient Epidaurus Limera, of which it took the place. So extensive was its trade in wine that the name of the place became familiar throughout Europe as the distinctive appellation of a special kind—the Italian *Malvasia*, Spanish *Malvagia*, French *Malvoisie*, English *Malvesie* or *Malmsey*. The wine was not of local growth, but came for the most part from Tenos and others of the Cyclades.

As a fortress Malvasia played an important part in the struggles between Byzantium, Venice, and Turkey. The Byzantine emperors considered it one of their most valuable posts in the Morea, and rewarded its inhabitants for their fidelity by unusual privileges. Phrantzes (lib. iv. cap. xvi.) tells how Mauricius Tiberius made the city (previously dependent in ecclesiastical matters on Corinth) a metropolis or archbishop's see, and how Alexius Comnenus, and more especially Andronicus Palæologus, gave the Monembasiotes freedom from all sorts of exactions throughout the empire. In 1147 Malvasia bade defiance to the Normans, and in 1205 obliged Villehardouin, after a four years' siege, to swear to preserve its liberties and privileges (Fallmerayer, i. pp. 408-409). It was defended against the Turks by Manuel Palæologus in 1460. In 1689 it was the only town of the Morea which held out against Morosini, and Cornaro his successor only succeeded in reducing it by famine. In 1715 it capitulated to the Turks, and on the failure of the insurrection of 1770 the leading families were scattered abroad. As the first fortress which fell into the hands of the Greeks in 1821, it became in the following year the seat of the first national assembly.

See Curtius, *Peloponnesos*, ii. pp 293 and 328; Castellan, *Lettres sur la Morée* (1808) for a plan; and Valiero, *Hist. della guerra di Candia* (Venice, 1679) for details as to the fortress.

MALVERN, GREAT, a watering-place of Worcestershire, England, beautifully situated on the eastern slope of the Malvern hills, 8 miles south-west by south of Worcester, and 120 north-west by west of London. The town is irregularly built, but there are many villas, and on account of its fine situation in the centre of the Chase of Malvern, its pure air, and its chalybeate and bituminous springs, it is much frequented by summer visitors. At Malvern a hermitage was endowed by Edward the Confessor, which after the Conquest was changed into a Benedictine priory. Of the buildings, which date from 1083, there still remain the abbey gate, and also the church (partly rebuilt in the reign of Henry VII., and restored since 1861), a very fine structure, Norman and Perpendicular, with square embattled tower. There is a proprietary college, founded in 1863. At Little Malvern, about 3 miles south of Great Malvern, there was a Benedictine priory, founded in 1171, upon the site of which the dwelling-house of Malvern Court has been erected, preserving the tower and chancel of the old priory church. At Malvern Wells, 2 miles south of Malvern, is the celebrated "Holy Well," the water of which is of perfect purity. The population of Malvern in 1871 was 5693, and in 1881 it was 5847.

MÁLWÁ, an historical province of Central India, roughly coextensive with the western portion of the Central India agency, is bounded on the N. by Hindustan Proper, on the E. by Bundelkhand, on the S. by the Deccan, and on the W. by Rájputána. It consists of an upland region, with many fertile valleys, included within the main rivers of the Ganges, the Són, the Chambal, and the Nerbudda. In prehistoric times the capital was the ancient city of Ujain (Oojein), associated in Hindu legend with the great king Vikramáditya, the date of whose accession (57 B.C.) has given the "Samvat" era to all India. The Mohammedan chronicler Ferishta describes Málwá as the kingdom of an independent rájá, when Mahmúd of Ghazní invaded India in the beginning of the 11th century. It appears to have first fallen into the hands of the Moslems about 1309, during the reign of the Delhi emperor Alá-ud-dín. When the Tughlak dynasty was weakened by the repeated attacks of the Mughals, their viceroy in Málwá succeeded in establishing his independence. The first Moslem king of Málwá was Diláwar Khán Ghori, of Afghán origin, who ruled from 1387 to 1405, and placed his capital at Mandu. He was succeeded by his son Hoshang Ghori, to whom are attributed most of the magnificent ruins still to be seen at Mandu. In 1526 the Ghori dynasty came to an end, being overthrown by Bahádur Sháh of Guzerát; and in 1570 Málwá was, on the conquest of Guzerát by the emperor Akbar, incorporated in the Mughal dominions. On the decay of the Delhi empire in the 18th century, Málwá was one of the first provinces to be overrun by the Mahrattas. In 1737 the peshwá exacted *chauth* or one-fourth of the revenue, and at a later date the two great military chiefs Sindhia and Holkar carved out for themselves kingdoms, which their descendants still retain. But the Mahrattas set up no organized government, so that Málwá, besides its native population of predatory Bhíls, became the refuge of all the mercenary bandits of the peninsula. In the beginning of the present century, the depredations of these bandits or Pindárís led to what is sometimes known as the fourth Mahratta war of 1817, under the governor-generalship of Lord Hastings. As the result, the Pindárís were extirpated; and under the rule of Sir John Malcolm the Bhíls were tamed, and the jungles were cleared of wild beasts. Many of the Bhíls have been enlisted as British soldiers; and the headquarters of the Málwá Bhíl corps is at Sardárpur. At the present day Málwá is best known as giving its name to the opium which is annually exported from Bombay to the amount of about 37,000 chests.

MAMELUKE, a corruption of the Arabic *Mamlûk* (*Memlook*), a slave. The name of Mamelukes has passed into history from the body-guard of Turkish slaves first formed in Egypt under the successors of Saladin, who ultimately usurped the supreme power. For the history of the Mameluke sultans and Mameluke beys, see EGYPT, vol. vii. p. 755 *sq.*

MAMMALIA

MAMMALIA (French, *Mammifères*; German, *Säugethiere*) is the name invented by Linnæus (from the Latin, *mamma*), and now commonly used by zoologists, for one of the classes of vertebrated animals, which, though the best known and undoubtedly the most important group of the animal kingdom, has never received any generally accepted vernacular designation in our language. The unity of structure of the animals composing this class, and their definite demarcation from other vertebrates, were not recognized until comparatively modern times, and hence no word was thought of to designate what zoologists now term a mammal. The nearest equivalents in common use are "beast" and "quadruped," both of which, however, cover a different ground, as they are often used to include the larger four-footed reptiles, and to exclude certain undoubted mammals, as Man, Bats, and Whales.

The limits of the class as now understood by zoologists are perfectly well defined, and, although certain forms still existing on the earth (though not those mentioned above as excluded by the popular idea) are of exceedingly aberrant structure, exhibiting several well-marked characters which connect them with the lower vertebrated groups, common consent retains them in the class with which the great proportion of their characters ally them, and hitherto no traces of any species showing still more divergent or transitional characters have been discovered. There is thus a great interval, not bridged over by any known forms, recent or extinct, between mammals and other vertebrates.

In the gradual order of evolution of living beings, mammals taken altogether are certainly the highest in organization, as they were probably the last to appear on the earth's surface, though this must be said with some reservation, pending further knowledge of the early history of the class of birds. But, as in speaking of all other large and greatly differentiated groups, this expression must not be understood in too limited a sense. The tendency to gradual perfection for their particular station in life, which all groups manifest, leads to various lines of specialization, or divergence from the common or general type, which may or may not take the direction of elevation. A too complex and sensitive condition of organization may in some circumstances of life be disadvantageous, and modification may then take place in a retrograde direction. In mammals, as in other classes, there are low forms as well as high forms, but by any tests that can be applied, especially those based on the state of development of the central nervous system, it will be seen that the average exceeds the average of any other class, that many species of this class far excel those of any other in perfection of structure, and that it contains one form which is unquestionably the culminating point yet arrived at amongst organized beings.

With regard to the time of the first appearance of mammals upon the earth, the geological record is provokingly imperfect. At the commencement of the Tertiary period they were abundant, and already modified into most of the leading types at present existing. It was at one time thought that they first came into being at this date, but the discovery of fragments of numerous small species has revealed the existence of some forms of the class at various periods throughout almost the whole of the age of the deposition of the Secondary rocks. This subject will be reverted to later on.

It hardly need be said that mammals are vertebrated animals, and possess all the characteristics common to the members of that division of the animal kingdom. They are separated from the *Ichthyopsida* (fishes and amphibia) and agree with the *Sauropsida* (reptiles and birds) in the possession during their development of an amnion and allantois, and in never having external branchiæ or gills. They differ from reptiles and resemble birds in being warm-blooded, and having a heart with four cavities and a complete double circulation. They differ from both birds and reptiles in the red corpuscles of the blood being nucleated and, with very few exceptions, circular in outline; in the lungs being freely suspended in a thoracic cavity, separated from the abdomen by a complete muscular partition, the diaphragm, which is the principal agent in inflating the lungs in respiration; in having but one aortic arch, which curves over the left bronchus; in the skin being more or less clothed with hair, and never with feathers; in the greater perfection of the commissural system of the cerebral hemispheres, which has either a complete corpus callosum, or an incomplete one associated with a very large anterior commissure; in having no syrinx or inferior vocal organ, but a complete larynx at the upper end of the trachea; in having a mandible of which each ramus (except in very early developmental conditions) consists of a single bone on each side, articulating to the squamosal, without the intervention of a quadrate bone; in having a pair of laterally placed occipital condyles instead of one median one; and in the very obvious character of the female being provided with mammary glands, by the secretion of which the young (produced alive and not by means of externally hatched eggs) are nourished for some time after birth.

In common with all vertebrated animals, mammals have never more than two pairs of limbs. In the great majority of the class both are well-developed and functional, and adapted for terrestrial progression, as the larger number of mammals live ordinarily on the surface of the earth. They are, however, by no means limited to this situation. Some species spend the greater part of their lives beneath the surface, their fore limbs being specially modified for burrowing; others are habitually arboreal, their limbs being fitted for climbing or hanging to boughs of trees; some are as aerial as birds, the fore limbs being developed into wings of a special character; others are as aquatic as fishes, the limbs assuming the form of fins or paddles. In many of the latter the hinder extremities are either completely suppressed, or present only in a rudimentary state. In no known mammal are the fore limbs absent.

The hinder extremity of the axis of the body is usually prolonged into a tail, which may be a mere pendent appendage, or modified to perform various functions, as grasping boughs in climbing, or even gathering food, in the case of the prehensile-tailed Monkeys and Opossums, swimming in the *Cetacea*, and acting as a flap to drive away troublesome insects from the skin in the *Ungulata*.

GENERAL ANATOMICAL CHARACTERS OF THE MAMMALIA.

Tegumentary Structures.

The external surface of the greater number of members of the class is thickly clothed with a peculiarly modified form of epidermis, commonly called hair. This consists of hard, elongated, slender, cylindrical or tapering, filiform, unbranched masses of epidermic material, growing from a short papilla sunk at the bottom of a follicle in the derm or true skin. Such hairs upon different parts of the same Hair.

animal, or upon different animals, assume various forms, and are of various sizes and degrees of rigidity,—as seen in the delicate soft velvety fur of the Mole, the stiff bristles of the Pig, and the spines of the Hedgehog and Porcupine, all modifications of the same structures. These differences arise mainly from the different arrangement of the constituent elements into which the epithelial cells are modified. Each hair is composed usually of a cellular pithy internal portion, containing much air, and a denser or more horny cortical part. In some animals, as Deer, the substance of the hair is almost entirely composed of the medullary or cellular substance, and it is consequently very easily broken; in others the horny part prevails almost exclusively, as in the bristles of the Wild Boar. In the Three-toed Sloth (*Bradypus*) the hairs have a central horny axis and a pithy exterior. Though generally nearly smooth, or but slightly scaly, the surface of some hairs is strongly imbricated, notably so in some Bats, while in the Two-toed Sloth (*Cholœpus*) they are longitudinally grooved or fluted. Though usually more or less cylindrical or circular in section, they are often elliptical or flattened, as in the curly-haired races of men, the terminal portion of the hair of Moles and Shrews, and conspicuously in the spines of the Rodents *Xerus* and *Platacanthomys*. Hair having a property of mutual cohesion or "felting," which depends upon a roughened scaly surface and a tendency to curl, as in domestic Sheep (in which animals this property has been especially cultivated by selective breeding), is called "wool."

In a large number of mammals hairs of one kind only are scattered pretty evenly over the surface, but in many there are two kinds, one longer, stiffer, and alone appearing on the surface, and the other shorter, finer, and softer, constituting the under fur, analogous to the down of birds. In most cases hairs of a different character from those of the general surface grow in special regions, forming ridges or tufts on the median dorsal or ventral surface or elsewhere. The tail is very often completed in this way by variously disposed elongated hairs. The margins of the eyelids are almost always furnished with a special row of stiffish hairs, called *ciliæ* or eyelashes, and in most mammals specially modified hairs, constituting the *vibrissæ* or whiskers, endowed, through the abundant nerve supply of their basal papillæ, with special tactile powers, grow from the lips and cheeks. In some mammals the hairy covering is partial and limited to particular regions; in others, as the Hippopotamus and the *Sirenia*, though scattered over the whole surface, it is extremely short and scanty; but in none is it reduced to so great an extent as in the *Cetacea*, in which it is limited to a few small bristles confined to the neighbourhood of the lips and nostrils, and often only present in the young or even fœtal condition.

Some kinds of hairs, as those of the mane and tail of the Horse, appear to persist throughout the life-time of the animal; but more generally, as in the case of the body hair of the same animal, they are shed and renewed periodically, generally annually. Many mammals have a longer hairy coat in winter, which is shed as summer comes on; and some few, which inhabit countries covered in winter with snow, as the Arctic Fox, Variable Hare, and Ermine, undergo a complete change of colour in the two seasons, being white in winter, and grey or brown in summer. The several species of Cape Mole (*Chrysochloris*), the Desmans or Water Moles (*Myogale*), and *Potamogale velox* are remarkable as being the only mammals whose hair reflects those iridescent tints so common in the feathers of tropical birds.

The principal and most obvious purpose of the hairy covering is to protect the skin against external influences, especially cold and damp. Its function in the hairless *Cetacea* is supplied by the specially modified and thickened layer of adipose tissue beneath the skin called "blubber."

Scales, &c.

True scales, or flat imbricated plates of horny material, covering the greater part of the body, so frequently occurring in reptiles, are found in one family only of mammals, the *Manidæ* or Pangolins; but these are also associated with hairs growing from the intervals between the scales or on the parts of the skin not covered by them. Similarly imbricated epidermic productions form the covering of the under surface of the tail of the flying Rodents of the genus *Anomalurus*; and flat scutes, with the edges in apposition, and not overlaid, clothe both surfaces of the tail of the Beaver, Rats, and others of the same order, and also of some Insectivores and Marsupials. The Armadillos alone have an ossified exoskeleton, composed of plates of true bony tissue, developed in the derm or corium, and covered with scutes of horny epidermis. Other epidermic appendages are the horns of Ruminants and Rhinoceroses,—the former being elongated, tapering, hollow caps of hardened epidermis of fibrillated structure, fitting on and growing from conical projections of the frontal bone, and always arranged in pairs, while the latter are of similar structure, but without any internal bony support, and situated in the median line. Callosities, or bare patches covered with hardened and thickened epidermis, are found over the ischial tuberosities of many apes, the sternum of camels, on the inner side of the limbs of the *Equidæ*, the grasping under surface of the tail of prehensile-tailed monkeys, &c. The greater part of the skin of both species of one-horned Asiatic Rhinoceros is immensely thickened and stiffened by increase of the tissue both of the derm and epiderm, constituting the well known jointed "armour-plated" hide of those animals.

Nails, claws, hoofs.

With very few exceptions, the terminal extremities of the digits of both limbs are more or less protected or armed by epidermic plates or sheaths, constituting the various forms of nails, claws, or hoofs. These are wanting in the *Cetacea* alone. A perforated spur, with a special secreting gland in connexion with it, is found attached to the hind leg of the males of the two species of *Monotremata*, the *Ornithorhynchus* and *Echidna*.

Odour-secreting glands.

Besides the universally distributed sebaceous glands connected with the pilose system, most mammals have special glands situated in modified portions of the integument, often involuted to form a shallow recess or a deep sac with a narrow opening, situated in various parts of the surface of the body, and which secrete odorous substances, by the aid of which individuals appear to recognize one another, and which probably afford the principal means by which wild animals are able to become aware of the presence of other members of the species, even at great distances. Although the commencement of the modifications of portions of the external covering for the formation of special secretions may be at present difficult to understand, the principle of natural selection will readily explain how such organs can become fixed and gradually increase in development in any species, especially as there would probably be a corresponding modification and increased sensibility of the olfactory organs. Such individuals as by the intensity and peculiarity of their scent had greater power of attracting the opposite sex would certainly be those most likely to leave descendants to inherit and in their turn propagate the modification.

To this group of structures belong the suborbital gland or "crumen" of Antelopes and Deer, the frontal gland of the Muntjak and of Bats of the genus *Phyllorhina*, the submental gland of the Chevrotains and of *Taphozous* and some other Bats, the post-auditory follicle of the Chamois, the temporal gland of the Elephant, the lateral glands of the Musk-Shrew, the lumbar gland of the Peccary, the inguinal glands of Antelopes, the preputial glands of the Musk Deer and Beaver (both so well known for the use made of their powerfully odorous secretion in medicine and perfumery) and also of the Swine and Hare, the anal glands of *Carnivora*, the perineal gland of the Civet (also of commercial value), the caudal glands of the Fox and Goat, the gland on the humeral membrane of Bats of the genus *Saccopteryx*, the post-digital gland of the Rhinoceros, the inter-digital glands of the Sheep and many Ruminants, and numerous others. In some of these cases the glands are peculiar to, or more largely developed in, the male; in others they are found equally developed in both sexes.

Dental System.

The dental system of mammals may be considered rather more in detail than space permits for some other portions of their structure, both on account of the important part it plays in the economy of the animals of this class, and of its interest to zoologists as an aid in classification and identification of species. Owing to the imperishable nature of their tissues, teeth are preserved for an indefinite time, and in the case of extinct species often offer the only indications available from which to derive an idea of the characters, affinities, and habits of the animal to which they have belonged. Hence even their smallest modifications have received great attention from comparative anatomists, and they have formed the subject of many special monographs.[1]

Teeth are present in nearly all mammals, and are applied to various purposes. They are, however, mainly subservient to the function of alimentation, being used either in procuring food by seizing and killing living prey or gathering and biting off portions of vegetable material, and more indirectly in tearing or cutting through the hard protective coverings of food substances, as the husks and shells of nuts, or in pounding, crushing, or otherwise mechanically dividing the solid materials before swallowing, so as to prepare them for digestion in the stomach. Certain teeth are also in many animals most efficient weapons of offence and defence, and for this purpose alone, quite irrespective of subserviency to the digestive process, are they developed in the male sex of many herbivorous animals, in the females of which they are absent or rudimentary.

Teeth belong essentially to the tegumentary or dermal system of organs, and, as is well seen in the lower vertebrates, pass by almost insensible gradations into the hardened spines and scutes formed upon the integument covering the outer surface of the body, but in mammals they are more specialized in structure and limited in locality. In this class they are developed only in the gums or fibro-mucous membrane covering the alveolar borders of the upper and lower jaw or the premaxillary and maxillary bones and the mandible. In the process of development, for the purpose of giving them that support which is needful for the performance of their functions, they almost always become implanted in the bone,—the osseous tissue growing up and moulding itself around the lengthening root of the tooth, so that ultimately they become apparently parts of the skeleton. In no mammal, however, does ankylosis or bony union between the tooth and jaw normally take place, as in many fishes and reptiles,—a vascular layer of connective tissue, the alveolo-dental membrane, always intervening.[2]

Cuvier, *Des Dents des Mammifères considérées comme caractères zoologiques*, 1822–25; R. Owen, *Odontography*, 1840–45; C. G. Giebel, *Odontographie*, 1855; C. S. Tomes, *Manual of Dental Anatomy, Human and Comparative*, 2d ed., 1882.

[2] The lower incisors of some species of Shrews are, however, said to become ankylosed to the jaw in adult age.

The presence of two or more roots, frequently met with in mammals, implanted into corresponding distinct sockets of the jaw, is peculiar to animals of this class.

Structure of teeth. The greater number of mammalian teeth when fully formed are not simple and homogeneous in structure, but are composed of several distinct tissues.

Pulp. 1. The *pulp*, a soft substance, consisting of a very delicate gelatinous connective tissue, in which numerous cells are imbedded, and abundantly supplied with blood-vessels and nerves, constitutes the central axis of all the basal part of the tooth, and affords the means by which the vitality of the whole is preserved. The nerves which pass into the pulp and endow the tooth with sensibility are branches of the fifth pair of cranial nerves. The pulp occupies a larger relative space, and performs a more important purpose in the young growing tooth than afterwards, as by the calcification and conversion of its outer layers the principal hard constituent of the tooth, the dentine, is formed. In teeth which have ceased to grow the pulp occupies a comparatively small space, which in the dried tooth is called the pulp cavity. This communicates with the external surface of the tooth by a small aperture at the apex of the root, through which the branches of blood-vessels and nerves, by which the tooth receives its nutrition and sensitiveness, pass in to be distributed in the pulp. In growing teeth the pulp cavity is widely open below, while in advanced age it often becomes obliterated, and the pulp itself entirely converted into bone-like material.

Dentine. 2. The *dentine* or *ivory* forms the principal constituent of the greater number of teeth. When developed in its most characteristic form, it is a very hard but elastic substance, white, with a yellowish tinge, and slightly translucent. It consists of an organic matrix, something like but not identical with that of bone, richly impregnated with calcareous salts (chiefly phosphate of lime), these constituting in a fresh human tooth 72 per cent. of its weight. When subjected to microscopical examination it is seen to be everywhere permeated by nearly parallel branching tubes which run, in a slightly curving or wavy manner, in a general direction from the centre towards the free surface of the tooth. These tubes communicate by open mouths with the pulp cavity, and terminate usually near the periphery of the dentine, by closed ends or loops, though in Marsupials and certain other mammals they penetrate into the enamel. They are occupied in the living tooth by soft gelatinous fibrils connected with the cells of the pulp. A variety of dentine, permeated by canals containing blood-vessels, met with commonly in fishes and in some few mammals, as the Megatherium, is called vaso-dentine. Other modifications of this tissue occasionally met with are called osteo-dentine and secondary dentine,—the latter being a dentine of irregular structure which often fills up the pulp cavity of old animals.

Enamel. 3. The *enamel* constitutes a thin investing layer, complete or partial, of the outer or exposed and working surface of the dentine of the crown of the teeth of most mammals. This is the hardest tissue met with in the animal body, containing from 95 to 97 per cent. of mineral substances (chiefly phosphate and some carbonate of lime, with traces of fluoride of calcium). Its ultimate structure consists of prismatic fibres, placed generally with their long axes at right angles to the free surface of the tooth. Enamel is easily distinguished from dentine with the naked eye, by its clear, bluish-white, translucent appearance.

Cementum. 4. The *cementum* or *crusta petrosa* is always the most externally placed of the hard tissues of which teeth are composed, as will be understood when the mode of development of these organs is considered. It is often only found as a thin layer upon the surface of the root, but sometimes, as in the complex-crowned molar teeth of the Horse and

Elephant, it is a structure which plays a very important part, covering and filling in the interstices between the folds of the enamel. In appearance, histological structure, and chemical composition it is closely allied to osseous tissue, containing lacunæ and canaliculi, though only when it is of considerable thickness are Haversian canals present in it.

Development.

Development of the Teeth.—The two principal constituents of the teeth, the dentine and the enamel, are developed from the two layers of the buccal mucous membrane, the dentine from the submucous, the enamel from the epithelial layer. The latter dips down into the substance of the gum, and forms the enamel organ or germ, the first rudiment of the future tooth, which is constantly present even in those animals in which the enamel is not found as a constituent of the perfectly-formed tooth. Below the mass of epithelial cells thus embedded in the substance of the gum, and remaining connected by a narrow neck of similar structure with the epithelium of the surface, a portion of the vascular submucous areolar tissue becomes gradually separated and defined from that which surrounds it, and assumes a distinct form, which is that of the crown of the future tooth,—a single cone in the case of simple teeth, or with two or more eminences in the complex forms. This is called the dental papilla or dentine germ, and by the gradual conversion of its tissue into dentine the bulk of the future tooth is formed, the uncalcified central portion remaining as the pulp. The conversion of the papilla into hard tissue commences at the outer surface of the apex, and gradually proceeds downwards and inwards, so that the form of the papilla exactly determines the form of the future dentine, and no alteration either in shape or size of this portion of the tooth, when once calcified, can take place by addition to its outer surface. In the meanwhile calcification of portion of the cells of the enamel organ, which adapts itself like a cap round the top of the dentinal papilla, and has assumed a somewhat complex structure, results in the formation of the enamel coating of the crown of the tooth. While these changes are taking place the tissues immediately surrounding the tooth germ become condensed and differentiated into a capsule, which appears to grow up from the base of the dental papilla, and encloses both this and the enamel germ, constituting the follicle or tooth sac. By the ossification of the inner layer of this follicle, the cementum is formed. This substance therefore, unlike the dentine, increases from within outwards, and its growth may therefore be the cause of considerable modification of form and enlargement, especially of the roots, of certain teeth, as those of Seals and some *Cetacea*. The delicate homogeneous layer which coats the enamel surface of newly-formed teeth, in which cementum is not found in the adult state, and known as Nasmyth's membrane, is considered by Tomes as probably a film of this substance, too thin to exhibit its characteristic structure, though by others it is believed to be derived from the external layer of the enamel organ. The homology of the teeth with the dermal appendages, hairs, scales, and claws has already been alluded to, and it will now be seen that in both cases two of the primary embryonic layers are concerned in their development, the mesoblast and epiblast, although in very different proportions. In the hair or nail the part derived from the epiblast forms the principal bulk of the organ, the mesoblast only constituting the papilla or matrix. In the tooth the epiblastic portion is limited to the enamel, always of relatively small bulk and often absent, while the dentine (the principal constituent of the tooth) and the cementum are formed from the mesoblast.

When more than one set of teeth occur in mammals, those of the second set are developed in a precisely similar manner to the first, but the enamel germ, instead of being derived directly from an independent part of the oral epithelium, is formed from a budding out of the neck of the germ of the tooth succeeded. In the case of the true molars which have no predecessors, the germ of the first has an independent origin, but that of the others is derived from the neck of the germ of the tooth preceding it in the series. The foundations of the permanent teeth are thus laid as it were almost simultaneously with those of their predecessors, although they remain in many cases for years before they are developed into functional activity.

Although the commencement of the formation of teeth takes place at an early period of embryonic life, they are in nearly all mammals still concealed beneath the gum at the time of birth. The period of eruption, or "cutting" of the teeth as it is called, that is, their piercing through and rising above the surface of the mucous membrane, varies much in different species. In some, as Seals, the whole series of teeth appear almost simultaneously; but more often there are considerable intervals between their appearance, the front teeth usually coming into place first, and those at the back of the mouth at a later period.[1]

Forms of teeth.

General Characters.—The simplest form of tooth may be exemplified on a large scale by the tusk of the Elephant (fig. 1, I.). It is a hard mass almost entirely composed of dentine, of a conical shape at first, but during growth becoming more and more cylindrical or uniform in width. The enamel covering, present on the apex in its earliest condition, soon disappears, but a thin layer of cementum covers the circumference of the tooth throughout life. On section it will be seen that the basal portion is hollow, and contains a large conical pulp, as broad at the base as the tooth itself, and deeply imbedded in the bottom of a recess or socket in the upper maxillary bone. This pulp continues to grow during the lifetime of the animal, and to be converted at its surface into dentine. The tooth therefore continually elongates, but the use to which the animal subjects it in its natural state causes the apex to wear away, at a rate generally proportionate to the growth at the base, otherwise it would become of inconvenient length and weight. Such teeth of indefinite growth are said to be "rootless," or to have "persistent pulps."

One of the corresponding front teeth of man (fig. 1, II. and III.) may be taken as an example of a very different condition. After its crown is fully formed by calcification of the germ, the pulp, though continuing to elongate, begins to contract in diameter; a neck or slight constriction is formed; and the remainder of the pulp is converted into the root (or fang), a tapering conical process which is imbedded in the alveolar cavity of the bone, and has at its extremity a minute perforation, through which the vessels and nerves required to maintain the vitality of the tooth enter the pulp cavity, very different from the widely open cavity at the base of the growing tooth. When the crown of the tooth is broad and complex in character, instead of having a single root, it may be supported by two or more roots, each of which is implanted in a distinct alveolar recess or socket, and to the apex of which a branch of the common pulp cavity is continued (fig. 1, IV.). Such teeth are called "rooted teeth." When they have once attained their position in the jaw, with the neck a little way above the level of the upper margin of the alveolus, and embraced by the gum or tough fibro-vascular membrane which covers the alveolar border, and having the root fully formed, they can never increase in length or alter their position. If they appear to do so in old age it is only in consequence of absorption and retrocession of the surrounding alveolar margins. If, as

[1] See the conclusion of the article DIGESTIVE ORGANS, vol. vii. p. 233 *sq.*, for a more detailed and illustrated account of the structure and development, especially of the human teeth.

often happens, their surface wears away in mastication, it is never renewed. The open cavity at the base of the imperfectly developed rooted tooth (fig. 1, II.) causes it to resemble the persistent condition of the rootless tooth. The latter is therefore a more primitive condition, the formation of the root being a completion of the process of tooth development. Functionally it is, however, difficult to say that the one is a higher form than the other, as they both serve important and different purposes in the animal economy.

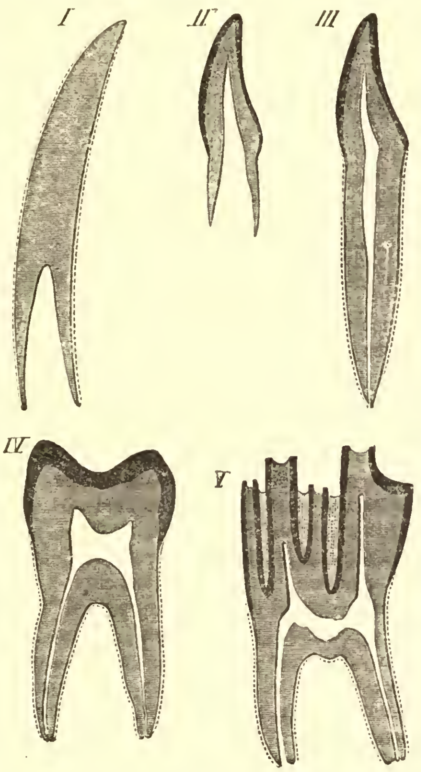

FIG. 1.—Diagrammatic Sections of various forms of Teeth. I. Incisor of Elephant, with pulp cavity persistently open at base. II. Human incisor during development, with root imperfectly formed, and pulp cavity widely open at base. III. Completely formed human incisor, with pulp cavity contracted to a small aperture at the end of the root. IV. Human molar, with broad crown and two roots. V. Molar of Ox, with enamel covering the crown deeply folded and with the depressions filled up with cementum. The surface is worn by use; otherwise the enamel coating would be continuous at the top of the ridges. In all the figures the enamel is black, the pulp white, the dentine represented by horizontal lines, and the cementum by dots.

As is almost always the case in nature, intermediate conditions between these two forms of teeth are met with. Some, as the molars of the Horse, and of many Rodents, are for a time rootless, and have growing pulps producing a very long crown with parallel sides, the summit of which may be in use and beginning to wear away while the base is still growing, but ultimately the pulp contracts, forms a neck and distinct roots, and ceases to grow. The canine tusks of the Musk Deer and of the Walrus have persistent pulps, and are open at their base until the animal is of advanced age, when they close, and the pulp ceases to be renewed.

The simplest form of the crown of a tooth is that of a cone; but this may be variously modified. It may be flattened, with its edges sharp and cutting, and pointed at the apex, as in the laterally compressed premolars of most *Carnivora*, or it may be chisel- or awl-shaped, with a straight truncated edge, as in the human incisors; or it may be broad, with a flat or rounded upper surface. Very often there is a more or less prominent ridge encircling the whole or part of the base of the crown just above the neck, called the cingulum, which serves as a protection to the edge of the gum in masticating, and is best developed in flesh-eating and insectivorous animals, in which the gums are liable to be injured by splinters of bone or other hard fragments of their food. The form of the crown is frequently rendered complex by the development upon its surface of elevations or tubercles called cusps, or by ridges usually transverse, but sometimes variously curved or folded. When the crown is broad and the ridges greatly developed, as in the molars of the Elephant, Horse, and Ox (fig. 1, V.), the interspaces between them are filled with cementum, which supports them and makes a solid compact mass of the whole tooth. When such a tooth wears away at the surface by friction against the opposed tooth of the other jaw, the different density of the layers of the substances of which it is composed—enamel, dentine, and cementum—arranged in characteristic patterns, causes them to wear unequally, the hard enamel ridges projecting beyond the others, thus giving rise to a grinding surface of great mechanical advantage.

Succession of teeth.

Succession of Teeth.—The dentition of all mammals consists of a definite set of teeth almost always of constant and determinate number, form, and situation, and, with few exceptions, persisting in a functional condition throughout the natural term of the animal's life. In many species these are the only teeth which the animal ever possesses. —the set which is first formed being permanent, or, if accidentally lost, or decaying in extreme old age, not being replaced by others. These animals are called Monophyodont. But, in the larger number of mammals, certain of the teeth are preceded by others, which may be only of a very transient, rudimentary, and functionless character (being in the Seals, for example, shed either before or within a few days after birth), or may be considerably developed, and functionally occupy the place of the permanent teeth for a somewhat lengthened period, during the growth and development of the latter and of the jaws. In all cases these teeth disappear (by the absorption of their roots and shedding of the crowns) before the frame of the animal has acquired complete maturity as evidenced by the coalescence of the epiphyses of the osseous system. As these teeth are, as a general rule, present during the period in which the animal is nourished by the milk of the mother, the name of "milk teeth" (French *dents de lait*, German *Milchzähne*) has been commonly accorded to them, although it must be understood that the epoch of their presence is by no means necessarily synchronous with that of lactation. Animals which possess such teeth are called Diphyodont. No mammal is known to have more than two sets of teeth; and the definite and orderly replacement of certain members of the series is a process of quite a different nature from the indefinite succession which takes place in all the teeth continuously throughout the lifetime of the lower vertebrates.

When the milk teeth are well developed, and continue in place during the greater part of the animal's growth, as is especially the case with the *Ungulata*, and, though to a less degree, with the *Primates* and *Carnivora*, their use is obvious, as taken all together they form structurally a complete epitome on a small scale of the more numerous and larger permanent set (see fig. 3), and, consequently, are able to perform the same functions, while time is allowed for the gradual maturation of the latter, and especially while the jaws of the growing animal are acquiring the size and strength sufficient to support the permanent teeth. Those animals, therefore, that have a well-developed and tolerably persistent set of milk teeth may be considered to be in a higher state of development, *quoad* dentition, than those that have the milk teeth absent or rudimentary.

It is a very general rule that individual teeth of the milk and permanent set have a close relationship to one another, being originally formed, as mentioned above, in exceedingly near proximity, and with, at all events as far as the enamel germ is concerned, a direct connexion. Moreover, as the latter ultimately come to occupy the position in the alveolar border temporarily held by the former, they are spoken of respectively as the predecessors or successors of each other. But it must be understood that milk teeth may be present which have no successors in the permanent series, and, what is far more general, permanent teeth may have no predecessors in the milk series.

The complete series of permanent teeth of most mammals forms a complex machine, with its several parts adapted for different functions,—the most obvious structural modification for this purpose being an increased complexity of the individual components of the series from the anterior towards the posterior extremity of such series. Since, as has just been said, the complete series of the milk teeth often presents structurally and functionally a similar machine, but composed of fewer individual members, and the anterior of which are as simple, and the posterior as complex, as those occupying corresponding positions in the permanent series,—and since the milk teeth are only developed in relation to the anterior or lateral, never to the most posterior of the permanent series,—it follows that the hinder milk teeth are usually more complex than the teeth of which they are the predecessors in the permanent series, and represent functionally, not their immediate successors, but those more posterior permanent teeth which have no direct predecessors. This character is clearly seen in those animals in which the various members of the molar series are well differentiated from each other in form, as the *Carnivora*, and also in Man.

In animals which have two sets of teeth the number of the teeth of the permanent series which are preceded by milk teeth varies greatly, being sometimes, as in Marsupials and some Rodents, as few as one on each side of each jaw, and sometimes including the larger portion of the series.

Although there are difficulties in some cases in arriving at a satisfactory solution of the question, it is, on the whole, safest to assume that when only one set of teeth is present, these correspond to the permanent teeth of the Diphyodonts. When this one set is completely developed, and remains in use throughout the animal's life, there can be no question on this subject. When, on the other hand, the teeth are rudimentary and transient, as in the Whalebone Whales, it is possible to consider them as representing the milk series; but there are weighty reasons in favour of the opposite conclusion.[1]

Arrangement and classification of teeth.

General Arrangement, Homologies, and Notation of Teeth of Mammals.—The teeth of the two sides of the jaws are always alike in number and character, except in cases of accidental or abnormal variation, and in the one remarkable instance of constant deviation from bilateral symmetry among mammals, the tusks of the Narwhal (see fig. 49, p. 398), in which the left is of immense size, and the right rudimentary. In those animals also, as the Dolphins and some Armadillos, which have a very large series of similar teeth, not always constant in number in different individuals, there may be differences in the two sides; but, apart from these, in describing the dentition of any mammal, it is quite sufficient to give the number and characters of the teeth of one side only. As the teeth of the upper and the lower jaws work against each other in masticating, there is a general correspondence or harmony between them, the projections of one series, when the mouth is closed, fitting into corresponding depressions of the other. There is also a general resemblance in the number, characters, and mode of succession of both series, so that, although individual teeth of the upper and lower jaws may not be in any strict sense of the term homologous parts, there is a great convenience in applying the same descriptive terms to the one which are used for the other.

The simplest dentition as a whole is that of many species of Dolphin (fig. 2), in which the crowns are single-pointed, slightly curved cones, and the roots also single and tapering, and all alike in form from the anterior to the posterior end of the series, though it may be with some slight difference in size, those at the two extremities of the series being rather smaller than the others. Such a dentition is called Homodont, and in the case cited, as the teeth are never changed, it is also Monophyodont. Such teeth are adapted only for catching slippery living prey, as fish.

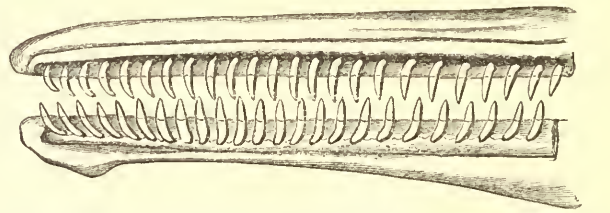

FIG. 2.—Upper and Lower Teeth of one side of the Mouth of a Dolphin (*Lagenorhynchus*), as an example of the homodont type of dentition. The bone covering the outer side of the roots of the teeth has been removed to show their simple character.

In a very large number of mammals the teeth of different parts of the series are more or less differentiated in character, and have different functions to perform. The front teeth are simple and one-rooted, and are adapted for cutting and seizing. They are called "incisors." The back teeth have broader and more complex crowns, tuberculated or ridged, and they are supported on two or more roots. They crush or grind the food, and are hence called "molars." Many animals have, between these two sets, a tooth at each corner of the mouth, longer and more pointed than the others, adapted for tearing or stabbing, or for fixing struggling prey. From the conspicuous development of such teeth in the *Carnivora*, especially the Dogs, they have received the name of "canines." A dentition with its component parts so differently formed that these distinctive terms are applicable to them is called Heterodont. In most cases, though by no means invariably, animals with Heterodont dentition are also Diphyodont.

This general arrangement is extremely obvious in a considerable number of mammals; and closer examination shows that, under very great modifications in detail, there is a remarkable uniformity of essential characters in the dentition of a large number of members of the class belonging to different orders and not otherwise closely allied, so much that it has been possible (chiefly through the researches of Professor Owen) to formulate a common plan of dentition from which the others have been derived by the alteration of some and suppression of other members of the series, and occasionally, but very rarely, by addition. The records of palæontology fully confirm this view, as by tracing back many groups now widely separated in dental characters we find a gradual approximation to a common type. In this generalized form of mammalian dentition (which is best exemplified in the genera *Anoplotherium* and *Homalodontotherium*) the entire number of teeth present is 44, or 11 above and 11 below on each side. Those of each jaw are placed in continuous series without intervals between them; and, although the anterior teeth are simple and single-rooted, and the posterior teeth complex and with several roots, the transition between the two kinds is gradual.

In dividing and grouping such teeth for the purpose of description and comparison, more definite characters are required than those derived merely from form or function. The first step towards a classification has been made by the observation that the upper jaw is composed of two bones, the premaxilla and the maxilla, and that the suture between these bones separates the

[1] This and other questions concerning the homologies, notation, and succession of the teeth of mammals are more fully developed in two memoirs by the present writer:—"Remarks on the Homologies and Notation of the Teeth of the Mammalia," in the *Journal of Anatomy and Physiology*, vol. iii. p. 262, 1869; and "Notes on the First or Milk Dentition of the Mammalia," in the *Trans. Odontological Society of Great Britain*, 1871.

three anterior teeth from the others. These three teeth then, which are implanted by their roots in the premaxilla, form a distinct group, to which the name of "incisor" is applied. This distinction is, however, not so important as it appears at first sight, for, as mentioned when speaking of the development of the teeth, their connexion with the bone is only of a secondary nature, and, although it happens conveniently for our purpose that in the great majority of cases the segmentation of the bone coincides with the interspace between the third and fourth tooth of the series, still, when it does not happen to do so, as in the case of the Mole, we must not give too much weight to this fact, if it contravenes other reasons for determining the homologies of the teeth. The eight remaining teeth of the upper jaw offer a natural division, inasmuch as the posterior three never have milk predecessors, and, although some of the anterior teeth may be in the same case, the particular one preceding these three always has such a predecessor. These three then are grouped apart as the "molars," or "true molars," as some of the teeth in front of them often have a molariform character. Of the five teeth between the incisors and molars the most anterior, or that which is usually situated close behind the premaxillary suture, almost always, as soon as any departure takes place from the simplest and most homogeneous type, assumes a lengthened and pointed form, and is the tooth so developed as to constitute the "canine" or "laniary" tooth of the *Carnivora*, the tusk of the Boar, &c. It is customary therefore to call this tooth, whatever its size or form, the "canine." The remaining four are the "premolars" or "false molars." This system of nomenclature has been objected to as being artificial, and in many cases not descriptive, the distinction between premolars and canine especially being sometimes not obvious, but the terms are now in such general use, and are so practically convenient—especially if, as it is best to do in all such cases, we forget their original signification, and treat them as arbitrary signs—that it is not likely they will be superseded by any that have been proposed as substitutes for them.

With regard to the lower teeth the difficulties are greater, owing to the absence of any suture corresponding to that which defines the incisors above; but, as the number of the teeth is the same, as the corresponding teeth are preceded by milk teeth, and as in the large majority of cases it is the fourth tooth of the series which is modified in the same way as the canine (or fourth tooth) of the upper jaw, it is quite reasonable to adopt the same divisions as with the upper series, and to call the first three, which are implanted in the part of the mandible opposite to the premaxilla, the incisors, the next the canine, the next four the premolars, and the last three the molars. It may be observed that when the mouth is closed, especially when the opposed surfaces of the teeth present an irregular outline, the corresponding upper and lower teeth are not exactly opposite, otherwise the two series could not fit into one another, but as a rule the points of the lower teeth shut into the interspaces in front of the corresponding teeth of the upper jaw. This is seen very distinctly in the canine teeth of the *Carnivora*, and is a useful guide in determining the homologies of the teeth of the two jaws. Objections have certainly been made to this view, because, in certain rare cases, the tooth which, according to it, would be called the lower canine has the form and function of an incisor (as in Ruminants and Lemurs), and on the other hand (as in *Oreodon*, an extinct Ungulate from North America) the tooth that would thus be determined as the first premolar has the form of a canine; but it should not be forgotten that, as in all such cases, definitions derived from form and function alone are quite as open to objection as those derived from position and relation to surrounding parts, or still more so.

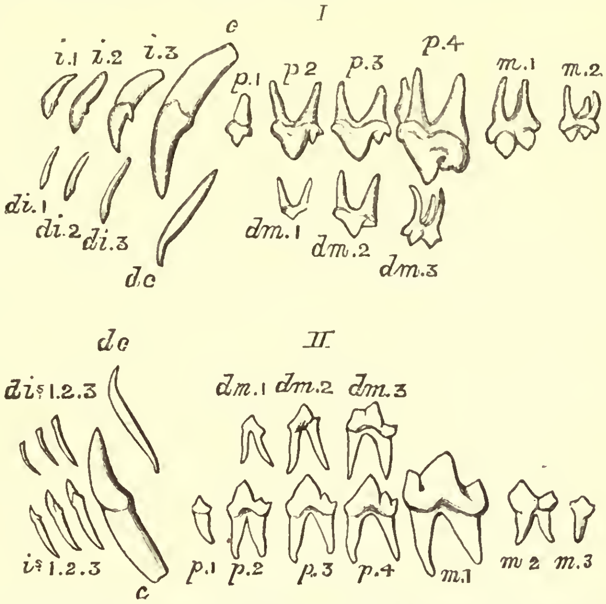

FIG. 3.—Milk and Permanent Dentition of Upper (I.) and Lower (II.) Jaw of the Dog (*Canis familiaris*), with the symbols by which the different teeth are commonly designated. The third upper molar (*m* 3) is the only tooth wanting in this animal to complete the typical heterodont mammalian dentition.

Dental formulæ. For the sake of brevity the complete dentition, arranged according to these principles, is often described by the following formula, the numbers above the line representing the teeth of the upper, those below the line those of the lower jaw:—incisors $\frac{3-3}{3-3}$, canines $\frac{1-1}{1-1}$, premolars $\frac{4-4}{4-4}$, molars $\frac{3-3}{3-3}=\frac{11-11}{11-11}$; total 44. As, however, initial letters may be substituted for the names of each group, and it is quite unnecessary to give more than the numbers of the teeth on one side of the mouth, the formula may be conveniently abbreviated into—

$$i\,\tfrac{3}{3},\ c\,\tfrac{1}{1},\ p\,\tfrac{4}{4},\ m\,\tfrac{3}{3}=\tfrac{11}{11}\text{; total 44.}$$

The individual teeth of each group are always enumerated from before backwards, and by such a formula as the following—

$$\frac{i\,1,\ i\,2,\ i\,3,\ c,\ p\,1,\ p\,2,\ p\,3,\ p\,4,\ m\,1,\ m\,2,\ m\,3}{i\,1,\ i\,2,\ i\,3,\ c,\ p\,1,\ p\,2,\ p\,3,\ p\,4,\ m\,1,\ m\,2,\ m\,3}$$

a special numerical designation is given by which each one can be indicated. In mentioning any single tooth, such a sign as $\underline{m\,1}$ will mean the first upper molar, $\overline{m\,1}$ the first lower molar, and so on. The use of such signs saves much time and space in description.

It was part of the view of the founder of this system of dental notation that, at least throughout the group of mammals whose dentition is derived from this general type, each tooth has its strict homologue in all species, and that in those cases in which fewer than the typical number are present (as in all existing mammals except the genera *Sus*, *Gymnura*, *Talpa*, and *Myogale*) the teeth that are missing can be accurately defined. According to this view, when the number of incisors falls short of three it is assumed that the absent ones are missing from the outer and posterior end of the series. Thus when there is but one incisor present, it is *i* 1; when two, they are *i* 1 and *i* 2. Furthermore, when the premolars and the molars are below their typical number, the absent teeth are missing from the fore part of the premolar series, and from the back part of the molar series. If this were invariably so, the labours of those who describe teeth would be greatly simplified; but there are unfortunately so many exceptions that a close scrutiny into the situation, relations, and development of a tooth may be required before its nature can be determined, and in some cases the evidence at our disposal is scarcely sufficient for the purpose.

The milk dentition is expressed by a similar formula, *d* for deciduous being commonly added before the letter expressive of the nature of the tooth. As the three molars and (almost invariably[1]) the first premolar of the permanent series have no predecessors, the typical milk dentition would be expressed as follows—$di\ \frac{3}{3}$, $dc\ \frac{1}{1}$, $dm\ \frac{3}{3} = \frac{7}{7} = 28$. The teeth which precede the premolars of the permanent series are all called molars in the milk dentition, although, as a general rule, in form and function they represent in a condensed form the whole premolar and molar series of the adult. When there is a marked difference between the premolars and molars of the permanent dentition, the first milk molar resembles a premolar, and the last has the characters of the posterior true molar.

Exceptions from generalized type.

The dentition of all the animals of the orders *Primates*, *Carnivora*, *Insectivora*, *Chiroptera*, and *Ungulata* can clearly be derived from the above-described generalized type. The same may be said of the Rodents, and even the *Proboscidea*, though with greater modification, at least in the existing members of the order. It is also apparent in certain extinct Cetaceans, as *Zeuglodon* and *Squalodon*, but it is difficult to find any traces of it in existing *Cetacea*, *Sirenia*, or any of the so-called *Edentata*. All the Marsupials, different as they are in their general structure and mode of life, and variously modified as is their dentition, present in this system of organs some deep-lying common characters which show their unity of origin. The generalized type to which their dentition can be reduced presents considerable resemblance to that of the placental mammals, yet differing in details. It is markedly heterodont, and susceptible of division into incisors, canines, premolars, and molars upon the same principles. The whole number is, however, not limited to forty-four. The incisors may be as numerous as five on each side, and are almost always different in number in the upper and the lower jaw. The premolars and molars are commonly seven, as in the placental mammals, but their arrangement is reversed, as there are four true molars and three premolars; and finally the milk dentition of all known Marsupials, existing or extinct, is (if not entirely absent) limited to a single tooth on each side of each jaw, this being the predecessor of the last permanent premolar.

In very few mammals are teeth entirely absent. Even in the Whalebone Whales their germs are formed in the same manner and at the same period of life as in other mammals, and even become partially calcified, but they never rise above the gums, and completely disappear before the birth of the animal. In some species of the order *Edentata*, the true Anteaters and the Pangolins, no traces of teeth have been found at any age. The *Monotremata* are in like case, although the *Ornithorhynchus* has flattened, ridged, horny plates at the back of both jaws, which answer the purpose of molar teeth.

Modifications of the Teeth in Relation to their Functions.—The principal functional modifications noticed in the dentition of *Mammalia* may be roughly grouped as (1) piscivorous, (2) carnivorous, (3) insectivorous, (4) omnivorous, and (5) herbivorous, each having, of course, numerous variations and transitional conditions.

Piscivorous dentition.

1. The essential characters of a piscivorous dentition are best exemplified in the Dolphins, and also (as modifications of the carnivorous type) in the Seals. It consists of an elongated, rather narrow mouth, wide gape, with numerous subequal, conical, sharp-pointed, recurved teeth adapted simply to rapidly seize, but not to divide or masticate, active, slippery, but not powerful prey. All animals which feed on fish as a rule swallow and digest them entire, a process which the structure of prey of this nature, especially the intimate interblending of delicate, sharp-pointed bones with the muscles, renders very advantageous, and for which the above-described type of dentition is best adapted.

Carn voro

2. The carnivorous type of dentition is shown in its most perfect development among existing mammals in the *Felidæ*. The function being here to seize and kill struggling animals, often of large size and great muscular power, the canines are immensely developed, trenchant, and piercing, and are situated wide apart so as to give the firmest hold when fixed in the victim's body. The jaws are as short as is consistent with the free action of the canines, so that no power may be lost. The incisors are very small, so as not to interfere with the penetrating action of the canines, and the crowns of the molar series are reduced to scissor-like blades, with which to pare off the soft tissues from the large bones, or to divide into small pieces the less dense portions of the bone for the sake of nutriment afforded by the blood and marrow it contains. The gradual modification between this and the two following types will be noticed in their appropriate places.

Inse voro

3. In the most typical insectivorous animals, as the Hedgehogs and Shrews, the central incisors are elongated, pointed, and project forwards, those of the upper and lower jaw meeting like the blades of a pair of forceps, so as readily to secure small active prey, quick to elude capture, but powerless to resist when once seized. The crowns of the molars are covered with numerous sharp edges and points, which working against each other, rapidly cut up the hard cased insects into little pieces, fit for swallowing and digestion.

Omn voro

4. The omnivorous type, especially that adapted for the consumption of soft vegetable substances, such as fruits of various kinds, may be exemplified in the dentition of Man, of most Monkeys, and of the less modified Pigs. The incisors are moderate, subequal, and cutting. If the canines are enlarged, it is usually for other purposes than those connected with food, and only in the male sex. The molars have their crowns broad, flattened, and elevated into rounded tubercles.

Herb voro

5. In the most typically herbivorous forms of dentition, as seen in the Horse and Kangaroo, the incisors are well developed and trenchant, adapted for cutting off the herbage on which the animals feed; the canines are rudimentary or suppressed; the molars are large, with broad crowns, which in the simplest forms have strong transverse ridges, but may become variously complicated in the higher degrees of modification which this type of tooth assumes.

The natural groups of mammals, or those which in our present state of knowledge we have reason to believe are truly related to each other, may each contain examples of more than one of these modifications. Thus the *Primates* have both omnivorous and insectivorous forms. The *Carnivora* show piscivorous, carnivorous, insectivorous, and omnivorous modifications of their common type of dentition. The *Ungulata* and the *Rodentia* have among them the omnivorous and various modifications, both simple and complex, of the herbivorous type. The *Marsupialia* exhibit examples of all forms, except the purely piscivorous. Other orders, more restricted in number or in habits, as the *Proboscidea* and *Cetacea*, naturally do not show so great a variety in the dental structure of their members.

In considering the taxonomic value to be assigned to

[1] *Hyrax* alone among existing mammals which have four premolars has also four milk molars.

ıxo- omy.

the modifications of teeth of mammals, two principles, often opposed to each other, which have been at work in producing these modifications, must be held in view:—(1) the type, or ancestral form, as we generally now call it, characteristic of each group, which in most mammals is itself derived from the still more generalized type described above; and (2) variations which have taken place from this type, generally in accordance with special functions which the teeth are called upon to fulfil in particular cases. These variations are sometimes so great as completely to mask the primitive type, and in this way the dentition of many animals of widely different origin has come to present a remarkable superficial resemblance, as in the case of the Wombat (a Marsupial), the Aye-Aye (a Lemur), and the Rodents, or as in the case of the Thylacine and the Dog. In all these examples indications may generally be found of the true nature of the case by examining the earlier conditions of dentition; for the characters of the milk teeth or the presence of rudimentary or deciduous members of the permanent set will generally indicate the route by which the specialized dentition of the adult has been derived. It is perhaps owing to the importance of the dental armature to the well-being of the animal in procuring its sustenance, and preserving its life from the attacks of enemies, that great changes appear to have taken place so readily, and with such comparative rapidity, in the form of these organs, changes often accompanied with but little modification in the general structure of the animal. Of this proposition the Aye-Aye (*Chiromys*) among Lemurs, the Walrus among Seals, and the Narwhal among Dolphins form striking examples; as, in all, the superficial characters of their dentition would entirely separate them from the animals with which all other evidence (even including the mode of development of their teeth) proves their close affinity.

The Skeleton.

The skeleton is a system of hard parts, forming a framework which supports and protects the softer organs and tissues of the body. It consists of dense fibrous and cartilaginous tissues, of which portions remain through life in this state, but the greater part is transformed during the growth of the animal into bone or osseous tissue. This is characterized by a peculiar histological structure and chemical composition, being formed mainly of a gelatinous basis, strongly impregnated with salts of lime, chiefly phosphate, and disposed in a definite manner, containing numerous minute nucleated spaces or cavities called lacunæ, connected together by delicate channels or canaliculi, which radiate in all directions from the sides of the lacunæ. Parts composed of bone are, next to the teeth, the most imperishable of all the organs of the body, often retaining their exact form and internal structure for ages after every trace of all other portions of the organization has completely disappeared, and thus, in the case of extinct animals, affording the only means of attaining a knowledge of their characters and affinities.[1]

In the Armadillos and their extinct allies alone is an ossified exoskeleton, or bony covering developed in the skin, present. In all other mammals the skeleton is completely internal. It may be described as consisting of an axial portion belonging to the head and trunk, and an appendicular portion belonging to the limbs. There are also certain bones called splanchnic, being developed within the substance of some of the viscera. Such are the *os cordis* and *os penis* found in some mammals.

It is characteristic of all the larger bones of the *Mammalia* that their ossification takes its origin from several distinct centres. One near the middle of the bone, and spreading throughout its greater portion, constitutes the *diaphysis*, or "shaft," in the case of the long bones. Others near the extremities, or in projecting parts, form the *epiphyses*, which remain distinct during growth, but ultimately coalesce with the rest of the bone.

Axial skeleton.

The axial skeleton consists of the skull, the vertebral column (prolonged at the posterior extremity into the tail), the sternum, and the ribs.

Skull.

In the *skull* of adult mammals, all the bones, except the lower jaw, the auditory ossicles, and the bones of the hyoid arch, are immovably articulated together, their edges being

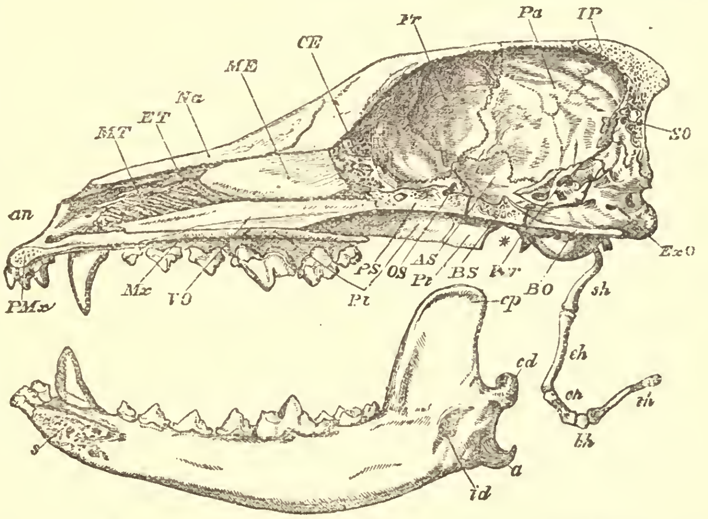

Fig. 4.—Longitudinal and Vertical Section of the Skull of a Dog (*Canis familiaris*), with mandible and hyoid arch. *an*, anterior narial aperture; *MT*, maxillo-turbinal bone; *ET*, ethmo-turbinal; *Na*, nasal; *ME*, ossified portion of the mesethmoid; *CE*, cribriform plate of the ethmo-turbinal; *Fr*, frontal; *Pa*, parietal; *IP*, interparietal; *SO*, supra-occipital; *ExO*, ex-occipital; *BO*, basi-occipital; *Per*, periotic; *BS*, basi-sphenoid; *Pt*, pterygoid; *AS*, ali-sphenoid; *OS*, orbito-sphenoid; *PS*, presphenoid; *Pl*, palatine; *Vo*, vomer; *Mx*, maxilla; *PMx*, premaxilla; *sh*, stylo-hyal; *eh*, epi-hyal; *ch*, cerato-hyal; *bh*, basihyal; *th*, thyro-hyal; *s*, symphysis of mandible; *cp*, coronoid process; *cd*, condyle; *a*, angle; *id*, inferior dental canal. The mandible is displaced downwards, to show its entire form; the * indicates the part of the cranium to which the condyle is articulated.[2]

in close contact, often interlocking by means of fine denticulations projecting from one bone and fitting into corresponding depressions of the other, and held together by the periosteum, or fibrous membrane investing the bones, passing directly from one to the other, permitting no motion, beyond perhaps a slight yielding to external pressure. In old animals there is a great tendency for the different bones to become actually united by the extension of ossification from one to the other, with consequent obliteration of the sutures. The cranium, thus formed of numerous originally independent ossifications, retaining through life more or less of their individuality, or all fused together, according to the species, the age, or even individual peculiarity, consists of a brain case, or bony capsule for enclosing and protecting the brain, and a face for the support of the organs of sight, smell, and taste and of those concerned in seizing and masticating the food. The brain case articulates directly with the anterior cervical vertebra, by means of a pair of oval eminences, called condyles, placed on each side of the large median foramen which transmits

[1] See for the principal modifications of the skeleton of this class, the large and beautifully illustrated *Ostéographie* of De Blainville, 1835–54; the section devoted to this subject in Bronn's *Klassen und Ordnungen des Thier-Reichs*, by Giebel, 1874–79; and *An Introduction to the Osteology of the Mammalia*, by W. H. Flower, 2d ed. 1876.

[2] This and many of the following figures are taken from Flower's *Osteology of the Mammalia*, Macmillan, 1876.

the spinal cord. It consists of a basal axis, continuous serially with the axes or centra of the vertebræ, and of an arch above, roofing over and enclosing the cavity which contains the cephalic portion of the central nervous system (see fig. 4). The base with its arch is composed of three segments placed one before the other, each of which is comparable to a vertebra with a greatly expanded neural arch. The hinder or occipital segment consists of the basi-occipital, ex-occipital, and supra-occipital bones; the middle segment of the basi-sphenoid, ali-sphenoid, and parietal bones; and the anterior segment of the pre-sphenoid, orbito-sphenoid, and frontal bones. The axis is continued forwards into the mesethmoid, or septum of the nose, around which the bones of the face are arranged in a manner so extremely modified for their special purposes that anatomists who have attempted to trace their serial homologies with the more simple portions of the axial skeleton have arrived at very diverse interpretations. The characteristic form and structure of the face of mammals is mainly dependent upon the size and shape of (1) the orbits, a pair of cup-shaped cavities for containing the eye-ball and its muscles, which may be directed forwards or laterally, placed near together or wide apart, and may be completely or only partially encircled by bone; (2) the nasal fossæ, cavities on each side of the median nasal septum, and forming the passage for the air to pass between the external and the internal nares, and containing in their upper part the organ of smell; (3) the zygomatic arch, a bridge of bone for the purpose of muscular attachment, which extends from the side of the face to the skull, overarching the temporal fossa; (4) the roof of the mouth, with its alveolar margin for the implantation of the upper teeth. The face is completed by the mandible, or lower jaw, consisting of two lateral rami, articulated by a hinge joint with the squamosal (a cranial bone interposed between the posterior and penultimate segment of the brain case, where also the bony capsule of the organ of hearing is placed), each being composed of a single solid piece of bone, and united together in the middle line in front, at the symphysis,—which union may be permanently ligamentous or become completely ossified. Into the upper border of the mandibular rami the lower teeth are implanted.

In only those species in which the brain holds a large relative proportion to the rest of the body, as in Man and the smaller species of the *Primates* and some other orders, does the external form of the skull receive much impress from the real shape of the cavity containing the brain. The size and form of the mouth, and the modifications of the jaws for the support of teeth of various shape and number, the ridges and crests on the cranium for the attachment of the muscles necessary to put this apparatus in motion, outgrowths of bone for the enlargement of the external surface required for the support of sense organs or of weapons, such as horns or antlers (which outgrowths, to prevent undue increase of weight, are filled with cells containing air), cause the principal variations in the general configuration of the skull. These variations are, however, only characteristically developed in perfectly adult animals, and are in many cases more strongly marked in the male than the female sex. Throughout all the later stages of growth up to maturity the size and form of the brain case remain comparatively stationary, while the accessory parts of the skull rapidly increase and take on their distinctive development characteristic of the species.

The hyoidean apparatus in mammals supports the tongue and larynx, and consists of a median portion below, the basi-hyal, from which two pairs of half arches, or cornua, extend upwards and outwards. The anterior is the most important, being connected with the periotic bone of the cranium. It may be almost entirely ligamentous, but more often has several ossifications, the largest of which is usually the stylo-hyal. The posterior cornu (thyro-hyal) is united at its extremity with the thyroid cartilage of the larynx, which it suspends in position. The median portion, or basi-hyal, is sometimes, as in the Howling Monkeys, enormously enlarged and hollowed, admitting into its cavity an air-sac connected with the organ of voice.

Ver- colu-

The *vertebral column* consists of a series of distinct bones called vertebræ, arranged in close connexion with each other along the dorsal side of the neck and trunk, and in the median line.[1] It is generally prolonged posteriorly beyond the trunk, to form the axial support of the appendage called the tail. Anteriorly it is articulated with the occipital region of the skull. The number of distinct bones of which the vertebral column is composed varies greatly among the *Mammalia*, the main variation being due to the elongation or otherwise of the tail. Apart from this, in most mammals the number is not far from thirty, though it may fall as low as twenty-six (as in some Bats), or rise as high as forty (*Hyrax* and *Cholœpus*). The different vertebræ, with some exceptions, remain through life quite distinct from each other, though closely connected by means of fibrous structures which allow of a certain, but limited, amount of motion between them. The exceptions are the following:—near the posterior part of the trunk, in nearly all mammals which possess completely developed hinder limbs, two or more vertebræ become ankylosed together to form the "sacrum," the portion of the vertebral column to which the pelvic girdle is attached; also, in certain species of Whales and of Armadillos, there are constant ossific unions of certain vertebræ of the cervical region.

Although the vertebræ of different regions of the column of the same animal or of different animals present great diversities of form, there is a certain general resemblance among them, or a common plan on which they are constructed, which is more or less modified by alteration of form or proportions, or by the addition or suppression of parts to fit them to fulfil their special purpose in the economy. An ordinary or typical vertebra consists in the first place of a solid piece of bone, the body or centrum (fig. 5, *c*), of the form of a disk or short cylinder. The bodies of contiguous vertebræ are connected together by a very dense, tough, and elastic material called the "intervertebral substance," of peculiar and complex arrangement. This substance forms the main, and in some cases the only, union between the vertebræ. Its elasticity provides for the vertebræ always returning to their normal relation to each other and to the column generally, when they have been disturbed therefrom by muscular action. A process (*p*) arises on each side from the dorsal surface of the body. These, meeting in the middle line above, form together an arch, surmounting a space or short canal (*nc*). As in this space lies the posterior prolongation of the great cerebro-spinal nervous axis, or spinal cord, it is called the neural canal, and the arch is called the neural arch, in contradistinction to another arch on the ventral surface of the

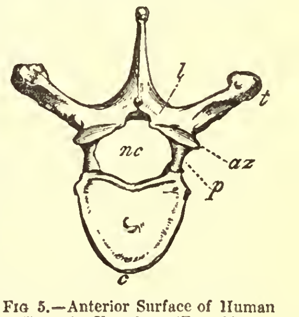

FIG 5.—Anterior Surface of Human Thoracic Vertebra (Fourth). *c*, body or centrum; *nc*, neural canal; *p*, pedicle, and *l*, lamina of the arch; *t*, transverse process; *az*, anterior zygapophysis.

---

[1] For the sake of uniformity, in all the following descriptions of the vertebral column, the long axis of the body is supposed to be in the horizontal position.

body of the vertebra, called the hæmal arch. The last is, however, never formed in mammals by any part of the vertebra itself, but only by certain distinct bones placed more or less in apposition to it—the ribs in the thoracic, and the "chevron bones" in the caudal region. In most cases the arch of one vertebra is articulated with that of the next by distinct surfaces with synovial joints, placed one on each side, called "zygapophyses" (*z*), but these are often entirely wanting when flexibility is more needed than strength, as in the greater part of the caudal region of long-tailed animals. In addition to the body and the arch, there are certain projecting parts called processes, chiefly serving for the attachment of the numerous muscles which move the vertebral column. Of these two are single and median,—the spinous process or neural spine, or neurapophysis (*s*), arising from the middle of the upper part of the arch, and the hypapophysis from the under surface of the body. This, however, is as frequently absent as the former is constant. The other processes are paired and lateral. They are transverse processes (*t*), of which there may be two, an upper and a lower, in which case the former is called, in the language of Owen (to whom we are indebted for the terminology of the parts of vertebræ in common use), "diapophysis," and the latter "parapophysis." Other processes less constantly present are called respectively "metapophyses" (*m*) and "anapophyses" (*a*).

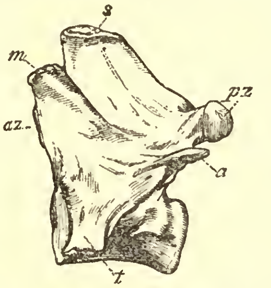

FIG. 6.—Side View of the First Lumbar Vertebra of a Dog (*Canis familiaris*). *s*, spinous process; *az*, anterior zygapophysis; *pz*, posterior zygapophysis; *m*, metapophysis; *a*, anapophysis; *t*, transverse process.

The vertebral column is divided for convenience of description into five regions, the cervical, thoracic or dorsal, lumbar, sacral, and caudal. This division is useful, especially as it is not entirely arbitrary, and in most cases is capable of ready definition; but at the contiguous extremities of the regions the characters of the vertebræ of one are apt to blend into those of the next region, either normally or as peculiarities of individual skeletons.

vical ebræ.

The *cervical* region constitutes the most anterior portion of the column, or that which joins the cranium. The vertebræ which belong to it are either entirely destitute of movable ribs, or if they have any these are small, and do not join the sternum. As a general rule they have a considerable perforation through the base of the transverse process (the vertebrarterial canal (fig. 7, *t*), or, as it is sometimes described, they have two transverse processes, superior and inferior, which, meeting at their extremities, enclose a canal. This, however, rarely applies to the last vertebra of the region, in which only the upper transverse process is usually developed. The transverse process, moreover, very often sends down near its extremity a more or less compressed plate (inferior lamella), which, being considered to be serially homologous with the ribs of the thoracic vertebræ (though not developed autogenously), is often called the "costal" or "pleurapophysial" plate. This is usually largest on the sixth, and altogether wanting on the seventh vertebra. The first and second cervical vertebræ, called respectively "atlas" and "axis," are specially modified for the function of supporting and permitting the free movements of the head. They are not united together by the intervertebral substance, but connected only by ordinary ligaments and synovial joints.

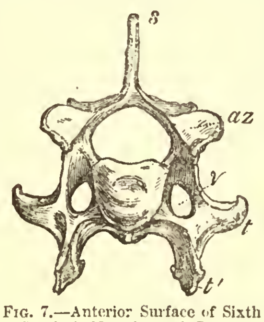

FIG. 7.—Anterior Surface of Sixth Cervical Vertebra of Dog. *s*, spinous process; *az*, anterior zygapophysis; *v*, vertebrarterial canal; *t*, transverse process; *t'*, its inferior lamella.

The cervical region in mammals presents the remarkable peculiarity that, whatever the length or flexibility of the neck, the number of vertebræ is the same, viz., seven, with only three known exceptions, the Manatee and Hoffman's Two-toed Sloth (*Cholœpus hoffmanni*), which both have but six, and the Three-toed Sloth (*Bradypus tridactylus*), which has nine, though in this case the last two usually support movable ribs, though not sufficiently developed to reach the sternum.

Dorsal vertebræ.

The *dorsal* (or *thoracic*, as it would be more correctly termed) region consists of the vertebræ which succeed those of the neck, having ribs movably articulated to them. These ribs arch round the thorax,—the anterior one, and most usually the greater number of those that follow, being attached below to the sternum.

Lumbar vertebræ.

The *lumbar* region consists of those vertebræ of the trunk in front of the sacrum which bear no movable ribs. It may happen that, as the ribs decrease in size posteriorly, the last being sometimes more or less rudimentary, the step from the thoracic to the lumbar region may be gradual and rather undetermined in a given species. But most commonly this is not the case, and the distinction is as well defined here as in any other region. As a general rule there is a certain relation between the number of the thoracic and lumbar vertebræ, the whole number being tolerably constant in a given group of animals, and any increase of the one being at the expense of the other. Thus in all known Artiodactyle *Ungulata* there are 19 dorso-lumbar vertebræ; but these may consist of 12 dorsal and 7 lumbar vertebræ, or 13 dorsal and 6 lumbar, or 14 dorsal and 5 lumbar. The smallest number of dorso-lumbar vertebræ in mammals occurs in some Armadillos, which have but 14. The number found in Man, the higher Apes, and most Bats, viz., 17, is exceptionally low 19 prevails in the Artiodactyles, nearly all Marsupials, and very many Rodents; 20 or 21 in *Carnivora* and most *Insectivora*; and 23 in *Perissodactyla*. The highest and quite exceptional numbers are in the Two-toed Sloth (*Cholœpus*) 27, and the Hyrax 30. The prevailing number of rib-bearing vertebræ is 12 or 13, any variation being generally in excess of these numbers.

Sacral vertebræ.

The *sacral* region offers more difficulties of definition. Taking the human "os sacrum" for a guide for comparison, it is generally defined as consisting of those vertebræ between the lumbar and caudal regions which are ankylosed together to form a single bone. It happens, however, that the number of such vertebræ varies in different individuals of the same or nearly allied species, especially as age advances, when a certain number of the tail vertebræ generally become incorporated with the true sacrum. Other suggested tests, as those vertebræ which have a distinct additional (pleurapophysial) centre of ossification between the body and the ilium, those to which the ilium is directly articulated, or those in front of the insertion of the ischio-sacral ligaments, being equally unsatisfactory or unpractical, the old one of ankylosis, as it is found to prevail in the average condition of adults in each species, is used in the enumeration of the vertebræ in the following pages. The *Cetacea*, having no iliac bones, have no part of the vertebral column modified into a sacrum.

Caudal vertebræ.

The *caudal* vertebræ are those placed behind the sacrum, and terminating the vertebral column. They vary in number greatly,—being reduced to 5, 4, or even 3, in a most rudimentary condition, in Man and in some Apes and Bats, and being numerous and powerfully developed, with strong and complex processes, in many mammals, especially among the *Edentata*, *Cetacea*, and *Marsupialia*. The highest known number, 46, is possessed by the African Long-tailed Manis. Connected with the under surface of the caudal vertebræ of many mammals which have the tail well developed are certain bones formed more or less like an inverted arch, called chevron bones, or by the French *os en V*. These are always situated nearly opposite to an intervertebral space, and are generally articulated both to the vertebra in front and the vertebra behind, but sometimes chiefly or entirely either to one or the other.

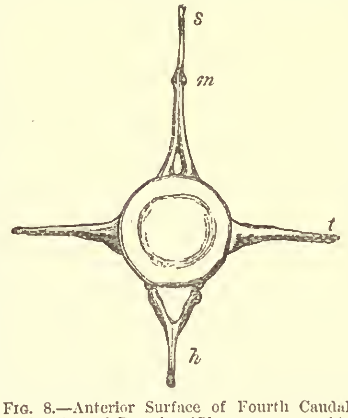

Fig. 8.—Anterior Surface of Fourth Caudal Vertebra of Porpoise (*Phocæna communis*). *s*, spinous process; *m*, metapophysis; *t*, transverse process; *h*, chevron bone.

Sternum. The *sternum* of mammals is a bone, or generally a series of bones, placed longitudinally in the mesial line, on the inferior or ventral aspect of the thorax, and connected on each side with the vertebral column by a series of more or less ossified bars called "ribs." It is present in all mammals, but varies much in character in the different groups. It usually consists of a series of distinct segments placed one before the other, the anterior being called the presternum or "manubrium sterni" of human anatomy, and the posterior the xiphisternum, or xiphoid or ensiform process, while the intermediate segments, whatever their number, constitute the mesosternum or "body." In the Whalebone Whales the presternum alone is developed, and but a single pair of ribs is attached to it.

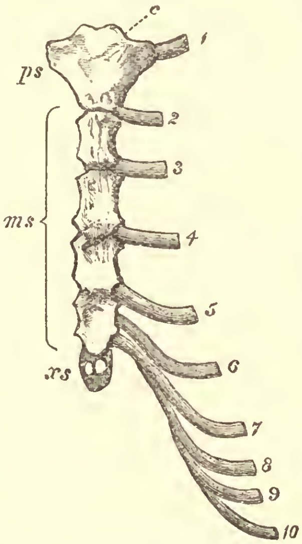

Fig. 9.—Human Sternum and Sternal Ribs. *ps*, presternum; *ms*, mesosternum; *xs*, xiphisternum; *c*, point of attachment of clavicle; 1 to 10, the cartilaginous sternal ribs.

Ribs. The *ribs* form a series of long, narrow, and more or less flattened bones, extending laterally from the sides of the vertebral column, curving downwards towards the median line of the body below, and mostly joining the sides of the sternum. The posterior ribs, however, do not directly articulate with that bone, but are either attached by their extremities to the edges of each rib in front of them, and thus only indirectly join the sternum, or else they are quite free below, meeting no part of the skeleton. These differences have given rise to the division into "true" and "false" ribs (by no means good expressions), signifying those that join the sternum directly and those that do not; and of the latter, those that are free below are called "floating" ribs. The portion of each rib nearest the vertebral column and that nearest the sternum differ in their characters, the latter being usually but imperfectly ossified, or remaining permanently cartilaginous. These are called "costal cartilages," or when ossified "sternal ribs."

In the anterior part of the thorax the vertebral extremity of each rib is divided into two parts, "head" and "tubercle"; the former is attached to the side of the body of the vertebra, the latter to its transverse process; the former attachment corresponds to the interspace between the vertebræ, the head of the rib commonly articulating partly with the hinder edge of the body of the vertebra antecedent to that which bears its tubercle. Hence the body of the last cervical vertebra usually supports part of the head of the first rib. In the posterior part of the series the capitular and tubercular attachments commonly coalesce, and the rib is attached solely to its corresponding vertebra. The number of pairs of ribs is of course the same as that of the thoracic vertebræ.

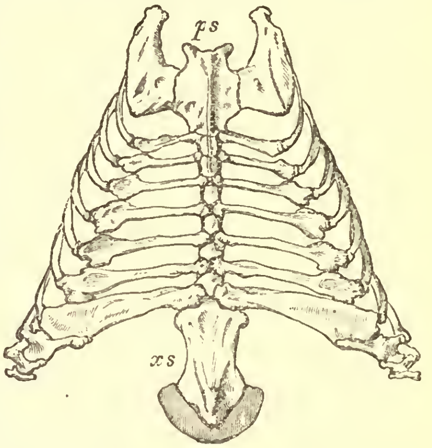

Fig. 10.—Sternum and strongly ossified Sternal Ribs of Great Armadillo (*Priodon gigas*). *ps*, presternum; *xs*, xiphisternum.

The appendicular portion of the framework consists, when completely developed, of two pairs of limbs, anterior and posterior. Ap[pen]dicu[lar] skel[eton].

The anterior limb is present and fully developed in all mammals, being composed of a shoulder girdle and three segments belonging to the limb proper, viz., the upper arm or brachium, the fore-arm or antibrachium, and the hand or manus. Ant[erior] limb.

The *shoulder girdle* in the large majority of mammals is in a rudimentary or rather modified condition, compared to that in which it exists in other vertebrates. In the *Monotremata* (*Ornithorhynchus* and *Echidna*) alone is the ventral portion, or coracoid, complete and articulates with the sternum below, as in the *Sauropsida*. In all other mammals this portion, though ossified from a distinct centre, forms only a process, sometimes a scarcely distinct tubercle, projecting from the anterior border of the glenoid cavity of the scapula. The last-named bone is always well developed, generally broad and flat (whence its vernacular name "blade bone"), with a ridge called the "spine" on its outer surface, generally ending in a free curved process, the "acromion." As the scapula affords attachment to many of the muscles which act upon the anterior limb, its form and the development of its processes are greatly modified according to the uses to which the member is put. It is most reduced and simple in character in those animals whose limbs are mere organs of support, as the Ungulates, and most complex when they are also used for grasping, climbing, or digging. The development or absence of the clavicle or "collar-bone," an accessory bar which connects the sternum with the scapula and steadies the shoulder-joint, has a somewhat similar relation, though its complete absence in the Bears shows that this is not an invariable rule. A complete clavicle is found in Man and all the *Primates*, in *Chiroptera*, all *Insectivora* (except *Potamogale*), in many Rodents, in most Edentates, and in all Marsupials, except *Perameles*. More or less rudimentary clavicles (generally suspended freely in the muscles) are found in the Cat, Dog, and most *Carnivora*, *Myrmecophaga*, and some Rodents. Clavicles are altogether absent in most of the *Ursidæ*, all the *Pinnipedia*, Manis among Edentates, the *Cetacea*, *Sirenia*, *Proboscidea*, all Ungulates, and some Rodents. Sho[ulder] gird[le].

The proximal segment of the limb proper contains a single bone, the humerus, and the second segment two rachi- n and itibra- iium.

bones, the radius and the ulna, placed side by side, articulating with the humerus at their proximal, and with the carpus at their distal extremity. In their primitive and unmodified condition these bones may be considered as placed one on each border of the limb, the radius being preaxial or anterior, and the ulna postaxial or posterior, when the distal or free end of the limb is directed outwards or away from the trunk. This is their position in the earliest embryonic condition, and is best illustrated in adult mammals in the *Cetacea*, where the two bones are fixed side by side and parallel to each other. In the greater number of mammals the bones assume a very modified and adaptive position, usually crossing each other in the forearm, the radius in front of the ulna, so that the preaxial bone (radius), though external (in the ordinary position of the limb) at the upper end, is internal at the lower end; and the hand, being mainly fixed to the radius, also has its preaxial border internal. In the large majority of mammals the bones are fixed in this position, but in some few, as in Man, a free movement of crossing and uncrossing—or pronation and supination, as it is termed—is allowed between them, so that they can be placed in their primitive parallel condition, when the hand (which moves with the radius) is said to be supine, or they may be crossed, when the hand is said to be prone.

In most mammals which walk on four limbs, and in which the hand is permanently prone, the ulna is much reduced in size, and the radius increased, especially at the upper end; and the articular surface of the latter, instead of being confined to the external side of the trochlea of the humerus, extends all across its anterior surface, and the two bones, instead of being external and internal, are anterior and posterior. In many hoofed or ungulated mammals, and in Bats, the ulna is reduced to little more than its upper articular extremity, and firmly ankylosed to the radius,—stability of these parts being more essential than mobility.

'anus. The terminal segment of the anterior limb is the hand or manus. Its skeleton consists of three divisions :—(1) the "carpus," a group of small, more or less rounded or angular bones with flattened surfaces applied to one another, and, though articulating by synovial joints, having scarcely any motion between them; (2) the "metacarpus," a series of elongated bones placed side by side, with their proximal ends articulating by almost immovable joints with the carpus; (3) the "phalanges" or bones of the digits, usually three in number to each, articulating to one another by freely movable hinge-joints, the first being connected in like manner to the distal end of the corresponding metacarpal bone.

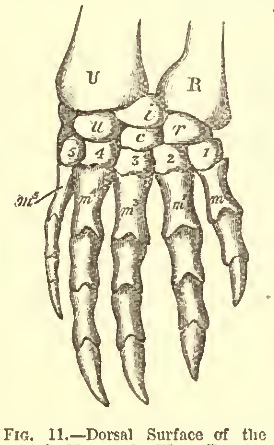

FIG. 11.—Dorsal Surface of the Right Manus of a Water Tortoise (*Chelydra serpentina*). After Gegenbaur. U, ulna; R, radius; *u*, ulnare; *i*, intermedium; *r*, radiale; *c*, centrale; 1–5, the five bones of the distal row of the carpus; m^1–m^5, the five metacarpals.

'arpus. To understand thoroughly the arrangement of the bones of the carpus in mammals, it is necessary to study their condition in some of the lower vertebrates. Fig. 11 represents the manus in one of its most complete and at the same time most generalized forms, as seen in one of the Water Tortoises (*Chelydra serpentina*). The carpus consists of two principal rows of bones. The upper or proximal row contains three bones, to which Gegenbaur has applied the terms *radiale* (*r*), *intermedium* (*i*), and *ulnare* (*u*), the first being on the radial or preaxial side of the limb. The lower or distal row contains five bones, called *carpale* 1, 2, 3, 4, and 5 respectively, commencing on the radial side. Between these two rows, in the middle of the carpus, is a single bone, the *centrale* (*c*). In this very symmetrical carpus it will be observed that the *radiale* supports on its distal side two bones, *carpale* 1 and 2; the *intermedium* is in a line with the *centrale* and *carpale* 3, which together form a median axis of the hand, while the *ulnare* has also two bones articulated with its distal end, viz., *carpale* 4 and 5. Each of the carpals of the distal row supports a metacarpal.

In the carpus of the *Mammalia* there are usually two additional bones developed in the tendons of the flexor muscles, one on each side of the carpus, which may be called the radial and ulnar sesamoid bones; the latter is most constant and generally largest, and is commonly known as the pisiform bone. The fourth and fifth carpals of the distal rows are always united into a single bone, and the centrale is very often absent. As a general rule all the other bones are present and distinct, though it not unfrequently happens that one or more may have coalesced to form a single bone, or may be altogether suppressed.

The following table shows the principal names in use for the various carpal bones,—those in the second column being the terms most generally employed by English anatomists :—

Radiale	= Scaphoid	= *Naviculare.*
Intermedium	= Lunar	= *Semilunare, Lunatum.*
Ulnare	= Cuneiform	= *Triquetrum, Pyramidale.*
Centrale	= Central	= *Intermedium* (Cuvier).
Carpale 1	= Trapezium	= *Multangulum majus.*
Carpale 2	= Trapezoid	= *Multangulum minus.*
Carpale 3	= Magnum	= *Capitatum.*
Carpale 4 } *Carpale* 5 }	= Unciform	= *Hamatum, Uncinatum.*

The metacarpal bones, with the digits which they support, are never more than five in number, and are described numerically—first, second, &c., counting from the radial towards the ulnar side. The digits are also sometimes named (1) the pollex, (2) index, (3) medius, (4) annularis, (5) minimus. One or more may be in a rudimentary condition, or altogether suppressed. If one is absent, it is most commonly the first. Excepting the *Cetacea*, no mammals have more than three phalanges to each digit, but they may occasionally have fewer by suppression or ankylosis. The first or radial digit is an exception to the usual rule, one of its parts being constantly absent, for, while each of the other digits has commonly a metacarpal and three phalanges, it has only three bones altogether; whether the missing one is a metacarpal or one of the phalanges is a subject which has occasioned much discussion, and has not yet been satisfactorily decided. The terminal phalanges of the digits are usually specially modified to support the nail, claw, or hoof, and are called "ungual phalanges." In walking, some mammals (as the Bears) apply the whole of the lower surface of the carpus, metacarpus, and phalanges to the ground; to these the term "plantigrade" is applied. Many others (as nearly all the *Ungulata*) only rest on the last one or two phalanges of the toes, the first phalanx and the metacarpals being vertical and in a line with the fore-arm. These are called "digitigrade." Intermediate conditions exist between these two forms, to which the terms "phalangigrade" (as the Camel) and "subplantigrade," (as in most *Carnivora*) are applied. When the weight is borne entirely on the distal surface of the ungual phalanx, and the horny structures growing around it, as in the Horse, the mode of progression is called "unguligrade." Metacarpus and phalanges.

In the *Chiroptera* the digits are enormously elongated, and support a cutaneous expansion constituting the organ of flight. In the *Cetacea* the manus is formed into a paddle, being covered by continuous integument, which conceals all trace of division into separate digits, and without sign of nails or claws. In the Sloths the manus is long and very narrow, habitually curved, and terminating in two or three pointed curved claws in close apposition with each other, incapable, in fact, of being divaricated, so that it is reduced to the condition of a hook, by which the animal suspends itself to the boughs of the trees among which it lives. These are only examples of the endless modifications to which the distal extremity of the limb is subjected in adaptation to the various purposes to which it is applied.

Posterior limb. The posterior limb is constructed upon a plan very similar to that of the anterior extremity. It consists of a pelvic girdle and three segments belonging to the limb proper, viz., the thigh, the leg, and the foot or pes.

Pelvic girdle. The pelvic girdle is present in some form in all mammals, though in the *Cetacea* and the *Sirenia* it is in an exceedingly rudimentary condition. In all mammals except those belonging to the two orders just named, each lateral half of the pelvic girdle consists essentially, like the corresponding part of the anterior limb, of a flattened rod of bone crossing the long axis of the trunk, having an upper or dorsal and a lower or ventral end. The upper end diverges from that of the opposite side, but the lower end approaches, and, in most cases, meets it, forming a symphysis, without the intervention of any bone corresponding to the sternum. The pelvic girdle differs from the shoulder girdle in being firmly articulated to the vertebral column, thus giving greater power to the hinder limb in its function of supporting and propelling the body. Like the shoulder girdle, it bears on its outer side, near the middle, a cup-shaped articular cavity ("acetabulum"), into which the proximal end of the first bone of the limb proper is received. Each lateral half of the girdle is called the "os innominatum," and consists originally of three bones which unite at the acetabulum. The "ilium" or upper bone is that which articulates with the sacral vertebræ. Of the two lower bones the anterior or "pubis" unites with its fellow of the other side at the symphysis; the posterior is the "ischium." These two form two bars of bone, united above and below, but leaving a space between them in the middle, filled only by membrane, and called the "thyroid" or "obturator" foramen. The whole circle of bone formed by the two innominate bones and the sacrum is called the pelvis. In the *Monotremata* and *Marsupialia*, a pair of thin, flat, elongated bones called epipubic or marsupial bones are attached to the fore part of the pubis, and project forward into the muscular wall of the abdomen.

Thigh and leg. The first segment of the limb proper has one bone, the femur, corresponding with the humerus of the upper limb. The second segment has two bones, the tibia and fibula, corresponding with the radius and ulna. These bones always lie in their primitive unmodified position, parallel to each other, the tibia on the preaxial and the fibula on the postaxial side, and are never either permanently crossed or capable of any considerable amount of rotation, as in the corresponding bones of the fore limb. In the ordinary walking position the tibia is internal, and the fibula external. In many mammals the fibula is in a more or less rudimentary condition, and it often ankyloses with the tibia at one or both extremities. The patella or "knee-cap" is found in an ossified condition in all mammals, with the exception of some of the *Marsupialia*. It is a large sesamoid bone developed in the tendon of the extensor muscles of the thigh, where the tendon passes over the front of the knee-joint, to which it serves as a protection. There are frequently smaller ossicles, one or two in number, situated behind the femoral condyles, called "fabellæ."

The terminal segment of the hind limb is the foot or pes. Foot. Its skeleton presents in many particulars a close resemblance to that of the manus, being divisible into three parts:—(1) a group of short, more or less rounded or square-shaped bones, constituting the tarsus; (2) a series of long bones placed side by side, forming the metatarsus; and (3) the phalanges of the digits or toes.

The bones of the tarsus of many of the lower *Vertebrata* closely resemble both in number and arrangement those of the carpus, as shown in fig. 11. They have been described in their most generalized condition by Gegenbaur under the names expressed in the first column of the following table. The names in the second column are those by which they are most generally known to English anatomists, while in the third column some synonyms occasionally employed are added

Tibiale } *Intermedium* }	= Astragalus	= *Talus.*
Fibulare	= Calcaneum	= *Os calcis.*
Centrale	= Navicular	= *Scaphoideum.*
Tarsale 1	= Internal cuneiform	= *Entocuneiforme.*
Tarsale 2	= Middle cuneiform	= *Mesocuneiforme.*
Tarsale 3	= External cuneiform	= *Ectocuneiforme.*
Tarsale 4 } *Tarsale* 5 }	= Cuboid.	

The bones of the tarsus of mammals present fewer diversities of number and arrangement than those of the carpus. The proximal row (see fig. 12) always consists of two bones, the astragalus (*a*, which probably represents the coalesced scaphoid and lunar of the hand) and the calcaneum (*c*). The former is placed more to the dorsal side of the foot than the latter, and almost exclusively furnishes the tarsal part of the tibio-tarsal or ankle-joint. The calcaneum, placed more to the ventral or "plantar" side of the foot, is elongated backwards to form a more or less prominent tuberosity, the "tuber calcis," to which the tendon of the great extensor muscles of the foot is attached. The navicular bone (*n*) is interposed between the proximal and distal row on the inner or tibial side of the foot, but on the outer side the bones of the two rows come into contact. The distal row, when complete, consists of four bones, which, beginning on the inner side, are the three cuneiform bones, internal (c^1), middle (c^2), and external (c^3), articulated to the distal surface of the navicular, and the cuboid (*cb*), articulated with the calcaneum. Of these the middle cuneiform is usually the smallest in animals in which all five digits are developed; but when the hallux is wanting the internal cuneiform may be rudimentary or altogether absent. The three cuneiform bones support respectively the first, second, and third metatarsals, and the cuboid supports the fourth and fifth; they thus exactly correspond with the four bones of the distal row of the carpus.

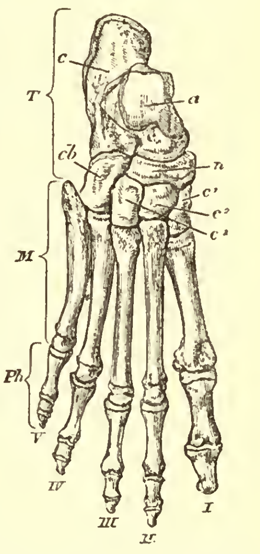

FIG. 12.—Bones of the Right Human Foot. *T*, tarsus; *M*, metatarsus; *Ph*, phalanges; *c*, calcaneum; *a*, astragalus; *cb*, cuboid; *n*, navicular; c^1, internal cuneiform; c^2, middle cuneiform; c^3, external cuneiform. The digits are indicated by Roman numerals, counting from the tibial to the fibular side.

In addition to these constant tarsal bones, there may be supplemental or sesamoid bones:—one situated near the middle of the tibial side of the tarsus, largely developed in many *Carnivora* and *Rodentia*; another, less frequent, on the fibular side; and a third, often developed in the tendons of the plantar surface of the tarsus, is especially large in Armadillos. There is also usually a pair of sesamoid bones on the plantar aspect of each metatarso-phalangeal articulation.

The metatarsal bones never exceed five in number, and the phalanges follow the same numerical rule as in the manus, never exceeding three in each digit. Moreover, the first digit, counting from the tibial side, or hallux, resembles the pollex of the hand in always having one segment less than the other digits. As the function of the hind foot is more restricted than that of the hand, the modifications of its structure are less striking. In the *Cetacea* and the *Sirenia* it is entirely wanting, though in some members of the first-named order rudiments of the bones of the first and second segment of the limb have been detected.

Digestive System.

The search after the purpose which every modification of structure subserves in the economy is always full of interest, and, if conducted with due caution and sufficient knowledge of all the attendant circumstances, may lead to important generalizations. It must always be borne in mind, however, that adaptation to its special function is not the only cause of the particular form or structure of an organ, but that this form, having in all probability been arrived at by the successive and gradual modification of some other different form from which it is now to a greater or less degree removed, has other factors besides use to be taken into account. In no case is this principle so well seen as in that of the organs of digestion. These may be considered as machines which have to operate upon alimentary substances in very different conditions of mechanical and chemical combination, and to reduce them in every case to the same or precisely similar materials; and we might well imagine that the apparatus required to produce flesh and blood out of coarse fibrous vegetable substances would be different from that which had to produce exactly the same results out of ready-made flesh or blood; and in a very broad sense we find that this is so. If we take a large number of carnivorous animals, belonging to different fundamental types, and a large number of herbivorous animals, and strike a kind of average of each, we shall find that there is, pervading the first group, a general style, if we may use the expression, of the alimentary organs, different from that of the others. There is a specially carnivorous and a specially herbivorous modification of these parts. But, if function were the only element which has guided such modification, it might be inferred that, as one form must be supposed to be best adapted and most perfect in its relation to a particular kind of diet, that form would be found in all the animals consuming that diet. But this is far from being the case. The Horse and the Ox, for instance,—two animals whose food in the natural state is precisely similar,—are yet most different as regards the structure of their alimentary canal, and the processes involved in the preparation of that food. Again, the Seal and the Porpoise, both purely fish-eaters, which seize and swallow and digest precisely the same kind of prey in precisely the same manner, have a totally different arrangement of the alimentary canal. If the Seal's stomach is adapted in the best conceivable manner for the purpose it has to fulfil, why is not the Porpoise's stomach an exact facsimile of it, and *vice versa*? We can only answer, the Seal and Porpoise belong to different natural groups of animals, formed on different primitive types, or descended from differently constructed ancestors. On this principle only can we account for the fact that, whereas, owing to the comparatively small variety of the different alimentary substances met with in nature, few modifications would appear necessary in the organs of digestion, there is really endless variety in the parts devoted to this purpose.

The digestive apparatus of mammals, as in other vertebrates, consists mainly of a tube with an aperture placed at or near either extremity of the body,—the oral and the anal orifice,—with muscular walls, the fibres of which are so arranged as by their regular alternate contraction and relaxation to drive onwards the contents of the tube from the first to the last of these apertures. The anterior or commencing portion of this tube and the parts around it are greatly and variously modified in relation to the functions assigned to them of selecting and seizing the food, and preparing it by various mechanical and chemical processes for the true digestion which it has afterwards to undergo before it can be assimilated into the system. For this end it is dilated into a chamber or cavity called the mouth, bordered externally by the lips, usually muscular and prehensile, and supported by a movable framework which carries the teeth,—organs the structure and modifications of which have been already described. The roof of the mouth is formed by the palate, terminating behind by a muscular, contractile arch, having in Man and some few other species a median projection called uvula, beneath which the mouth communicates with the pharynx. The anterior part of the palate is composed of mucous membrane tightly stretched over the flat or slightly concave bony lamina which separates the mouth from the nasal passages, and is generally raised into a series of transverse ridges, which sometimes, as in Ruminants, attain a considerable development. In the floor of the mouth, between the rami of the mandible, and supported behind by the hyoidean apparatus, lies the tongue, an organ the free surface of which, especially in its posterior part, is devoted to the sense of taste, but which also by its great mobility, being composed almost entirely of muscular fibres, performs important mechanical functions connected with masticating and procuring food. Its modifications of form in different mammals are very numerous. Between the long, extensile, vermiform tongue of the Anteaters, which is essential to the peculiar mode of feeding of those animals, and the short, sessile, and almost functionless tongue of the Porpoise, every intermediate condition is found. Whatever the form, the upper surface is always covered with numerous fine papillæ, in which the terminal filaments of the gustatory nerve are distributed.

The mouth.

Salivary glands.

In connexion with the buccal cavity is an extensive and complex glandular apparatus which pours its secretions into it—secretions which constitute the fluid commonly known as saliva. This apparatus consists of small glands embedded in the mucous membrane or submucous tissue lining the cavity of the mouth, and which are of two kinds (the follicular and the racemose), and of others in which the secreting structure is aggregated in distinct masses removed some distance from the cavity, other tissues besides the lining membrane being usually interposed, and pouring their secretion into the cavity by a distinct tube or duct, which traverses the mucous membrane. To the latter alone the name of "salivary glands" is ordinarily appropriated, although the distinction between them and the smaller racemose glands is only one of convenience for descriptive purposes, their structure being more or less identical; and, as the fluids secreted by all become mixed in the mouth, their functions are, at all events in great part, common. Under the name of salivary glands are commonly included —(1) the "parotid," situated very superficially on the side of the head, below or around the cartilaginous external auditory meatus, and the secretion of which enters the mouth by a duct (often called Steno's or Stenson's) which crosses the masseter muscle and opens into the upper and back part of the cheek; and (2) the "submaxillary," situated in the neck, near or below the angle of the mandible, and sending a long duct (Wharton's) forwards to open in the fore-part of the floor of the cavity of the mouth, below the apex of the tongue. These are the most largely developed and constant of the salivary glands, being met with in various degrees of development in almost all animals of the class. Next in constancy are (3) the "sublingual," closely associated with the last-named, at all events in the locality in which the secretion is poured out; and (4) the "zygomatic," found only in some animals in the cheek, just under cover of the anterior part of the zygomatic arch, its duct entering the buccal cavity near that of the parotid.

The most obvious function common to the secretion of these various glands, and to that of the smaller ones placed in the mucous membrane of the lips, the cheeks, the tongue, the palate and fauces, is the mechanical one of moistening and softening the food, to enable it the more readily to be tasted, masticated, and swallowed, though each kind of gland may contribute in different manner and different degree to perform this function. The saliva is, moreover, of the greatest importance in the first stage or introduction to the digestive process, as it dissolves or makes a watery extract of all soluble substances in the food, and so prepares them to be further acted on by the more potent digestive fluids met with subsequently in their progress through the alimentary canal. In addition to these functions it seems now well established by experiment that saliva serves in Man and many animals to aid directly in the digestive process, particularly by its power of inducing the saccharine transformation of amylaceous substances. As a general rule, in mammals the parotid saliva is more watery in its composition, while that of the submaxillaries, and still more the sublingual, contains more solid elements and is more viscid, so much so that some anatomists consider the latter, together with the small racemose glands of the cheeks, lips, and tongue, as mucous glands, retaining the name of salivary only for the parotid. These peculiar properties are sometimes illustrated in a remarkable degree, as, for example, the great secretion of excessively viscid saliva which lubricates the tongue of the Anteaters and Armadillos, associated with enormously developed submaxillary glands; while, on the other hand, the parotids are of great size in those animals which habitually masticate dry and fibrous food.

After the preparation which the aliment has undergone in the mouth,—the extent of which varies immensely in different forms, being reduced almost to nothing in such animals as the Seals and Cetaceans, which, to use the familiar expression, "bolt" their food entire,—it is swallowed, and is carried along the œsophagus by the Stomach. action of its muscular coats into the stomach. In the greater proportion of mammals this organ is a simple saccular dilatation of the alimentary canal, but in others it undergoes remarkable modifications and complexities. The lining of the stomach is thickly beset with tubular glands, which are generally considered to belong to two different forms, recognizable by their structure, and different in their function—the most numerous and important secreting the gastric juice (the active agent in stomachic digestion), and hence called "peptic" glands, the others concerned only in the elaboration of mucus. The relative distribution of these glands in different regions of the walls of the stomach varies greatly in different animals, and in many species there are large tracts of the mucous membrane which do not secrete a fluid having the properties of gastric juice, and often constitute more or less distinct cavities devoted to storing and perhaps softening or otherwise preparing the food for digestion. Sometimes there is a great aggregation of glands forming distinct thickened patches of the stomach wall, as in the Beaver and Koala, or even collected in pyriform pouches with a common narrow opening into the cavity, as in the Manatee and the curious African Rodent *Lophyomys*. The action of the gastric fluid is mainly exerted upon the nitrogenous elements of the food, which it dissolves and modifies so as to render them capable of undergoing absorption, which is partly effected by the blood-vessels of the stomach, though the greater part passes through the pylorus, an aperture surrounded by a circular muscular valve, into the intestinal canal. Here it comes in contact with the secretion of a vast number of small glands called the crypts of Lieberkuhn, somewhat similar to those of the stomach, and also of several special glands of a different character, namely, the small racemose, duodenal, or Brunner's glands, the pancreas, and the liver.

The intestinal canal varies greatly in relative length and capacity in different animals, and it also offers manifold peculiarities of form, being sometimes a simple cylindrical tube of nearly uniform calibre throughout, but more often subject to alterations of form and capacity in different portions of its course,—the most characteristic and constant being the division into an upper and narrower and a lower and wider portion, called respectively the small and the large intestine, the former being divided quite arbitrarily and artificially into duodenum, jejunum, and ileum, and the latter into colon and rectum. One of the most striking peculiarities of this part of the alimentary canal is the frequent presence of a diverticulum or blind pouch, the *caput cæcum coli*, as it was first called, a name generally abbreviated into "cæcum," situated at the junction of the large and the small intestine, a structure presenting an immense variety of development, from the smallest bulging of a portion of the side wall of the tube to a huge and complex sac, greatly exceeding in capacity the remainder of the alimentary canal. It is only in herbivorous animals that the cæcum is developed to this great extent, and among these there is a curious complementary relationship between the size and complexity of the organ and that of the stomach. Where the latter is simple the cæcum is generally the largest, and *vice versa*. Both cæcum and colon are often sacculated, a disposition caused by the arrangement of the longitudinal bands of muscular tissue in their walls; but the small intestine is always smooth and simple-walled externally, though its lining membrane often exhibits various contrivances for increasing the absorbing surface without adding to the general bulk of the organ, such as the numerous small villi by which it is everywhere beset, and the more obvious transverse, longitudinal, or reticulating folds projecting into the interior, met with in many animals, of which the "valvulæ conniventes" of Man form well-known examples. Besides the crypts of Lieberkuhn found throughout the intestinal canal, and the glands of Brunner confined to the duodenum, there are other structures in the mucous membrane, about the nature of which there is still much uncertainty, called "solitary" and "agminated" glands, the latter more commonly known by the name of "Peyer's patches." These were formerly supposed to be secretory organs, which discharged some kind of fluid into the intestine, but are now more generally considered to belong to the group of structures of somewhat mysterious function of which the lymphatic and lacteal

Intest canal.

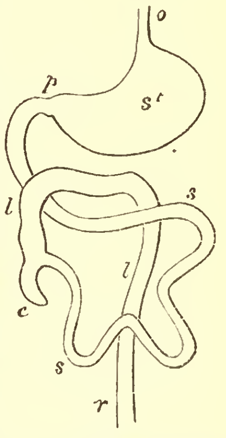

Fig. 13.—Diagrammatic Plan of the general arrangement of the Alimentary Canal in a typical Mammal. *o*, œsophagus; *st*, stomach; *p*, pylorus; *ss*, small intestine (abbreviated); *c*, cæcum; *ll*, large intestine or colon, ending in *r*, the rectum.

glands are members. The solitary glands are found scattered irregularly throughout the whole intestinal tract; the agminated, on the other hand, are always confined to the small intestine, and are most abundant in its lower part. They are subject to great variation in number and in size, and even in different individuals of the same species, and also differ in character at different periods of life, becoming atrophied in old age.

iver. The distinct glands situated outside of the walls of the intestinal canal, but which pour their secretion into it, are the pancreas and the liver. The latter is the most important on account of its size, if not on account of the direct action of its secretion in the digestive process. This large gland, so complex in structure and function, is well developed in all mammals, and its secreting duct, the bile duct, always opens into the duodenum or that portion of the canal which immediately succeeds the stomach. It is situated in the right side of the abdomen in contact with the diaphragm and the stomach, but varies greatly in relative size, and also in form, in different groups of mammals. In most mammals a gall-bladder, consisting of a pyriform diverticulum from the gall duct, is present, but in many it is wanting, and it is difficult to find the rationale of its presence or absence in relation to use or any other circumstance in the animal economy.

The descriptions of the livers of various animals to be met with in treatises or memoirs on comparative anatomy are very difficult to understand for want of a uniform system of nomenclature. The difficulty usually met with arises from the circumstance that this organ is divided sometimes, as in Man, Ruminants, and the *Cetacea*, into two main lobes, which have been always called respectively right and left, and in other cases, as in the lower Monkeys, *Carnivora*, *Insectivora*, and many other orders, into a larger number of lobes. Among the latter the primary division usually appears at first sight tripartite, the whole organ consisting of a middle, called "cystic" or "suspensory" lobe, and two lateral lobes, called respectively right and left lobes. This introduces confusion in describing livers by the same terms throughout the whole series of mammals, as the right and left lobes of the Monkey or Dog, for instance, do not correspond with parts designated by the same name in Man and the Sheep. There are, moreover, conditions in which neither the bipartite nor the tripartite system of nomenclature will answer, which we should have considerable difficulty in describing without some more general system. In order to arrive at such a system it appears desirable to consider the liver in all cases as primarily divided by the umbilical vein (see fig. 14, *u*) into two segments, right and left. This corresponds with its development and with the condition characteristic of the organ in the inferior classes of vertebrates. The situation of this division can almost always be recognized in adult animals by the persistence of some traces of the umbilical vein in the form of the round ligament, and by the position of the suspensory ligament.

When the two main parts into which the liver is thus divided are entire, as in Man, the Ruminants, and *Cetacea*, they may be spoken of as the right and left lobes; when fissured, as the right and left segments of the liver, reserving the term lobe for the subdivisions. This will involve no ambiguity, for the terms right and left lobe will no longer be used for divisions of the more complex form of liver. In the large majority of mammals each segment is further divided by a fissure, more or less deep, extending from the free towards the attached border, which are called right and left lateral fissures (fig. 14, *rlf* and *llf*). When these are more deeply cut than the umbilical fissure (*u*), the organ has that tripartite or trefoil-like form just spoken of, but it is easily seen that it is really divided into four regions or lobes, those included between the lateral fissures being the right and left central (*rc* and *lc*) separated by the umbilical fissure, and those beyond the lateral fissures on each side being the right and left lateral lobes (*rl* and *ll*). The essentially bipartite character of the organ and its uniformity of construction throughout the class are thus not lost sight of, even in the most complex forms. The left segment of the liver is rarely complicated to any further extent, except in some cases by minor or secondary fissures marking off small lobules, generally inconstant and irregular, and never worthy of any special designation. On the other hand, the right segment is usually more complex. The gall bladder, when present, is always attached to the under surface of the right central lobe, sometimes merely applied to it, in other cases deeply embedded in its substance. In many cases the fossa in which it is sunk is continued to the free margin of the liver as an indent, or even a tolerably deep fissure (*cf*). The portal fissure (*p*), through which the portal vein and

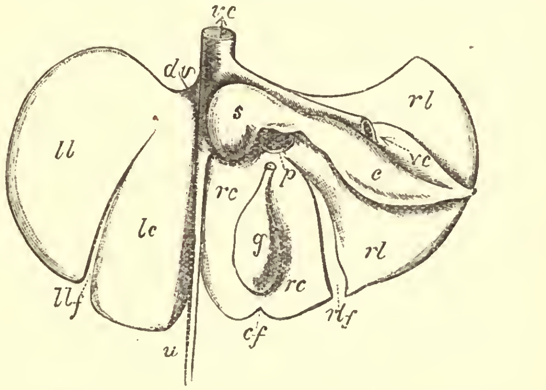

FIG. 14.—Diagrammatic Plan of the Inferior Surface of a Multilobed Liver of a Mammal. The posterior or attached border is uppermost. *u*, umbilical vein of the fœtus, represented by the round ligament in the adult, lying in the umbilical fissure; *dv*, the ductus venosus; *vc*, the inferior vena cava; *p*, the vena portæ entering the transverse fissure; *llf*, the left lateral fissure; *rlf*, the right lateral fissure; *cf*, the cystic fissure; *ll*, the left lateral lobe; *lc*, the left central lobe; *rc*, the right central lobe; *rl*, the right lateral lobe; *s*, the Spigelian lobe; *c*, the caudate lobe; *g*, the gall bladder.

hepatic artery enter and the gall duct emerges from the liver, crosses this lobe transversely, near the attached border of the liver. The right lateral lobe always has the great vena cava (*vc*) either grooving its surface or tunnelling through its substance near the inner or left end of its attached border; and a prolongation of the lobe to the left, between the vein and the portal fissure, sometimes a mere flat track of hepatic substance, but more often a prominent tongue-shaped process, is the so-called "Spigelian lobe" (*s*). From the under surface of the right lateral lobe a portion is generally partially detached by a fissure, and called the "caudate lobe" (*c*). In Man this is almost obsolete, but in most mammals it is of considerable magnitude, and has very constant and characteristic relations. It is connected by an isthmus at the left (narrowest or attached) end to the Spigelian lobe, behind which isthmus the vena cava is always in relation to it, channelling through or grooving its surface. It generally has a pointed apex, and is deeply hollowed to receive the right kidney, to the upper and inner side of which it is applied.

Considerations derived from the comparatively small and simple condition of the liver of the Ungulates, compared with its large size and complex form in the *Carnivora*, have led to the perhaps too hasty generalization that the first type is related to a herbivorous and the latter to a carnivorous diet. The exceptions to such a proposition are very numerous. The fact of the great difference between the liver of the *Cetacea* and that of the Seals cannot be accounted for by difference of habits of life, though it perhaps may be by difference of origin, upon the supposition that the former are modifications of the primary branch of mammals from which the Ungulates, and the latter of that from which the *Carnivora*, are derived.[1]

Circulatory, Absorbent, Respiratory, and Urinary Systems.

Blood. The blood of mammals is always red, and during the life of the animal hot, having a nearly uniform temperature, varying within a few degrees on each side of 100° Fahr. The corpuscles are, as usual in vertebrates, of two kinds:—(1) colourless, spheroidal, nucleated, and exhibiting amœboid movements; while (2) the more numerous, on which depends the characteristic hue of the fluid in which they are suspended, are coloured, non-nucleated, flattened, slightly biconcave disks, with circular outline in all known species except the Camels and Llamas, where they have the elliptical form characteristic of the red corpuscles of nearly all the other vertebrates, though adhering to the mammalian type in absence of nucleus and relatively small size. As a rule they are smaller as well as more numerous than in other classes, but vary considerably in size in different species, and not always in relation to the magnitude of the animal, a Mouse, for instance, having as large corpuscles as a Horse. Within the limits of any natural group there is, however, very often some such relation, the largest corpuscles being found among the large species and the smallest corpuscles among the small species of the group, but even to this generalization there are many exceptions. The transverse diameter of the red corpuscles in Man averages $\frac{1}{3200}$ of an inch, which is exceptionally large, and only exceeded by the Elephant ($\frac{1}{2745}$), and by some *Cetacea* and *Edentata*. They are also generally large in Apes, Rodents, and the *Monotremata*, and small in the Artiodactyles, least of all in the Chevrotains (*Tragulus*), being in *T. javanicus* and *meminna* not more than $\frac{1}{12325}$.[2]

Heart. The heart of mammals consists of four distinct cavities, two auricles and two ventricles. Usually the ventricular portion is externally of conical form, with a simple apex, but in the *Sirenia* it is broad and flattened, and a deep notch separates the apical portion of each ventricle. A tendency to this form is seen in the *Cetacea* and the Seals. It is characteristic of mammals alone among vertebrates that the right auriculo-ventricular valve is tendinous like the left, consisting of flaps held in their place by fibrous ends (*chordæ tendiniæ*) which arise from projections from the muscular walls of the ventricular cavity (*musculi papillares*). In the *Monotremata* a transition between this condition and the simple muscular flap of the *Sauropsida* is observed. In most of the larger Ungulates a distinct but rather irregular ossification is developed in the central tendinous portion of the base of the heart.

Blood-vessels. The orifices of the aorta and pulmonary artery are each guarded by three semilunar valves. The aorta is single, and arches over the left bronchial tube. After supplying the tissues of the heart itself with blood by means of the coronary arteries, it gives off large vessels ("carotid") to the head and ("brachial") to the anterior extremities. The mode in which these vessels arise from the aorta varies much in different mammals, and the study of their disposition affords some guide to classification. In nearly all cases the right brachial and carotid have a common origin (called "innominate artery" in anthropotomy). The other two vessels may come off from this, as is the rule in Ungulates, the common trunk constituting the "anterior aorta" of veterinary anatomy; or they may be detached in various degrees, both arising separately from the aorta, as in Man, or the left carotid from the innominate and the left brachial from the aorta, a very common arrangement, or the last two from a common second or left innominate as in some Bats and Insectivores. The aorta, after giving off the intercostal arteries, passes through the diaphragm into the abdomen, and, after supplying the viscera of that cavity by means of the gastric, hepatic, splenic, mesenteric, renal, and spermatic vessels, gives off in the lumbar region a large branch (iliac) to each of the hinder extremities, which also supplies the pelvic viscera, and is continued onwards in the middle line, greatly diminished in size, along the under surface of the tail. In certain mammals, arterial plexuses, called *retia mirabilia*, formed by the breaking up of the vessel into an immense number of small trunks, which may run in a straight course parallel to one another (as in the limbs of Sloths and Slow Lemurs), or form a closely packed network, as in the intracranial plexuses of Ruminants, or a sponge-like mass of convoluted vessels, as in the intercostals of Cetaceans, are peculiarities of the vascular system the meaning of which is not in all cases clearly understood. In the *Cetacea* they are obviously receptacles for containing a large quantity of oxygenated blood available during the prolonged immersion, with consequent absence of respiration, to which these animals are subject.

The vessels which return the blood to the heart from the head and upper extremities usually unite, as in Man, to form the single *vena cava superior* or precaval vein, but in some Insectivores, *Chiroptera*, and Rodents, and in the Elephant, and all Marsupials and Monotremes, the two superior caval veins enter the right auricle without uniting, as in birds. In Seals and some other diving mammals there is a large venous sinus or dilatation of the inferior cava immediately below the diaphragm. In the *Cetacea* the purpose of this is supplied by the immense abdominal venous plexuses. As a rule the veins of mammals are furnished with valves, but these are said to be altogether wanting in the *Cetacea*, and in the superior and inferior cava, subclavian and iliac veins, the veins of the liver (both portal and hepatic), heart, lungs, kidneys, brain, and spinal chord of other mammals. Many of the veins within the cranium are included in spaces formed by the separation of the laminæ of the dura mater, and do not admit of being dilated beyond a certain size; these are termed sinuses. The portal circulation in mammals is limited to the liver, the portal vein being formed by the superior and inferior mesenteric, the splenic, the gastro-epiploic, and the pancreatic veins. The kidney is supplied solely by arterial blood, and its veins empty their contents only into the inferior cava.

Lymphatic vessels. The *absorbent* or *lymphatic* system of vessels is very completely developed in the *Mammalia*. Its ramifications extend through all the soft tissues of the body, and convey a colourless fluid called lymph, containing nucleated corpuscles, and also, during the process of digestion, the chyle, a milky fluid taken up by the lymphatics (here called lacteals) of the small intestine, and pour them into the general vascular system, where they mix with the venous blood. The lymphatic vessels of the hinder extremities, as well as those from the intestinal canal, unite in the abdomen to form the "thoracic duct," the hinder end or commencement of which has a dilatation called the *receptaculum chyli*. The duct, which is of irregular size and sometimes double, often dividing and uniting again in its course, or even becoming plexiform, passes forwards close to the bodies of the thoracic vertebræ, and empties itself, by an orifice guarded by a valve, into the great left brachiocephalic vein, having previously received the lymphatics

[1] See "Lectures on the Comparative Anatomy of the Organs of Digestion of the Mammalia," *Medical Times and Gazette*, Feb.–Dec. 1872.

[2] G. Gulliver, *Proc. Zool. Soc.*, 1862, p. 91.

from the thorax and the left side of the head and left anterior extremity. Those from the right side of the head and right anterior limb usually enter by a small distinct trunk into the corresponding part of the right brachiocephalic vein. The duct, and also the principal lymphatic vessels, are provided with valves.

Lymphatic glands, rarely met with in the *Sauropsida*, are usually present in mammals, both in the general and in the lacteal system, the latter being called "mesenteric glands." They are round or oval masses, situated upon the course of the vessels, which break up in them and assume a plexiform arrangement, and then reunite as they emerge. No structures corresponding to the pulsating "lymphatic hearts" of the lower vertebrates have been met with in mammals.

Ductless glands. Associated with the vascular and lymphatic systems are certain bodies, the functions of which are not properly understood, and which are usually, on account of their general appearance, grouped together under the name of "ductless glands." Of these the "spleen" is the largest, and single, always placed in mammals in relation to the fundus or left end of the stomach, to which it is attached by a fold of peritoneum. It is dark-coloured and spongy in substance, and has a depression on one side or "hilus," into which the splenic artery, a branch of the cœliac axis of the abdominal aorta, enters, and from which the vein, which joins the portal system, emerges. It varies much in size and form in different mammals, being relatively very small in the *Cetacea*. It is sometimes almost spherical, but more often flattened, oval, triangular, or elongated, and occasionally, as in Monotremes and most Marsupials, triradiate. The "suprarenal bodies" or "adrenals" are two in number, each situated either in contact with or at a short distance in front of the anterior extremity of the kidney. They are abundantly supplied with nerves, and are much larger relatively in early than in adult life. The "thyroid body," or rather bodies, for there are generally two, though in Man and some other species connected by an isthmus passing across the middle line, are constant in mammals, though only met with in a rudimentary condition, if at all, in other vertebrates. They are situated in the neck, in contact with the sides of the anterior extremity of the trachea. The "thymus" lies in the anterior part of the thorax, between the sternum and the great vessels at the base of the heart, and differs from the thyroid in being median and single, and having a central cavity. It attains its greatest development during the period of lactation, and then diminishes and generally disappears before full growth is attained.

Nostrils. *Respiratory Organs.*—Mammals breathe occasionally through the mouth, but usually, and in many cases exclusively, through the nostrils or nares. These are apertures, always paired (except in the toothed *Cetacea*, where they unite to form a single external opening), and situated at the fore part of the face, generally at or beneath the end of the muzzle, a median prominence above the mouth. This is sometimes elongated to form a proboscis, to the extremity of which the nostrils are carried, and which attains its maximum of development in the Elephant. In the *Cetacea* the nostrils are situated at a considerable distance behind the anterior end of the face, upon the highest part of the head, and are called "blow-holes," from the peculiar mode of respiration of these animals. The nostrils are kept open by means of cartilages which surround their aperture, and which many animals have the power of moving so as to cause partial dilatation or contraction. In diving animals, as Seals and *Cetacea*, they can be completely closed at will so as to prevent the entrance of water when beneath the surface. The passage to which the nostrils lead is in most mammals filled by a more or less complex sieve-like apparatus, formed of the convoluted turbinal bones and cartilages, over which a moist, vascular, ciliated mucous membrane is spread, and which intercepts particles of dust, and also aids in warming the inspired air before it reaches the lungs. In the *Proboscidea*, in which these functions are performed by the walls of the long tubular proboscis, this apparatus is entirely wanting. The narial passages have the organ of smell situated in their upper part, and communicate posteriorly with the pharynx, and through the glottis with the "trachea" or windpipe, a tube by which the air is conveyed to and from the lungs. The permanent patency of the trachea during the varied movements of the neck is provided for by its walls being stiffened by a series of cartilaginous rings or hoops, which in most mammals are incomplete behind. Having entered the thorax, the trachea bifurcates into the two bronchi, one of which enters, and, dividing dichotomously, ramifies through, each lung. In some of the *Cetacea* and *Artiodactyla* a third bronchus is given off from the lower part of the trachea, above its bifurcation, and enters the right lung. Trachea.

Larynx. The upper end of the trachea is modified into the organ of voice or "larynx," the air passing through which to and from the lungs is made use of to set the edges of the "vocal cords," fibrous bands stretched one on each side of the tube, into vibration. The larynx is composed of several cartilages, of which the "thyroid," the "cricoid," and the "arytenoid" are the principal, moved upon one another by muscles, and suspended from the hyoidean arch. By alteration of the relative position of these cartilages the cords can be tightened or relaxed, approximated or divaricated, as required to modulate the tone and volume of the voice. A median tongue-shaped fibro-cartilage at the top of the larynx, the "epiglottis," protects the "glottis," or aperture by which the larynx communicates with the pharynx, from the entry of particles of food during deglutition. The form of the larynx and development of the vocal cords present many variations in different members of the class, the greatest modification from the ordinary type being met with in the *Cetacea*, where the arytenoid cartilages and epiglottis are united in a tubular manner, project into the nasal passage, and, being grasped by the muscular posterior margin of the palate, provide a direct channel of communication from the lungs to the external surface. An approach to this condition is met with in the Hippopotamus and some other Ungulates. Nearly all mammals have a voice, although sometimes it is only exercised at seasons of sexual excitement. Some Marsupials and Edentates appear to be quite mute. In no mammal is there an inferior larynx, or "syrinx, as in birds.

Diaphragm. The thoracic cavity of mammals differs from that of the *Sauropsida* in being completely separated from the abdomen by a muscular partition, the "diaphragm," attached to the vertebral column, the ribs, and the sternum. This is much arched, with the convexity towards the thorax, so that when its fibres contract it is flattened and the cavity of the thorax increased, and when they are relaxed the cavity is diminished.

Lungs. The lungs are suspended freely in the thorax, one on each side of the heart, being attached only by the root, which consists of the bronchus or air-tube, and pulmonary arteries and veins by which the blood is passed backwards and forwards between the heart and the lungs. The remaining part of the surface of each lung is covered by serous membrane, the "pleura," and, whatever the state of distension or contraction of the chest-wall, is accurately in contact with it. Inspiration is effected by the contraction of the diaphragm, and by the intercostal and other muscles elevating or bringing forward the ribs, and thus throwing the sternum farther away from the vertebral column. As the surface of the lung must follow the chest-wall, the organ is itself expanded, and air rushes in through the trachea to fill all the minute cells in which the ultimate ramifications of the bronchi terminate. In ordinary expiration very little muscular power is expended, the elasticity of the lungs and surrounding parts being sufficient to cause a state of contraction and to drive out at least a portion of the air contained in the cells, when the muscular stimulus is withdrawn. The lungs are sometimes simple externally, as in the *Sirenia* (where they are greatly elongated) and the *Cetacea*, but they are more often divided by deep fissures into one or more lobes. The right lung is usually larger and more subdivided than the left. It often has a small distinct lobe behind, wanting on the left side, and hence called *lobulus azygos*.

Air sacs. Most mammals have in connexion with the air passages certain diverticuli or pouches containing air, the use of which is not always easy to divine. The numerous air sinuses situated between the outer and inner tables of the bones of the head, which in Man are represented by the antrum of Highmore and the frontal and sphenoidal sinuses, and which attain their maximum of development in the Indian Elephant, are obviously for the mechanical purpose of allowing expansion of the bone surface without increase of weight. They are connected with the nasal passages. The Eustachian tubes pass from the back of the pharynx into the cavity of the tympanum, into which and the mastoid cells they allow air to pass. In the *Equidæ* there are large post-pharyngeal air sacs in connexion with them. The Dolphins have an exceedingly complicated system of air sacs in connexion with the nasal passages just within the nostrils, and the Tapir and Horses have blind sacs in the same situation. In the males of some Seals (*Cystophora* and *Macrorhinus*) large pouches, which the animal can inflate with air, but which at other times are flaccid, and which are not developed in the young animal or the female, arise from the upper part of the nasal passages, and lie immediately under the skin of the face. These are very analogous, although not in the same situation, to the gular pouch of the male Bustard. The larynx has frequently membranous pouches in connexion with it, into which air passes. These may be lateral and opening just above the vocal cords, constituting the *sacculi laryngis*, found in a rudimentary state in Man, and attaining an enormous development, reaching to the shoulders and axillæ, in some of the Anthropoid Apes; or they may be median, opening in front either above or below the thyroid and cricoid cartilages, as in the Howling and other Monkeys, and also in the Whalebone Whales and Great Anteater.

Kidneys. *Urinary Organs.*—The kidneys of mammals are more compact and definite in form than in other vertebrates, being usually more or less oval, with an indent on the side turned towards the middle line from and into which the vessels and ducts pass. They are distinctly divided into a cortical secretory portion, composed mainly of convoluted tubes, and containing Malpighian bodies, and a medullary excreting portion, formed of straight tubes converging towards a papilla, embraced by the commencement of the ureter or duct of the organ. The kidneys of some mammals, as most Monkeys, Carnivores, Rodents, &c., are simple, with a single papilla into which all the renal tubuli enter. In others, as Man, there are many pyramids of the medullary portion, each with its papilla, opening into a division (calyx) of the upper end of the ureter. Such kidneys are, either in the embryonic condition only or throughout life, lobulated on the surface. In some cases, as in Bears, Seals, and especially the *Cetacea*, the lobulation is carried further, the whole organ being composed of a mass of renules, loosely united by connective tissue, and with separate ducts, which soon join to form the common ureter. In all mammals except the Monotremes the ureters terminate by slit-like valvular openings in the urinary bladder. Bladder. This receptacle when filled discharges its contents through the single median urethra, which in the male is almost invariably included in the penis, and in the females of some species of Rodents, Insectivores, and Lemurs has a similar relation to the clitoris. In the Monotremes, though the bladder is present, the ureters do not enter into it, but into the urogenital canal some distance below it, the orifice of the genital duct intervening.

Nervous System and Organs of Sense.

The brain of mammals shows a higher condition of Brain. organization than that of other vertebrates. The cerebral hemispheres have a greater preponderance compared to other parts, especially to the so-called optic lobes, or corpora quadrigemina, which are completely concealed by them. The commissural system of the hemispheres is much more complete, both fornix and corpus callosum being present in some form; and, when the latter is rudimentary, as in Marsupials and Monotremes, its deficiency is made up for by the great size of the anterior commissure. The lateral lobes of the cerebellum, wanting in lower vertebrates, are well developed and connected by a transverse commissure, the pons Varolii. The whole brain, owing especially to the size of the cerebral hemispheres, is considerably larger relatively to the bulk of the animal than in other classes, but it must be recollected that the size of its brain depends upon many circumstances besides the degree of intelligence which an animal possesses, although this is certainly one. Man's brain is many times larger than that of all other known mammals of equal bulk, and even three times as large as that of the most nearly allied Ape. Equal bulk of body is here mentioned, because, in drawing any conclusions from the size of the brain compared with that of the entire animal, it is always necessary to take into consideration the fact that in every natural group of closely allied animals the larger species have much smaller brains relatively to their general size than the smaller species, so that, in making any effective comparison among animals belonging to different groups, species of the same size must be selected. It may be true that the brain of a Mouse is, as compared with the size of its body, larger than that of a Man, but, if it were possible to reduce an animal having the general organization of a Man to the size of a Mouse, its brain would doubtless be very many times larger; and conversely, as shown by the rapid diminution of the relative size of the brain in all the large members of the Rodent order, a Mouse magnified to the size of a Man would, if the general rule were observed, have a brain exceedingly inferior in volume. Although the brain of the large species of Whales is, as commonly stated, the smallest in proportion to the bulk of the animal of any mammal, this does not invalidate the general proposition that the *Cetacea* have very large brains compared with terrestrial mammals, as the *Ungulata*, or even the aquatic *Sirenia*, as may be proved by placing the brain of a Dolphin by the side of that of a Sheep or Pig, or a Manatee of equal general weight. It is only because the universally observed difference between the slower ratio of increase of the brain compared with that of the body becomes so enormous in these immense creatures that they are accredited with small brains.

The presence or absence of "sulci" or fissures on the surface of the hemisphere, dividing it into "convolutions" or "gyri," and increasing the superficies of the cortical grey matter, as well as allowing the pia mater with its nutrient blood-vessels to penetrate into the cerebral substance, follow somewhat similar rules. They are related partly to the high or low condition of organization of the species, but also in a great degree to the size of the cerebral hemispheres. In very small species of all groups, even the *Primates*, they are absent, and in the largest species of groups so low in the scale as the Marsupials and Edentates they are found. They reach their maximum of development in the *Cetacea*.

The researches of palæontologists, founded upon studies of casts of the interior of the cranial cavity of extinct forms, have shown that, in many natural groups of mammals, if not in all, the brain has increased in size, and also in complexity of surface foldings, with the advance of time,—indicating in this, as in so many other respects, a gradual progress from a lower to a higher type of development.

erves. The twelve pairs of cranial nerves generally recognized in vertebrates are all usually found in mammals, though the olfactory nerves are excessively rudimentary, if not altogether absent, in the Toothed Whales. The spinal cord, or continuation of the central nervous axis, lies in the canal formed by the neural arches of the vertebræ, and gives off the compound double-rooted nerves of the trunk and the extremities corresponding in number to the vertebræ, through the interspaces between which they pass out to their destination. The cord is somewhat enlarged at the two points where it gives off the great nerves to the anterior and the posterior extremities, which from their interlacements soon after their origin are called respectively the brachial and lumbar plexuses. The ganglionic or sympathetic portion of the nervous system is well developed, and presents few modifications.

ense of uch. The sense of touch is situated in the skin generally, but is most acute in certain regions more or less specialized for the purpose by the presence of tactile papillæ, such as portions of the face, especially the lips and end of the snout, and the extremities of the limbs when these are used for other purposes than mere progression, and the under surface of the end of the tail in some Monkeys. The "vibrissæ" or long stiff bristles situated on the face of many mammals are rendered extremely sensitive to touch by the abundant supply of branches from the fifth nerve to their basal papillæ. In Bats, the extended wing membranes, and probably also the large ears and the folds and prominences of skin about the face of some species, are so sensitive as to receive impressions even from the different degrees of resistance of the air, and so enable the animals to avoid coming in contact with obstacles to their nocturnal flight.

The organs of the other special senses are confined to the head. Taste is situated in the papillæ scattered on the dorsal surface of the tongue. The organ of smell is present in all mammals except the Toothed Whales. It consists of a ramification of the olfactory nerves over a plicated, moist, mucous membrane, supported by folded plates of bone, placed on each side of the septum nasi in the roof, or often in a partially distinct upper chamber of the nasal passage, so arranged that, of the air passing into the lungs in inspiration, some comes in contact with it, causing the perception of any odorous particles with which it may be charged. Many mammals possess intense powers of smelling certain odours which others are quite unable to appreciate, and the influence which this sense exercises over the well-being of many species is very great, especially in indicating the proximity of others of the same kind, and giving warning of the approach of enemies. The development and modification of the sense of smell is probably associated with that of the odorous secretion of the cutaneous glands.

aste. mell.

ight. The organ of sight is quite rudimentary, and even concealed beneath the integument, in some burrowing Rodents and Insectivores, and is most imperfectly developed in the *Platanista*, or Freshwater Dolphin of the rivers of India. In all other mammals the eyeball has the structure characteristic of the organ in the higher *Vertebrata*, consisting of parts through which the rays of light are admitted, regulated, and concentrated upon the sensitive expansion of the optic nerve lining the posterior part of the ball. A portion of the fibro-vascular and highly pigmented layer, the choroid, which is interposed between the retina and the outer sclerotic coat, is in many mammals modified into a brilliantly coloured light-reflecting surface, the *tapetum lucidum*. There is never a pecten or marsupium, as in the *Sauropsida*, nor is the sclerotic ever supported by a ring of flattened ossicles, as is so frequently the case in the lower vertebrated classes. The eyeball is moved in various directions by a series of muscles—the four recti, two obliqui, and, except in the higher *Primates*, a posterior retractor muscle called choanoid. It is protected by the lids, generally distinctly separated into an upper and a lower movable flap, which, when closed, meet over the front of the eye in a more or less horizontal line; but sometimes, as in the *Sirenia*, the lids are not distinct, and the aperture is circular, closing to a point. In almost all mammals below the *Primates*, except the *Cetacea*, a "nictitating membrane" or third eyelid is placed at the inner corner of the eyeball, and works horizontally across the front of the ball within the true lids. Its action is instantaneous, being apparently for the purpose of cleaning the front of the transparent cornea, a function which is unnecessary in animals whose eyes are habitually bathed in water, and which in Man and his nearest allies is performed by winking the true eyelids. Except in *Cetacea* the surface is kept moist by the secretion of the lacrymal gland, placed under the upper lid at its outer side, and the lids are lubricated by the Harderian and Meibomian glands, the former being situated at the inner side of the orbit, and especially related to the nictitating membrane, the latter in the lining membrane of the lids.

The organ of hearing is enclosed in a bony capsule (periotic) situated in the side of the head, intercalated between the posterior (occipital) and the penultimate (parietal) segment of the skull. It has, in common with other vertebrates, three semicircular canals and a vestibule, but the cochlea is more fully developed than in *Sauropsida*, and, except in the Monotremes, spirally convoluted. The tympanic cavity is often dilated below, forming a smooth rounded prominence on the base of the skull, the tympanic bulla. The three principal ossicles, the "malleus," "incus," and "stapes," are always present, but variable in characters. In the *Sirenia*, *Cetacea*, and Seals they are massive in form, being in the first-named order of larger size than in any other mammals. In the *Cetacea* the malleus is ankylosed to the tympanic; in other mammals it is connected only with the membrana tympani. The stapes in the lower orders —Edentates, Marsupials, and Monotremes—has a great tendency to assume the columnar form of the corresponding bone in *Sauropsida*, its two rami entirely or partially coalescing.[1] The tympanic membrane (drum of the ear) forms the outer wall of the cavity. In the fœtal state it is level with the external surface of the skull, and remains so permanently in a few mammals, as the American Monkeys; but commonly, by the growth of the squamosal bone, it becomes deeply buried at the bottom of a bony tube (*meatus auditorius externus*), which is continued to the surface of the skin in a fibrous or fibro-cartilaginous form. In Whales, owing to the thickness of the subcutaneous adipose tissue, this is of great length, and is also extremely narrow. In most aquatic and burrowing animals the meatus opens upon the surface by a simple aperture, but

Hearing.

[1] The modifications of these bones are fully described by A. Doran, "Morphology of the Mammalian *Ossicula auditus*," *Trans. Linn. Soc.*, ser. 2, vol. i. pp. 371–497, pl. lviii.–lxiv., 1878.

in the large majority of the class there is a projecting fold of skin, strengthened by fibro-cartilages, called the pinna or auricle, or "external ear," of very variable size and shape, generally movably articulated on the skull, and provided with muscles to vary its position, as it helps to collect and direct the vibrations of sound into the meatus.

Reproductive Organs.

Testes. In the male the testes retain nearly their primitive or internal position throughout life in the *Monotremata*, *Sirenia*, *Cetacea*, most *Edentata*, *Hyracoidea*, *Proboscidea*, and Seals, but in other orders they either periodically (as in *Rodentia*, *Insectivora*, and *Chiroptera*) or permanently pass out of the abdominal cavity through the inguinal canal, forming a projection beneath the skin of the perineum, or becoming suspended in a distinct pouch of the integument called scrotum. All the Marsupials have a pedunculated scrotum, the position of which differs from that of other mammals, being in front of, instead of behind, the preputial orifice. The presence, absence, or comparative size and number of the accessory generative glands—prostate, vesicular, and Cowper's glands, as they are called—vary much in different groups of mammals.

Penis. The penis is almost always completely developed, consisting of two corpora cavernosa attached to the ischial bones, and of a median corpus spongiosum enclosing the urethra, and forming the glans at the distal portion of the organ. In Marsupials, Monotremes, and the Sloths and Anteaters, the corpora cavernosa are not attached directly to the ischia, and in the last-named the penis is otherwise of a very rudimentary character, the corpus spongiosum not being present. In many Marsupials the glans penis is bifurcated. In most *Primates*, *Carnivora*, *Rodentia*, *Insectivora*, and *Chiroptera*, but in no other orders, an *os penis* is present.

Ovaries and oviduct. In the female, the ovaries retain permanently their original abdominal position, or only descend a short distance into the pelvis. They are of comparatively smaller size than in other vertebrates, and have a definite flattened oval form, and are enclosed in a more or less firm "tunica albugenia." The oviduct has a trumpet-like, and usually fimbriated abdominal aperture, and is more or less differentiated into three portions:—(1) a contracted upper part, called in Man and the higher mammals "Fallopian tube"; (2) an expanded part with muscular walls, in which the ovum undergoes the changes by which it is developed into the fœtus, called the "uterus"; (3) a canal, the "vagina," separated from the last by a valvular aperture, and terminating in the urino-genital canal, or common urinal and genital passage, which in higher mammals is so short as scarcely to be distinct from the last. The complete distinction of the oviducts of the two sides throughout their whole length, found in all lower vertebrates, only occurs in this class in Monotremes, a prevailing mammalian characteristic being their more or less perfect coalescence in the middle line to form a single median canal. In the Marsupials this union only includes the lower part of the vagina; in most *Placentalia* it extends to the whole vagina and a certain portion of the uterus, which cavity is then described as "bicornuate." In the higher mammals, as in Man, and also in some of the Edentates, the whole of the uterus is single, the contracted upper portion of the oviducts or Fallopian tubes, as they are then called, entering its upper lateral angles by small apertures. In certain lower forms of mammals the urino-genital canal opens with the termination of the rectum into a common cloaca, as in other vertebrates; but it is characteristic of the majority of the class that the two orifices are more or less distinct externally.

Mammary glands. Mammary glands, which secrete the milk by which the young are nourished during the first portion of their existence after birth, are present in both sexes in all mammals, though usually only functional in the female. In the Monotremes alone, their orifices are mere scattered pores in the skin, but in all others they are situated upon the end of conical elevations, called mammillæ or teats, which, taken into the mouth of the young animal, facilitate the process of sucking. These are always placed in pairs upon some part of the ventral surface of the body, but varying greatly in number and position in different groups. In the *Cetacea*, where the prolonged action of sucking would be incompatible with their subaqueous life, the ducts of the glands are dilated into large reservoirs from which the contents are injected into the mouth of the young animal by the action of a compressor muscle.

Secondary sexual characters. Secondary sexual characters, or modifications of structure peculiar to one sex, but not directly related to the reproductive function, are very general in mammals. They almost always consist of the acquisition or perfection of some character by the male as it attains maturity, which is not found in the female or the young in either sex. In a large number of cases these clearly relate to the combats in which the males of many species engage for the possession of the females during the breeding season; others are apparently ornamental, and of many it is still difficult to apprehend the meaning. Many suggestions on this subject will, however, be found in the chapters devoted to it in Darwin's work on *The Descent of Man and Selection in Relation to Sex*, where most of the best-known instances are collected. Superiority of size and strength in the male of many species is a well-marked secondary sexual character related to the purpose indicated above, being probably perpetuated by the survivors or victors in combats transmitting to their descendants those qualities which gave them advantages over others of their kind. To the same category belong the great development of the canine teeth of the males of many species which do not use these organs in procuring their food, as the Apes, Swine, Musk and some other Deer, the tusk of the male Narwhal, the antlers of Deer, which are present in most cases only in the males, and the usual superiority in size and strength of the horns of the *Bovidæ*. Other secondary sexual characters, the use of which is not so obvious, or which may only relate to ornament, are the presence of masses or tufts of long hair on different parts of the body, as the mane of the male Lion and Bison, the beards of some Ruminants and Bats (as *Taphozous melanopogon*), Monkeys, and of Man, and all the variations of coloration in the sexes, in which, as a general rule, the adult male is darker and more vividly coloured than the female. Here may also be mentioned the presence or the greater development of odoriferous glands in the male, as in the Musk Deer, and the remarkable perforated spur with its gland and duct, so like the poison-tooth of the venomous serpents, found in the males of both *Ornithorhynchus* and *Echidna*, the use of which is at present unknown.

Placenta. *Placenta.*—The development of the mammalian ovum, and the changes which the various tissues and organs of the body undergo in the process of growth, are too intricate subjects to be explained without entering into details incompatible with the limits of this article, especially as they scarcely differ, excepting in their later stages, from those of other vertebrates, upon which, owing to the greater facilities these present for examination and study, the subject has been more fully worked out. There are, however, some points which require notice, as peculiar to the mammalian class, and as affording at least some hints upon the difficult subject of the affinities and classification of the members of the group.

The nourishment of the fœtus during intra-uterine life takes place through the medium of certain structures, partly belonging to the fœtus itself and partly belonging to the inner parietes of the uterus of the parent. These in their complete form constitute the complex organ called the "placenta," which serves as the medium of communication between the mother and fœtus, and in which the physiological processes that are concerned in the nutrition of the latter take place; but, as we shall see, though a placenta, in the usual acceptation of the term, is peculiar to the mammalian class, it is not in all of its members that one is developed. The structures to which we shall have especially to refer are the outer tunic of the ovum, to which, however formed, the term "chorion" is commonly applied, and two sac-like organs connected with the body cavity of the embryo, both formed from the splanchnic mesoblast, lined by a layer of the hypoblast. These are the "umbilical vesicle" or "yolk sac" and the "allantois."

The umbilical vesicle is a thin membrane enclosing the yolk, which by the doubling in of the ventral walls of the embryo becomes gradually formed into a distinct sac external to the body, with a pedicle (the omphalo-enteric duct) by which for a time a communication is maintained between its cavity and the intestinal canal. In the walls of this sac blood-vessels (omphalo-meseraic or vitelline) are developed in connexion with the vascular system of the embryo, through which, either by their contact with the outer surface of the walls of the ovum, or by the absorption through them of the contents of the yolk sac, the nutrition of the embryo in the lower vertebrates chiefly takes place. In mammals the umbilical vesicle plays a comparatively subordinate part in the nourishment of the fœtus, its function being generally superseded by the allantois.

The last-named sac commences at a very early period as a diverticulum from the hinder end of the alimentary tract of the embryo. Its proximal portion afterwards becomes the urinary bladder, the contracted part between this and the cavity of the allantois proper constituting the urachus, which passes out of the body of the fœtus at the umbilicus together with the vitelline duct. The mesoblastic tissue of the walls of the allantois soon becomes vascular; its arteries are supplied with fœtal blood by the two hypogastric branches of the iliacs, or main divisions of the abdominal aorta, and the blood is returned by venous trunks which unite to form the single umbilical vein which runs to the under surface of the liver, where, part of it joining the portal vein and part entering the vena cava directly, it is brought to the heart. These are the vessels which, with their surrounding membranes, constitute the umbilical cord, the medium of communication between the fœtus and the placenta, when that organ is fully developed.

The nature of the fœtal membranes of the *Monotremata* is not known. In the *Marsupialia* the observations made many years ago by Professor Owen, upon the development of the Kangaroo, have recently been confirmed by Dr H. C. Chapman,[1] but fuller investigations in different species and at different stages are still much to be desired. As far as is known, up to the period of the very premature birth of these animals the outer covering of the ovum or chorion is free from villi and not adherent to the uterine walls, for, though fitting into the folds of the latter, it is perfectly and readily separable in its entire extent from them. The umbilical vesicle is large, vascular, and adherent to a considerable portion of the chorion, while the allantois is relatively small, and, though the usual blood-vessels can be traced in it, it does not appear to contract any connexion with the chorion, and therefore much less with the walls of the uterus, of such a nature as to constitute a placenta. While in the uterus the nourishment of the fœtus seems therefore to be derived from the umbilical vesicle, as in reptiles and birds, rather than from the uterine walls by means of the allantoic vessels, as in the higher mammals. The latter vessels, in fact, play even a much less important part in the development of these animals, not only than in the placental mammals, but even than in the *Sauropsida*, for they can scarcely have the respiratory function assigned to them in that group. Pulmonary respiration and the lacteal secretion of the mother very early supersede all other methods of providing the due supply both of oxygen and of food required for the development and growth of the young animal. In this sense the Marsupials may be looked upon as the most typically "mammalian" of the whole class. In no other group do the milk-secreting glands play such an important part in providing for the continuity of the race.

In the third primary division of the *Mammalia*, the so-called *Placentalia*, the umbilical vesicle generally does not quite unite with the chorion, and disappears as development proceeds, so that no trace of it can be seen in the membranes of an advanced embryo; but it may persist until the end of intra-uterine life as a distinct sac in the umbilical cord, or lying between the allantois and amnion. The disappearance or persistence of the umbilical vesicle does not, according to our present knowledge, appear to be correlated with a higher or lower general grade of development, as might be presupposed. It is stated to have been found in Man even up to the end of intra-uterine life, and also in the *Carnivora*, while in the *Ungulata* and *Cetacea* it disappears at an earlier age. In many, if not all, of the *Rodentia*, *Insectivora*, and *Chiroptera*, it plays a more important part, becoming adherent to a considerable part of the inner surface of the chorion, to which it conveys blood-vessels, although villi do not appear to be developed from the surface of this part, as they are on the portion of the chorion supplied by the allantoic vessels. These orders thus present to a certain extent a transitional condition from the Marsupials, although essentially different, in possessing the structures next to be described.

The special characteristic of the whole of the placental mammals constituting the majority of the class, is that the allantois and its vessels become intimately blended with a smaller or greater part of the parieties of the ovum, forming a structure on the outer surface of which villi are developed, and which, penetrating into corresponding cavities of the "decidua," or soft, vascular, hypertrophied lining membrane of the uterus, constitutes the placenta. This organ may be regarded, as Professor Turner says, both in its function and in the relative arrangement of its constituent textures, as a specially modified secreting gland, the ducts of which are represented by the extremities of the blood-vessels of the fœtal system. The passage of material from the maternal to the fœtal system of vessels is not a simple percolation or diffusion through their walls, but is occasioned by the action of a layer of cells derived from the maternal or uterine structures, and interposed between the blood-vessels of the maternal part of the placenta and those of the villi covering the chorion, in which the embryonic vessels ramify.

The numerous modifications in the details of the structure of this organ relate to increasing the absorbing capacity of the vessels of the chorion, and are brought about either by increasing the complexity of the fœtal villi and maternal crypts over a limited area, or by increasing the area of the part of the chorion covered by the placental villi, or by various combinations of the two methods.

[1] *Proc. Acad. Nat. Sc. Philadelphia*, December 27, 1881; *Ann. Mag. Nat. Hist.*, April 1882.

The first class of variations has given rise to a distinction into two principal kinds of placenta—(1) simple or non-deciduate, and (2) deciduate. In the former the fœtal villi are received into corresponding depressions of the maternal surface, from which at the period of parturition they are simply withdrawn. In the second or more complex form the relation is more intimate, a layer of greater or less thickness of the lining membrane of the uterus, called "decidua," becoming so intimately blended with the chorion as to form part of the placenta proper, or that structure which is cast off as a solid body at parturition. In other words, in the one case the line of separation between the placenta and uterus at birth takes place at the junction of the fœtal and maternal structures, in the other through the latter, so that a portion of them, often of considerable thickness, and containing highly organized structures, is cast off with the former. It has been thought that the distinction between these two forms of placentation is so important as to constitute a sufficiently valid basis for a primary division of the placental mammals into two groups. It has, however, been shown that the distinction is one rather of degree than of kind, as intermediate conditions may exist, and it is not improbable that in different primary groups the simpler, non-deciduate form may have become developed independently into one or other of the more complex kinds.

Apart from its intimate structure, the placenta may be met with of very varied general form. It may consist of villi scattered more or less regularly over the greater part of the surface of the chorion, the two extremities or poles being usually more or less bare. This form is called the "diffused placenta." It is probably a primitive condition, from which most of the others are derived, although its existence must presuppose the absence of the umbilical vesicle as a constituent of the chorionic wall. It is found at present in the Manis among Edentates, the *Cetacea*, *Sirenia*, the Perissodactyle Ungulates, and the Camels, Pigs, and Chevrotains among the Artiodactyles. Such placentæ are always non-deciduate. In the true Ruminants or *Pecora*, among the Artiodactyle Ungulates, the villi are aggregated in masses called cotyledons, with bare spaces between. Such a placentation is called "polycotyledonary." In another modification the villi are collected in a more or less broad band encircling the chorion, leaving a very large portion of the two poles bare, constituting the "zonary placenta," characteristic of the *Carnivora*, and also occurring in the Elephant, Hyrax, and *Orycteropus*. The fact of the form of the placenta of these three last-named animals agreeing together, and with that of the *Carnivora*, does not, however, necessitate the ascription of zoological affinities, as the placenta of the *Carnivora* has been shown to be at first discoidal, and to become zonary by spreading round the chorion in the course of development. In the other cases, although it must be admitted that the early stages have not been well observed, it is quite probable that it may be derived from a diffused placenta, in which the fœtal villi have disappeared from a larger space than usual of the two poles of the ovum.

In another form one pole only of the chorion is non-vascular, the placenta assuming a dome or bell shape, as in the Lemurs and the Sloths. The transition from this, by the gradual restriction of the vascular area, is easy to the oval or discoidal form of placenta of the Anteaters, Armadillos, and *Primates*. The discoidal placenta of the Rodents, Insectivores, and *Chiroptera*, though showing so much superficial resemblance to that of the last-named order as to have caused them formerly to be associated in one primary group, is now known to be developed in another manner, not by the concentration of villi from a diffused to a limited area, but by retaining the area to which it was originally restricted in consequence of the large surface of chorion occupied, as before mentioned, by the umbilical vesicle. To compensate for the smallness of area, the complex or deciduate structure has been developed. We may conclude that, although the characters and arrangement of the fœtal structures may not have that extreme importance which has been attributed to them by some zoologists, they will form, especially when more completely understood, valuable aids in the study of the natural affinities and evolution of the *Mammalia*.[1]

CLASSIFICATION OF THE MAMMALIA.

As stated at the commencement of this article, the mammalian class, as at present known either by existing or extinct forms, is completely isolated from all other groups of the animal kingdom, but it is impossible to refrain from speculating as to its origin and nearest affinities. In arranging the classes of vertebrates in a linear series it is customary to place them in the following order—*Pisces*, *Amphibia*, *Reptilia*, *Aves*, *Mammalia*,—an order which may possibly indicate the relative degree of elevation to which the most completely developed members of each class attain, though it would be a great mistake to suppose that such an arrangement expresses the true relationship of one to the other, and still less must it be imagined that in the process of evolution any of the higher classes are necessarily derived directly from those nearest below them in this serial arrangement. On the contrary, some arguments recently set forth by Professor Huxley[2] point very strongly to the conclusion that, in looking among vertebrates for the progenitors of the *Mammalia*, we must pass over all known forms of birds and reptiles, and go straight down to the *Amphibia*. In addition to the characters derived from the conformation of the pelvis upon which the argument is primarily based, the following reasons are given for this conclusion:—"The *Amphibia* are the only air-breathing *Vertebrata* which, like mammals, have a dicondylian skull. It is only in them that the articular element of the mandibular arch remains cartilaginous, while the quadrate ossification is small, and the squamosal extends down over it to the osseous elements of the mandible, thus affording an easy transition to the mammalian condition of those parts. The pectoral arch of the Monotremes is as much amphibian as it is sauropsidian; the carpus and the tarsus of all *Sauropsida*, except the *Chelonia*, are modified away from the Urodele type, while those of the mammal are directly reducible to it. Finally, the fact that in all *Sauropsida* it is a right aortic arch which is the main conduit of arterial blood leaving the heart, while in mammals it is a left aortic arch which performs this office, is a great stumbling-block in the way of the derivation of the *Mammalia* from any of the *Sauropsida*. But, if we suppose the earliest forms of both the *Mammalia* and the *Sauropsida* to have had a common Amphibian origin, there is no difficulty in the supposition that, from the first, it was a left aortic arch in the one series, and the corresponding right aortic arch in the other, which became the predominant feeder of the arterial system."

There is so much in common between the very aberrant Monotremes, upon the structure of which the above conclusions are mainly based, and all other known mammals that we cannot but suppose they are derived, perhaps at some remote period, from one stock, some of the predominating characters of which survive in the existing

[1] For a full exposition of the present state of knowledge on this subject, see the various memoirs of Professor Turner, and especially F. M. Balfour's *Treatise on Comparative Embryology*, 1881, vol. ii.

[2] *Proceedings of the Royal Society of London*, vol. xxviii., 1879, p. 395.

Monotremes, though lost in most other members of the class. These "Prototheria," as Professor Huxley terms them, have in their turn probably been derived from the same source as that in which the existing *Amphibia* on the one hand and the *Sauropsida* on the other have had their origin. The great divisions of the *Vertebrata* may be looked upon therefore as parallel, or rather diverging groups, each tending towards its own specialization, not in any way in the light of ancestor and descendant. No further advance of the Sauropsidian type, which has reached its highest perfection in the modern volant birds, would bring it nearer to the mammalian organization.

Restricting ourselves now to the class of mammals, as differentiated from other vertebrates, it will be unnecessary to repeat the oft-told history of the various attempts to express the prevailing knowledge of their structure and affinities in a systematic manner called a classification. The systems of Ray, Linnæus, Cuvier, Owen, Milne-Edwards, Huxley, and others mark successive epochs of that knowledge. A perfect arrangement of any group of animals can only be obtained simultaneously with a perfect knowledge of their structure and life history, and from this, it need scarcely be said, we are still very far removed. If, as was formerly the case, classifications could be confined to existing species, the work would be far less difficult. By the extinction of intermediate forms the surviving groups have mostly come to be much isolated, and their limits can be readily determined and defined. The discovery of extinct species, which appears to be taking place at a constantly increasing rate, is by degrees breaking down these boundaries, and making definitions impossible, though at the same time it is throwing much light upon the affinities and probable origin of many groups now widely separated. A source of difficulty, and perhaps error, which this advancing knowledge has introduced, arises from the necessity of determining the position and relation of so many forms by the bones and teeth alone, without any hope of deriving aid from all those other structures of which we avail ourselves in the case of recent animals. These considerations will show that any classification advanced at present must be regarded as provisional. There are, however, some positions which seem to be so firmly established that it is very unlikely that we shall be dislodged from them by any further increase of knowledge, and which we should carefully distinguish from others which are acknowledged to be doubtful, and adopted rather for convenience, owing to the necessity of having some arrangement, than as representing unimpeachable truth.

ree at ural divisions.

One of the most certain and fundamental points in the classification of the *Mammalia* is, that all the animals now composing the class can be grouped primarily in three natural divisions, which, presenting very marked differentiating characters, and having no existing, or yet certainly demonstrated extinct, intermediate or transitional forms, may be considered as subclasses of equal value, taxonomically speaking, though very different in the numbers and importance of the animals at present composing them. These three groups are often called by the names originally proposed for them by De Blainville—(1) *Ornithodelphia*, (2) *Didelphia*, (3) *Monodelphia*,—the first being equivalent to the order *Monotremata*, the second to the *Marsupialia*, and the third including all the remaining members of the class. Although actual palæontological proof is wanting, there is much reason to believe that each of these, as now existing, are survivors of distinct branches to which the earliest forms of mammals have successively given rise, and for which hypothetical branches Huxley has proposed the names of *Prototheria*, *Metatheria*, and *Eutheria*,[1] names which, being far less open to objection than those of Blainville, we shall here use as equivalents for the latter.

Prototheria.

The characters of the *Prototheria* can only be deduced from the two existing families, as hitherto no extinct animals which can be referred to other divisions of this remarkable and well-characterized group have been discovered. These two isolated forms, in many respects widely dissimilar, yet having numerous common characters which unite them together and distinguish them from the rest of the *Mammalia*, are the *Ornithorhynchidæ* and the *Echidnidæ*, both restricted in their geographical range to the Australian region of the globe. Taken altogether they represent the lowest type of evolution of the mammalian class, and most of the characters in which they differ from the other two subclasses tend to connect them with the inferior vertebrates, the *Sauropsida* and *Amphibia*; for, though the name *Ornithodelphia* owes its origin to the resemblance of the structure of the female reproductive organs to those of birds, there is nothing especially bird-like about them.

Their principal distinctive characters are these. The brain has a very large anterior commissure, and a very small corpus callosum, agreeing exactly in this respect with the next group. The cerebral hemispheres, in *Echidna* at least, are well developed and convoluted on the surface. The auditory ossicles present a low grade of development, the malleus being very large, the incus small, and the stapes columelliform. They have no true teeth, though the jaws of *Ornithorhynchus* are provided with horny productions, which functionally supply their place. The coracoid bone is complete, and articulates with the sternum, and there is a large "interclavicle" or episternum in front of the sternum, and connecting it with the clavicles. There are also "epipubic" bones. The oviducts (not differentiated into uterine and Fallopian portions) are completely distinct, and open as in oviparous vertebrates separately into a cloacal chamber, and there is no distinct vagina. The testes of the male are abdominal in position throughout life, and the vasa deferentia open into the cloaca, not into a distinct urethral passage. The penis, attached to the ventral wall of the cloaca, is perforated by a canal in the greater part of its length, but not at the base, which is open as in reptiles and those birds which have such an organ, and brought only temporarily in contact with the termination of the vasa deferentia, so as to form a seminal urethra when required, but never transmits the urinary secretion. This condition is a distinct advance on that of the *Sauropsida* in the direction of the more complete development of these parts in most of the other *Mammalia*. The ureters do not open into the bladder, but behind it into the dorsal wall of the genito-urinary passage. The mammary glands have no distinct nipple, but pour out their secretion through numerous apertures in the skin. The early stages of the development of the young are not yet fully known, but they are produced in a very rudimentary condition, and appear never to be nourished by means of an allantoic placenta.

Metatheria.

The *Metatheria* or *Didelphia* are represented at present by numerous species, presenting great diversities of general appearance, structure, and habits, although all united by many essential anatomical and physiological characters, which, taken altogether, give them an intermediate position between the *Prototheria* and the *Eutheria*. In the structure of the brain and the presence of epipubic bones they agree with the former, while in the structure of the ear bones and the shoulder girdle and the presence of teats on the mammary glands they resemble the latter, the reproductive organs belonging to neither one nor the other type, but presenting a special character representing an intermediate grade of development. The ureters open into the base of the bladder. The oviducts are differentiated into

[1] *Proceedings of the Zoological Society*, 1880, p. 649.

uterine and Fallopian portions, and open into a long and distinct vagina, quite separate from the cystic urethra. The penis is large, but its crura are not directly attached to the ischia. The spongy body has a large bifurcated bulb. The young are born in an exceedingly rudimentary condition, and are never nourished by means of an allantoic placenta, but are transferred to the nipple of the mother, to which they remain firmly attached for a considerable time, nourished by the milk injected into the mouth by compression of the muscle covering the mammary gland. They are therefore, as previously remarked (see p. 369), the most typically mammalian of the whole class. The nipples are nearly always concealed in a fold of the abdominal integument or "pouch" (marsupium) which serves to support and protect the young in their early helpless condition. The existing species of this group are entirely confined to the Australian region and the American continent, though in former times they had a more extended geographical range. The earliest mammals hitherto discovered appear (as far as the scanty evidence at present obtainable permits any such conclusion to be hazarded) to have belonged to this type, although it is reasonable to conclude that *Prototheria* (unless upon the improbable supposition that the existing forms have resulted from a process of degradation), and perhaps *Eutheria*, were their contemporaries far back in the Mesozoic age

Eutheria. The *Eutheria*, *Monodelphia*, or "placental mammals" (so called because the fœtus is always nourished while within the uterus of the mother by means of an allantoic placenta) include at present by far the greater proportion of the class. While the survivors of the other groups have probably been for a long time in a stationary condition, these have, as there is already good evidence to show throughout all the Tertiary geological age, and by inference for some time before, been multiplying in numbers and variations of form, and attaining higher stages of development and specialization in various directions. They consequently exhibit far greater diversity of external or adaptive modification than is met with in either of the other subclasses,—some being fitted to live as exclusively in the water as fishes, and others to emulate the aerial flight of birds.

To facilitate the study of the different component members of this large group, it is usual to separate them into certain divisions which are called "orders." In the main zoologists are now of accord as to the general number and limits of these divisions among the existing forms, but the affinities and relationships of the orders to one another are far from being understood, and there are very many extinct forms already discovered which do not fit at all satisfactorily into any of the orders as commonly defined.

Commencing with the most easily-distinguished, we may first separate a group called *Edentata*, composed of several very distinct forms, the Sloths, Anteaters, and Armadillos, which under great modifications of characters of limbs and digestive organs, as well as habits of life, have just enough in common to make it probable that they are the very specialized survivors of an ancient group, most of the members of which are extinct, but which the researches of palæontology have not yet revealed to us. The characters of their cerebral, dental, and in many cases of their reproductive organs show an inferior grade of organization to that of the generality of the subclass. The next order, about the limits of which there is no difficulty, is the *Sirenia*, aquatic vegetable-eating animals, with complete absence of hind limbs, and low cerebral organization,—represented in our present state of knowledge by but two existing genera, the Dugongs and Manatees, and by a few extinct forms, which, though approaching a more generalized mammalian type, show no special characters allying them to any of the other orders. Another equally well-marked and equally isolated, though far more numerously represented and diversified order, is that of the *Cetacea*, composed of the various forms of Whales, Dolphins, and Porpoises. In aquatic habits, external fish-like form, and absence of hind limbs they resemble the last, though in all other characters they are as widely removed as are any two orders among the *Eutheria*. The association by systematists of the *Cetacea* and *Sirenia* in one group can only be made either in ignorance of their true structure, or in an avowedly artificial system.

All the remaining orders are more nearly allied together, the steps by which they have become modified from one general type being in most cases not difficult to realize. Their dentition especially, however diversified in detail, always responds to the formula already described (see p. 353); and, although the existing forms are broken up into groups in most cases easy of definition, the discoveries already made in palæontology have in great measure filled up the gaps between them.

Very isolated among existing *Eutheria* are the two species of Elephant constituting the order called *Proboscidea*. These, however, are now known to be the survivors of a large series of similar animals, Mammoths, Mastodons, and *Dinotheria*, which as we pass backwards in time gradually assume a more ordinary or generalized type; and the interval which was lately supposed to exist between even these and the rest of the class is partially bridged over by the discovery in American Eocene and early Miocene formations of the gigantic *Dinocerata*, evidently offshoots of the great group of hoofed animals, or *Ungulata*, represented in the actual fauna by the Horses, Rhinoceroses, Tapirs, Swine, and Ruminants. Almost as isolated as the *Proboscidea* among existing mammals are the few small species constituting the genus *Hyrax*, and in their case palæontology affords no help at present, and therefore, pending further discoveries, it has been thought advisable in most recent systems to give them the honour of an order to themselves, under the name of *Hyracoidea*. But the number of extinct forms already known allied to the *Ungulata*, but not coming under the definition of either of the two groups (*Artiodactyla* and *Perissodactyla*) under which all existing species range themselves, is so great that either many new orders must be made for their reception or the definition of the old order *Ungulata* so far extended as to receive them all, in which case both *Proboscidea* and *Hyracoidea* might be included within it. Again the *Rodentia*, or gnawing animals—Rabbits, Rats, Squirrels, Porcupines, Beavers, &c.—are, if we look only at the present state of the class, most isolated. No one can doubt what is meant by a Rodent animal, or have any difficulty about defining it clearly, at least by its dental characters; yet our definitions break down before the extinct South American *Mesotherium*, half Rodent and half Ungulate, which leads by an easy transition to the still more truly Ungulate Toxodon, for the reception of which a distinct order (*Toxodontia*) has been proposed. The *Insectivora* and the *Carnivora* again are at present quite distinct orders, but they merge into one another through fossil forms, and are especially connected by the large group of primitive *Carnivora*, so abundantly represented in the Eocene deposits both of America and Europe, to which Cope has given the name of *Creodonta*. The transition from the Insectivores to the Lemurs is not great, and, strange to say, however different they now appear, the early forms of Lemurs are not easily distinguished from the primitive Ungulates. The Bats or *Chiroptera* are allied to the *Insectivora* in all characters but the extraordinary modification of their anterior extremities into wings, but this, like the want of the hind limbs in the *Cetacea* and *Sirenia*, makes such a clear distinction between them and all other mammals that, in the absence of any knowledge of intermediate or transitional forms, they can be perfectly separated, and form as well defined an order as any in the class. Lastly, we have the important and well-characterized group, called *Primates*, including all the Monkeys and Man, and the question is not yet solved as to how and through what forms it is linked on to the other groups. It is commonly assumed that the Lemurs are nothing more than inferior *Primates*, but the interval between them in the actual fauna of the world is very great, and our knowledge of numerous extinct species recently discovered in America, said to be intermediate in characters, is not yet sufficiently perfect to enable us to form a definite opinion upon the subject.

The distinctive characters of the generally recognized orders of mammals, with an account of their subdivisions and the principal forms contained in each, will be given further on.

GEOGRAPHICAL DISTRIBUTION OF MAMMALIA.

The existing species of few classes of the animal kingdom are better known than those of the *Mammalia*, and, owing to the comparatively limited methods of locomotion or transport which most of them possess, the area of distribution of each species is more definite and restricted than in some other classes. In the articles BIRDS and DISTRIBUTION the various regions into which naturalists have divided the earth's surface, according to the prevailing characters of its animal inhabitants, have been described, and in the latter the main facts connected with the distribution of mammals have been treated of. In the account of each group contained in the present article the particular circumstances relating to its geographical range will be mentioned. There is little therefore needed here, except a brief summary of the most important facts relating to this interesting subject.

As regards their distribution over the surface of the earth, mammals may be divided into three groups according to their principal methods of locomotion—(1) aerial, (2) aquatic, and (3) terrestrial.

rial mm- als.

1. *Aerial Mammals.*—This group only comprises the animals composing the single order *Chiroptera*, which differ from all other mammals in the fact that their principal means of transport from place to place is by aerial flight, as in the majority of birds and insects. Broad expanses of water, which form natural barriers to the spread of terrestrial mammals, are therefore no obstacles to their distribution; accordingly we find the general rule that mammals are not inhabitants of oceanic islands modified in their case. But even in this group, notwithstanding their exceptional powers of locomotion, different species, genera, and families inhabit very definite areas. Each zoological region of the earth has its characteristic Bats; and those of the New World and of the Old World are, with very few exceptions, quite distinct. This subject will be more fully treated of under the order *Chiroptera*.

quatic mm- als.

2. *Aquatic Mammals.*—Many mammals grouped for the present purpose as terrestrial pass a great portion of their lives in brooks, lakes, or rivers, and, being dependent upon such waters for obtaining their subsistence, are necessarily confined to their vicinity; but the truly aquatic mammals, or those living constantly in the water, and unable to move their quarters from place to place by land, are the orders *Cetacea* and *Sirenia*, with which may also be grouped the Seals, forming the Pinniped division of the order *Carnivora*.

For the marine *Cetacea*, animals mostly of large size and endowed with powers of rapid locomotion, there are obviously no barriers to universal distribution over the surface of the earth covered by sea, except such as are interposed by uncongenial temperature or absence of suitable food. Nevertheless it was thought some years ago that the fact of a Whale or a Dolphin occurring in a sea distant from that in which it had usually been found was sufficient justification for considering it as a distinct species and imposing a new name upon it. There are now, however, so many cases known in which Cetaceans from the northern and southern seas, from the Atlantic and the Pacific Oceans, present absolutely no distinguishing external or anatomical characters upon which specific determination can be based that the opposite view is gaining ground; and, as some species are undoubtedly very widely distributed, almost cosmopolitan in fact, there seems little reason why many others should not be included in the same category. The evidence is satisfactory enough in those cases in which the intermediate regions are inhabited by the same forms, the cases of "continuous areas" of distribution. In those in which the areas of distribution are apparently discontinuous, there may be more room for doubt; but it must not be forgotten that the negative evidence is here of much less value than in the case of land animals, as the existence of Cetaceans in any particular part of the ocean is most easily overlooked. The great Sperm Whale (*Physeter macrocephalus*) is known to be almost cosmopolitan, inhabiting or passing through all the tropical and temperate seas, although not found near either pole. At least three of the well-known species of Rorqual (*Balænoptera*) of the British coasts are represented in the North Pacific, on the South American shores, and near New Zealand by species so closely allied that it is difficult to point out any valid distinctive characters, though it may perhaps be desirable to wait for a more complete examination of a large series of individuals before absolutely pronouncing them to be specifically identical. There is nothing yet known by which we can separate the "Humpback Whales" (*Megaptera*) of Greenland, the Cape of Good Hope, and Japan. The same may be said of the common Dolphin of the European seas (*Delphinus delphis*) and the so-called *D. bairdii* of the North Pacific and *D. forsteri* of the Australian seas. The Pilot Whale (*Globicephalus melas*) and the *Pseudorca* of the North Atlantic and of New Zealand are also precisely alike, as far as present knowledge enables us to judge. Many other similar cases might be given. Captain Maury collected much valuable evidence about the distribution of the larger *Cetacea*, and, finding Right Whales (*Balæna*) common in both northern and southern temperate seas, and absent in the intermediate region, laid down the axiom that "the torrid zone is to the Right Whale as a sea of fire, through which he cannot pass." Hence all cetologists have assumed that the Right Whale of the North Atlantic (*B. biscayensis*), that of the South Seas (*B. australis*), and that of the North Pacific (*B. japonica*) are necessarily distinct species. The anatomical structure and external appearance of all are, however, as far as yet known, marvellously alike, and, unless some distinguishing characters can be pointed out, it seems scarcely justifiable to separate them upon geographical position alone; as, although the tropical seas may be usually avoided by them, it scarcely seems impossible, or even improbable, that some individuals of animals of such size and rapid powers of swimming may not have at some time traversed so small a space of ocean as that which divides the present habitual localities of these supposed distinct species. If identity or diversity of structural characters is not to be allowed as a test of species in these cases, as it is usually admitted to be in others, the study of their geographical distribution becomes an impossibility.

Although many species are thus apparently of such wide distribution, others are certainly restricted; thus the

Arctic Right Whale (*Balæna mysticetus*) has been conclusively shown to be limited in its range to the region of the northern circumpolar ice, and no corresponding species has been met with in the southern hemisphere. In this case, not only temperature, but also the peculiarity of its mode of feeding, may be the cause. The Narwhal and the Beluga have a very similar distribution, though the latter occasionally ranges farther south. The Hyperoodons are restricted to the North Atlantic, never entering, as far as is yet known, the tropical seas. Other species are exclusively tropical or austral in their range. One of the true Whalebone Whales (*Neobalæna marginata*) has only been met with hitherto in the seas round Australia and New Zealand, a large Ziphioid (*Berardius arnouxi*) only near the last-named islands.

The *Cetacea* are not limited to the ocean, or even to salt water, some entering large rivers for considerable distances, and some being exclusively fluviatile. One species of *Platanista* is extensively distributed throughout nearly the whole of the river systems of the Ganges, Brahmaputra, and Indus, ascending as high as there is water enough to swim in, but apparently never passing out to sea. The individuals inhabiting the Indus and the Ganges must therefore have been for long ages isolated without developing any definite distinguishing anatomical characters, for those by which the supposed *P. indi* was formerly separated from *P. gangetica* have been shown by Anderson to be of no constant value. *Orcella fluminalis* appears to be limited to the Irawaddy river, and at least two distinct species of Dolphin, belonging to different genera, are found in the waters of the upper Amazon. It is remarkable, however, that none of the great lakes or inland seas of the world are, according to our present knowledge, inhabited by Cetaceans. A regular seasonal migration has been observed in many of the oceanic *Cetacea*, especially those inhabiting the North Atlantic, but further observations upon this subject are still much needed.

The great difference in the manner of life of the *Sirenia*, as compared with that of the *Cetacea*, causes a corresponding difference in their geographical distribution. Slow in their movements, and feeding exclusively upon vegetable substances, water-grasses, or fuci, they are confined to rivers, estuaries, or coasts where these grow, and are not denizens of the open sea, although of course there is a possibility of accidental transport by the assistance of oceanic currents across considerable distances. Of the three genera existing within historic times, one (*Manatus*) is exclusively confined to the shores of the tropical Atlantic and the rivers entering into it, individuals scarcely specifically distinguishable being found both on the American and the African side of the ocean. The Dugong (*Halicore*) is distributed in different colonies, at present isolated, throughout the Indian Ocean from Arabia to North Australia. The *Rhytina* or Northern Sea-Cow was, for some time before its extinction, limited to a single island in the extreme north of the Pacific Ocean.

The Pinnipeds, although capable of traversing long reaches of ocean, are less truly aquatic than the last two groups, always resorting to the land or to extensive ice-floes for the purposes of breeding. The geographical range of each species is generally more or less restricted, usually according to climate, as they are mostly inhabitants either of the Arctic or Antarctic seas and adjacent temperate regions, very few being found within the tropics. For this reason the northern and the southern species are for the most part quite distinct. In fact, the only known exception is the case of a colony of the Sea-Elephant (*Macrorhinus leoninus*), the general range of which is in the southern hemisphere, inhabiting the coast of California. Even in this case a different specific name has been given to the northern form, but the characters by which it is distinguished are not of great importance, and probably, except for the abnormal geographical distribution, would never have been discovered. The most remarkable circumstance connected with the distribution of the Pinnipeds is the presence of members of the order in the three isolated great lakes or inland seas of Central Asia—the Caspian, Aral, and Baikal—which, notwithstanding their long isolation, have varied but slightly from species now inhabiting the Polar Seas.

Terrestrial mammals.

3. *Terrestrial Mammals.*—One of the most important facts connected with the present distribution of terrestrial mammals, but one of which the cause is sufficiently obvious, is their entire absence, except where introduced by the direct agency of man, from all oceanic islands, including even the great New Zealand group. Another, equally striking, but less easily explained, is the very marked isolation as regards its mammalian fauna of the Australian region of zoologists. When once the narrow neutral ground on the border line between this and the Oriental region is passed, there is not found, notwithstanding the vast extent of land it comprises, a single indigenous placental or monodelphous mammal, except a few species of a single family (*Muridæ*) of the very wide spread order *Rodentia*,—the Wild Dog or Dingo having been in all probability introduced. On the other hand, the members of the other two subclasses, the *Prototheria* or *Ornithodelphia* and the *Metatheria* or *Didelphia*, are almost entirely restricted to this region. It might have been said entirely, but for the presence of one family (*Didelphidæ*) of the latter group in America.

The *Eutheria* or *Monodelphia* are distributed throughout the remaining geographical regions, as described in the article DISTRIBUTION, and in many cases form valuable indications by which the natural boundaries of these divisions have been traced. Many anomalies, otherwise inexplicable in the present range of families and species, have been cleared up by the study of their distribution in former geological epochs, a subject in relation to which the present facts of distribution should always be studied. There are few lines of evidence so conclusive as this in favour of the existing species being modified lineal descendants of those which have lived in previous times upon the earth.[1]

HISTORY OF THE MAMMALIA IN PAST TIMES.

As already intimated, such knowledge as we yet possess of the history of mammals in past times is of very recent growth, and is still extremely incomplete. The very rapid advances which have been made in the last few years, especially in consequence of the explorations of rich fossiliferous beds in North America, have not only completely changed the present aspect of the science, but give such promise for the future that any sketch which we might now attempt of this branch of the subject could only be regarded as representing a transient phase of knowledge. It will be well, however, to gather together in this place the leading facts now ascertained with regard to the most ancient forms, as, owing to the uncertainty of their relationship with any of the existing orders, they will be most conveniently treated of separately, while the ascertained facts relating to the geological history of the forms more nearly allied to those now living will be more appropriately described under the account of the different groups into which the class may now be divided.

---

[1] On this subject, see A. Murray, *Geographical Distribution of Mammals*, 1866; and especially A. R. Wallace, *The Geographical Distribution of Animals*, 2 vols., 1876, and *Island Life*, 1881.

Mammals of the Mesozoic Period.[1]

The hitherto discovered remains of mammals which existed anterior to the Tertiary period all belong to creatures of very small size, the largest scarcely exceeding the common Polecat or Squirrel. Some are known only by a few isolated teeth, others by nearly complete sets of these organs, and the majority by more or less perfect specimens of the rami of the lower jaw. It is a very curious circumstance that this part of the skeleton alone has been preserved in such a large number of instances. No complete cranium has ever been found, nor is there satisfactory evidence of the structure of the vertebral column or of the limbs of any single individual. The species already described from European strata amount to nearly thirty, which have been arranged in fifteen genera. Of these by far the greater number have been found at a single spot near Swanage in Dorsetshire, in a bed of calcareous mud only 40 feet long, 10 feet wide, and averaging 5 inches in depth. The marvellous results obtained by the exploration by Mr S. H. Beckles of this small fragment of the earth's surface show by what accidents, as it were, our knowledge of the past history of life has been gained, and what may still remain in store where little thought of at present. A bed, apparently equally rich, has recently been discovered in the Territory of Wyoming, North America, the contents of which are being made known by Professor Marsh.

1. *Mammals of the Triassic Period.*—The Rhætic formations, so named from the Rhætian Alps of Bavaria, are the highest beds of the Trias, and are situated above the New Red Sandstone, and just below the Lias. In 1847 Professor Pleininger of Stuttgart, while assiduously sifting some sand from this formation, belonging to the Keuper of Diegerloch and Steinenbronn, discovered, among an immense mass of teeth, scales, and unrecognizable fragments of skeletons of fish and saurians, two minute teeth, each with well-defined, enamelled, tuberculated crowns and distinct roots, plainly showing their mammalian character. These, the oldest known evidence of the class, were considered by their discoverer to indicate a predaceous and carnivorous animal of very small size, to which he gave the name of *Microlestes antiquus.* Subsequently Mr C. Moore discovered in a bone bed of Rhætic age filling a fissure in the mountain limestone at Holwell, near Frome in Somersetshire, various isolated teeth with their crowns much worn, but apparently including both upper and lower molars and a canine, which are assigned by Professor Owen to Pleininger's genus *Microlestes,* and described specifically as *M. moorei.* Under the name of *Hypsiprymnopsis rhæticus* Prof. Boyd Dawkins[2] has described a single tooth with two roots which he discovered in a Rhætic marlstone at Watchet in Somersetshire, and which may be even somewhat older than the last. Professor Dawkins finds the nearest analogue of this tooth among recent mammals in the large trenchant premolar of the Rat-Kangaroo or *Hypsiprymnus* (see vol. xiii. p. 840, fig. 4), a resemblance not concurred in by Professor Owen, who refers it to the genus *Microlestes.* The minute size and worn condition of the tooth render it extremely difficult to form a decided opinion upon its characters, and therefore upon the affinities of the animal to which it belonged.

Still more satisfactory evidence of the presence of mammals at a period at least as ancient as the European Trias is afforded by the discovery of three nearly perfect mandibular rami in the Chatham coal-field of North Carolina by Dr Emmons, who, however, placed them as far back in age as the Permian, or altogether beyond the Mesozoic stage, a conclusion not now received. Of this animal, called *Dromatherium sylvestre,* the complete dentition of the lower jaw is known, and consists of three pointed incisors, separated by intervals, one canine, and ten molars, of which the first three have simple subcompressed crowns, and the remainder are multicuspid. The jaw figured by Dr Emmons[3] is $\frac{9}{10}$ of an inch in length. He considered it to belong to a placental Insectivore, but the number of molar teeth exceeds that of any existing member of that order, and is only found in some Marsupials. It was associated in the same bed with thecodont reptiles.

2. *Mammals of the Jurassic Period.*—In the ascending order of geological age the next remains of mammals have been met with in the Lower Oolite at Stonesfield in Oxfordshire, where they are associated with wing cases of insects, Plesiosaurs, Crocodiles, and Pterodactyles. From this bed several specimens have been met with at various times, which have been placed in three genera.

A. *Amphitherium,* Blainville, 1838. The specimen (*A. prevostii,* see fig. 15) upon which this genus was founded, was discovered in 1812, and examined in 1818 at Oxford by Cuvier, who pronounced it to be mammalian, and to resemble the jaw of an Opossum. This conclusion was afterwards disputed by De Blainville and others, who

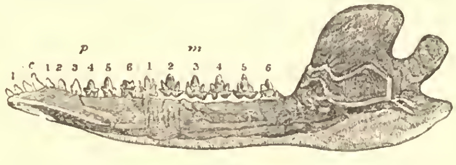

FIG. 15.—Lower Jaw and Teeth of *Amphitherium prevostii* (twice nat. size). From Owen.

believed it to be reptilian, but the original determination is now generally accepted.[4] Three rami of mandibles, all more or less perfect, are now known. The length of the jaw is rather less than an inch. It contains sixteen teeth, which, as defined by shape only, are—*i* 3, *c* 1, *p* 6, *m* 6, so that if the upper jaw had a corresponding number

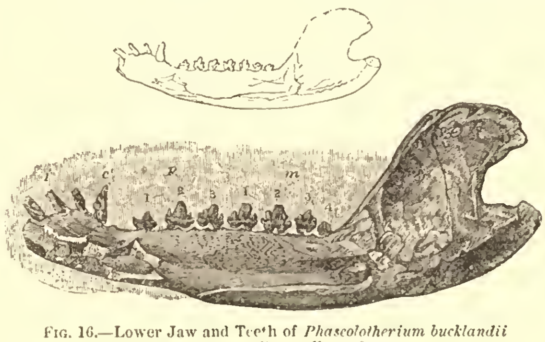

FIG. 16.—Lower Jaw and Teeth of *Phascolotherium bucklandii* (nat. size in outline). From Owen.

there would be sixty-four teeth in all,—a greater number than in any existing heterodont mammal, though equalled by some of the species from the Purbeck. The nearest approach to this number is in *Myrmecobius* among recent Marsupials. The incisors are rather long and slender, the canines apparently not much larger than the incisors, all the premolars and molars two-rooted—the former with a single large pointed cusp and small basal cusp on one or both sides, the latter quinquecuspidate. The lower margin

[1] The subjects referred to under this heading are mostly described and figured in detail in Owen's "Monograph of the Fossil Mammalia of the Mesozoic Formations," *Palæontographical Society's Publications,* 1871; and in various papers by Marsh, in the *American Journal of Science and Arts,* 1878–80.

[2] *Quart. Jour. Geol. Soc.,* vol. xx. p. 411, 1864.

[3] *American Geology,* part vi., p. 93, 1857.

[4] A full description of this interesting fossil, with a history of the discussion regarding its nature, is given in Owen's *British Fossil Mammals and Birds.*

of the angular process is slightly inflected, and the mylohyoid groove persistent, as in some of the existing Marsupials and in Whalebone Whales. This groove, a remnant of that which originally lodges Meckel's cartilage, mistaken for a suture, was once considered evidence of the reptilian nature of these jaws. A second species is described as *A. broderipii* (Owen).

B. *Phascolotherium*, Owen, 1839. This is founded on a right ramus of the lower jaw, presenting the inner side to view. Its length is 1·4 inch. The number of teeth resemble those of existing insectivorous mammals, being *i* 3 or 4, *c* 1, *p* and *m* 7, but not clearly defined from each other. One species, *P. bucklandii* (fig. 16).

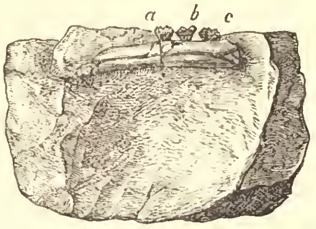

Fig. 17.—*Stereognathus.* Portion of Jaw, embedded in Oolitic matrix (nat. size). From Owen.

C. *Stereognathus*, Charlesworth, 1854. *S. ooliticus* (fig. 17) is founded on a fragment of a jaw of minute size with three molar teeth *in situ.* The grinding surface is of quadrate form, of very little height, and supports six subequal cusps. Its affinities are quite problematical.

The freshwater bed previously alluded to, situated at Durdlestone Bay near Swanage, belongs to the Middle Purbeck series, intervening between the Middle Oolite and the Wealden. The first discovery of mammalian bones was made in this spot by Mr W. R. Brodie in 1854, but the subsequent explorations of Mr S. H. Beckles have yielded a surprising number of species. They are associated with numerous saurians, insects, and freshwater shells, as *Paludina*, *Planorbis*, and *Cyclas.* No less than eleven genera from this locality alone are fully described in Professor Owen's memoir. These may be grouped as follows :—

A. With teeth arranged on the insectivorous type. Mandibular incisors more than two; canines well developed; premolars and molars cuspidate, seven or more :—(*a*) molars and premolars more than eight, mostly twelve (*Spalacotherium*, *Amblotherium*, *Peralestes*, *Achyrodon*, *Peraspalax*, *Peramus*, *Stylodon* and *Bolodon*—the last known only by the maxillary teeth);

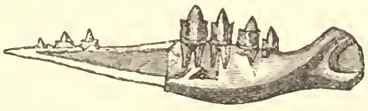

Fig. 18.—*Spalacotherium tricuspidens* (twice nat. size), Purbeck beds. From Owen.

(*b*) molars and premolars seven or eight (*Triconodon* and *Triacanthodon*). As any synopsis of the characters of these genera would be scarcely intelligible without minute descriptions and reference to figures, the reader who desires further information is referred to the memoir cited above.

Fig. 19.—Jaw of *Triconodon mordax* (nat. size). From Owen.

B. With a single, strong, pointed, slightly curved incisor, placed close to the median line as in Rodents. No canine. Three or four compressed, trenchant, obliquely grooved premolars, increasing in size from first to last, and two small molars with low multituberculated crowns. Genus *Plagiaulax*, Falconer. This remarkable and highly specialized type has been the occasion of one of the most interesting discussions on the inferences which may be drawn as to the affinities and habits of an otherwise unknown animal from the structure of a small portion of its organization which occurs in the annals of natural history, a discussion carried on with great ability, ingenuity, and wealth of illustration on both sides. Dr Falconer maintained that it was more nearly allied to the Rat-Kangaroo (*Hypsiprymnus*) than to any other existing form, and that, as it is known that these animals feed upon grass and roots, "it may be inferred of *Plagiaulax* that the species were herbivorous or frugivorous. I can see nothing in the character of their teeth," he adds, "to

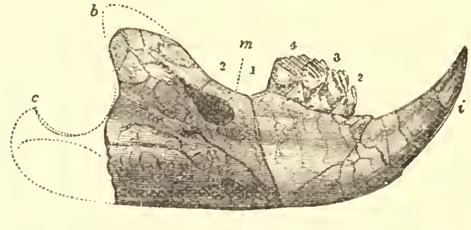

Fig. 20.—*Plagiaulax becclesii* (twice nat. size). From Owen.

indicate that they were either insectivorous or omnivorous." Professor Owen, on the other hand, from the same materials came to the conclusion that "the physiological deductions from the above-described characteristics of the lower jaw and teeth of *Plagiaulax* are that it was a carnivorous Marsupial. It probably found its prey in the contemporary small insectivorous mammals and Lizards, supposing no herbivorous form like *Stereognathus* to have co-existed during the Upper Oolite period."

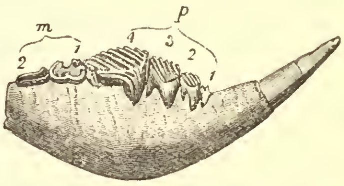

Fig. 21.—*Plagiaulax minor* (four times nat. size). From Lyell.

It is impossible here to give at any length the arguments by which these opposing views are respectively supported, but it may be indicated that the first-mentioned is strongly countenanced by the consideration of the following facts :—(1) all existing Marsupials may be divided, as far as their dentition is concerned, into two groups—(*a*) those which have a pair of large more or less procumbent incisors close to the symphysis of the lower jaw, and rudimentary or no canines (diprotodont dentition; families *Phascolomyidæ*, *Macropodidæ*, and *Phalangistidæ*), and (*b*) those which have numerous small incisors, and large pointed canines (polyprotodont dentition; families *Peramelidæ*, *Dasyuridæ*, and *Didelphidæ*); (2) the vast majority of the former group are purely vegetable feeders, and almost all of the latter are carnivorous or insectivorous; and (3) *Plagiaulax*, so far as its structure is known, belongs obviously to the former group, and, as we have no sure basis for inferences as to the habits of an unknown animal but the knowledge of the habits of such as are known, we have no grounds for supposing that its habits differed from those of its structural congeners.[1]

That the two types of dentition still found among Marsupials should have existed side by side in so remote a period of time as that in which the Purbeck bone bed was deposited, and that one of these types should have already attained so singular a degree of specialization, is one of the most remarkable facts yet revealed by mammalian palæontology. Whether the teeth of the upper jaw correspond also to the modern diprotodont type is a question of great interest, for the solution of which we must await future discoveries, of which we have more hope since the announcement by Professor Marsh of the existence, in considerable numbers, of small mammals in the American Jurassic formations of the Rocky Mountains, which conform in all

[1] The whole discussion is contained in the following memoirs :—(1) H. Falconer, "Description of Two Species of the Fossil Mammalian genus *Plagiaulax*, from Purbeck," *Quart. Jour. Geol. Soc.*, August 1857; (2) R. Owen, art. "Palæontology," *Encyclopædia Britannica*, 8th ed., 1859; (3) H. Falconer, "On the Disputed Affinity of the Mammalian genus *Plagiaulax*," *Quart. Jour. Geol. Soc.*, November 1860; (4) R. Owen, "Monograph of the Fossil Mammalia of the Mesozoic Formation," *Palæontographical Society*, 1871.

their general characters to those of the English Purbecks, some being even considered to be generically identical. Both polyprotodont and diprotodont types are represented, the latter by a species called by its discoverer *Ctenacodon serratus*, very closely allied to *Plagiaulax*.

It will be of very great interest to know the mode of succession of the teeth of those early mammals, as it may throw some light upon the question of the relation of the succession of teeth in mammals generally with the same process in the inferior classes of the *Vertebrata*. There is, however, as yet very little, if any, reliable evidence upon the subject, but such as there is rather points to the fact of an absence or very feeble development of the diphyodont condition, resembling that of modern Marsupials. If this is so, it may lead to the somewhat startling conclusion that in the transition from the lower vertebrate to the mammal, by whatever process it took place, the indefinite reproduction of the teeth of the former was lost, and that a monophyodont condition supervened, which was again superseded by the peculiar definite diphyodont mode of succession characteristic of the most highly organized mammals.

There is nothing yet known in the structure of these small mammals of the Mesozoic ages of the world to connect them with the surviving representatives (the Monotremes) of the hypothetical *Prototheria*; but whether their position was among the *Metatheria* or *Eutheria*, or whether they represented generalized forms from which both these branches have been derived, it is impossible at present to say. To avoid the difficulty of endeavouring to find places for them in any of the existing groups, Marsh proposes[1] to found two new orders for their reception—*Pantotheria* for those of the polyprotodont or insectivorous type of dentition, and *Allotheria* for *Plagiaulax* and its allies. The former may be convenient, but it is scarcely advisable to separate the latter ordinally, as long as we continue to place *Phascolomys* and *Thylacinus*, *Chiromys* and *Lemur*, *Trichecus* and *Phoca* in the same orders, for *Plagiaulax* and *Amphitherium* do not differ in the characters of their jaws and teeth more than any of these examples, which show how much the dentition may be modified with comparatively little general diversity of structure.

This scanty evidence of mammalian life must bear a very small proportion to that which doubtless existed during the greater part of the vast Mesozoic period. The Cretaceous formations have as yet yielded no trace of the presence of animals of this class; but the number and variety of species met with in the earliest Tertiary formations, when already differentiation into most of the existing leading divisions had taken place, strikingly proves the imperfect state of our geological record during the immediately antecedent ages of the world.

CHARACTERS OF THE DIFFERENT ORDERS AND FAMILIES AND OF THE PRINCIPAL FORMS OF THE MAMMALIA.

Subclass PROTOTHERIA or ORNITHODELPHIA.

The principal distinguishing characteristics of this group have been already given (p. 371). They apply not only to the subclass, but of course equally to the one order MONOTREMATA, in which the few known members of the group are commonly associated. In addition to the more important characters enumerated above, the following, which are common to all existing species, may be mentioned.

The dorso-thoracic vertebræ are nineteen in number, and have no terminal epiphyses to their bodies. The transverse processes of the cervical vertebræ are of autogenous formation, and remain suturally connected with the remainder of the vertebra until the animal is full-grown. Though in this respect they present an approximation to the *Sauropsida* (Reptiles and Birds), they differ from that group, inasmuch as there is not a gradual transition from these autogenous transverse processes of the neck (or cervical ribs, as they may be considered) into the thoracic ribs, for in the seventh vertebra the costal element is much smaller than in the other, indicative of a very marked separation of neck from thorax, not seen in the *Sauropsida*. The upper ends of the ribs are attached to the sides of the bodies of the dorsal vertebræ only, and not to the transverse processes. The sternal ribs are well ossified, and there are distinct partly ossified intermediate ribs. The cerebral cavity, unlike that of the lower Marsupials or the Reptiles, with which they have so many structural affinities, is large and hemispherical, flattened below and arched above, and about as broad as long. The cribriform plate of the ethmoid is nearly horizontal. The cranial walls are very thin, and smoothly rounded externally, and the sutures become completely obliterated in adult skulls, as in Birds. The broad occipital region slopes upwards and forwards, and the face is produced into a long and depressed rostrum. The bony palate is prolonged backwards, so that the posterior nares are nearly on a level with the glenoid fossa. The mandible is without distinct ascending ramus; the coronoid process and angle are rudimentary, and the two halves are loosely connected at the symphysis. The fibula has a broad, flattened process, projecting upwards from its upper extremity above the articulation, like an olecranon. In the male there is an additional, flat, curved ossicle on the hinder and tibial side of the plantar aspect of the tarsus, articulating chiefly to the tibia, which supports in the adult a sharp-pointed perforated horny spur, with which is connected the duct of a gland situated beneath the skin of the back of the thigh, the function of which is not yet clearly understood. (A rudimentary spur is found in the young female *Ornithorhynchus*, but this disappears when the animal becomes adult.) The stomach is subglobular, simple; the alimentary canal has no ileo-cæcal valve, or marked distinction between large and small intestine, but has a small, slender vermiform cæcum with glandular walls. The liver is divided into the usual number of lobes characteristic of the *Mammalia*, and is provided with a gall-bladder.

Although agreeing in so many important characters, the existing members of the group evidently represent two very diverging branches, perhaps as far removed as are the members of some of the accepted orders of the *Eutheria*. It would, however, be encumbering zoological science with new names to give them any other than the ordinarily known family designations of *Ornithorhynchidæ* and *Echidnidæ*.

Family ORNITHORHYNCHIDÆ.

One genus, *Ornithorhynchus*, Blumenbach, 1800.[2] Cerebral hemispheres smooth. Premaxillæ and mandible expanded anteriorly and supporting a horny beak something like that of a duck, bordered by a naked and very sensitive membranous expansion. The place of teeth supplied functionally by horny structures, elongated, narrow, and sharp-edged along the anterior part of the sides of the mouth, and broad, flat-topped or molariform behind. Legs short, fitted for swimming; feet webbed, each with five well-developed toes armed with large claws, and beyond which in the fore feet the interdigital membrane is extended. Vertebræ: C 7, D 17, L 2, S 2,

[1] "Notice of Jurassic Mammals representing two New Orders," *American Journal of Science*, xx., September 1880. Accounts of further discoveries of forms allied to *Plagiaulax*, some surviving even to the earliest Tertiary period, are given by Cope in the *American Naturalist* for November 1881 and May 1882.

[2] The name *Platypus*, bestowed by Shaw in 1799, was preoccupied by a genus of *Coleoptera*.

C 21. Acetabulum not perforated. Tongue not extensile. Mucous membrane of small intestine covered with delicate, close-set transverse folds or ridges. Tail rather short, broad, and depressed. Eyes very small. Fur close and soft. One species, *O. anatinus* (Shaw), *O. paradoxus* (Blum.), the duck-billed Platypus, or Water-Mole of the colonists, entirely aquatic in habits, diving with great facility, and burrowing in the banks of rivers. It feeds on water insects, small mollusca, and worms, and inhabits Australia and Tasmania. See ORNITHORHYNCHUS.

Family ECHIDNIDÆ.

Cerebral hemispheres larger and well convoluted. Facial portion of skull produced into a long, tapering, tubular rostrum, at the end of which the anterior nares are situated. Rami of mandible slender, styliform. Opening of mouth small, and placed below the extremity of the rostrum. No laterally placed horny teeth, though the palate and tongue are furnished with spines. Tongue very long, vermiform, slender, and protractile. Lining membrane of small intestine villous, but without transverse folds. Feet not webbed, but with long strong claws fitted for scratching and burrowing. The hinder feet with the ends of the toes turned outwards and backwards in the ordinary position of the animal when on the ground. Tail very short. Acetabulum with a large perforation, as in Birds. Calcaneal spur and gland of the male much smaller than in *Ornithorhynchus.* Fur intermixed with strong, sharp-pointed spines. Terrestrial and fossorial in habits, feeding exclusively on ants, and recalling in the structure of the mouth and various other parts relating to the peculiar mode of life the true Anteaters of the order *Edentata.*

Recent discoveries have shown that there are two distinct forms of this family, which may even be considered of generic value.

Echidna (Cuvier, 1797) or *Tachyglossus* (Illiger, 1811).[1]—Claws five on each foot. Rostrum moderately developed and straight. Vertebræ: C 7, D 16, L 3, S 3, C 12. Tongue tapering at the tip, the spines restricted to the basal portion. The best-known species is *E. aculeata* (Shaw), found in Australia and Tasmania. The specimens from the latter locality, with longer fur almost concealing the spines, have been separated specifically under the name of *E. setosa* (Cuv.). Another species, *E. lawesii* (Ramsay), has lately been discovered in southern New Guinea. See ECHIDNA.

Acanthoglossus (Gervais).—Ungual phalanges and claws present only on the three middle digits of both fore and hind feet. Rostrum much elongated and curved downwards at the end. Vertebræ: C 7, D 17, L 4, S 3, C 12. Tongue somewhat spoon-shaped near the tip, and armed on its dorsal surface with three rows of recurved spines. One species: *A. bruijnii* (Peters and Doria) (fig. 22), from

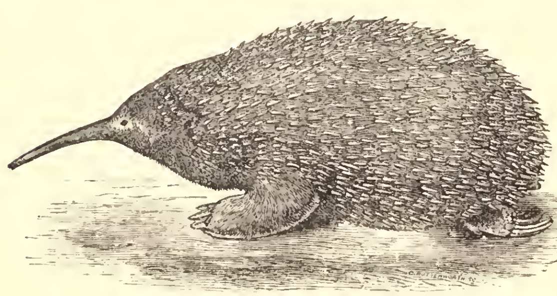

FIG. 22.—*Acanthoglossus bruijnii.* From Gervais.

the mountainous regions of the northern part of New Guinea; considerably larger than *E. aculeata.* The external characters and osteology of this animal, one of the most interesting of recent zoological discoveries, have been fully described and figured by Gervais (*Ostéographie des Monotrèmes*, Paris, 1878).

Among bones of extinct Marsupials of Pleistocene age from the Darling Downs, Mr Krefft found a portion of a humerus of an Echidna, considerably larger than the existing Australian species, which he has named *E. oweni.*[2] Notwithstanding the strong presumption of antiquity of the Monotrematous type, derived from its inferiority of structure, no fossil remains of earlier date, referable to it, or connecting it with the lower vertebrates on the one hand and the higher mammals on the other, have yet been discovered.

[1] The latter name is often used now, under the impression that *Echidna* is preoccupied by Forster (1778) for a genus of *Pisces*; but, as that was not characterized in a recognizable manner, the author even omitting to name the species for which it was intended, it is now generally considered a synonym for *Muræna* (see Günther's *Catalogue of Fishes*), and is scarcely sufficient to bar a name so universally acknowledged and so deeply rooted in mammalian literature. Merrem's genus *Echidna* (*Reptilia*) is of later date, viz., 1820.

[2] *Annals and Mag. Nat. Hist.*, 1868, vol. i. (ser. iv.) p. 113.

SUBCLASS METATHERIA OR DIDELPHIA.

Although the great diversity in external form, in many anatomical characters, and in mode of life of various animals of this section might lead to their division into groups equivalent to the orders of the *Eutheria*, it is more convenient on the whole to adhere to the usual custom of treating them all as forming one order called MARSUPIALIA, the limits of which are therefore equivalent to that of the subclass. The more essentially distinctive characters have been already pointed out (p. 371). These may be more fully stated as follows.

The brain is generally small in proportion to the size of the animal, and the surface folding of the cerebral hemispheres, though well marked in the larger species, is never very complex in character, and is absent in the smaller and medium-sized species. The arrangement of the folding of the inner wall of the cerebrum differs essentially from that of all known *Eutheria*, the hippocampal fissure being continued forward above the corpus callosum, which is of very small size. The anterior commissure is, on the other hand, greatly developed.[3]

There are always true teeth, implanted in the usual manner in both jaws, and divisible, according to their position and form, into incisors, canines, premolars, and molars; but they vary much in number and character in the different families. Except in the genus *Phascolomys*, the number of incisors in the upper and lower jaws is never equal. The true molars are very generally four in number on each side of each jaw. The chief peculiarity in the dentition lies, however, in the mode of succession. There is no vertical displacement and succession of the teeth, except in the case of a single tooth on each side of each jaw, which is always the hindermost of the premolar series, and is preceded by a tooth having more or less of the characters of a true molar (see fig. 23), and is the only tooth comparable to those

FIG. 23.—Teeth of Upper Jaw of Opossum (*Didelphys virginiana*), all of which are unchanged, except the third premolar, the place of which is occupied in the young animal by a molariform tooth, represented in the figure below the line of the other teeth.

called "milk teeth" in the diphyodont *Eutheria.* In some cases (as in *Hypsiprymnus*) this tooth retains its place and function until the animal has nearly, if not quite, attained its full stature, and is not shed and replaced by its successor until after all the other teeth of the permanent series, including the posterior molars, are fully in place and use. In others, as the Thylacine, it is most rudimentary in form and size, being shed or absorbed before any of the other teeth have cut the gum, and therefore quite functionless. It must further be noted that there are some Marsupials, as the Wombat, Koala, Myrmecobius, and the Dasyures, in which no such milk tooth, even in a rudimentary state, has yet been discovered, possibly in some cases from want of materials for observation at the right stage of development.

Epipubic or marsupial bones are present in both sexes of nearly all species. In one genus alone, *Thylacinus*, they are not ossified. The number of dorso-lumbar vertebræ is always nineteen, although there are some apparent exceptions caused by the last lumbar being

[3] W. H. Flower, "On the Commissures of the Cerebral Hemispheres of the *Marsupialia*," &c., *Phil. Trans.*, 1865, p. 633.

modified into a sacral vertebra. The number of pairs of ribs is nearly always thirteen. The tympanic bone remains permanently distinct. The carotid canal perforates the basi-sphenoid. The lacrymal foramen is situated upon or external to the anterior margin of the orbit, and there are generally large vacuities in the bony palate. The angle of the mandible is (except in *Tarsipes*) more or less inflected. The hyoid bones have always a peculiar form, consisting of a small, more or less lozenge-shaped basi-hyal, broad cerato-hyals, with the remainder of the anterior arch usually unossified, and stout, somewhat compressed thyro-hyals. There are two anterior venæ cavæ,[1] into each of which a "vena azygos" enters. In the male the testes are always contained in a scrotum which is suspended by a narrow pedicle to the abdomen in front of the penis. The vasa deferentia open into a complete and continuous urethra, which is also the passage by which the urine escapes from the bladder, and is perfectly distinct from the passage for the fæces, although the anus and the termination of the urethro-sexual canal are embraced by the same sphincter muscle. The glans is often bifurcated anteriorly. In the female the oviducts never unite to form a common cavity or uterus, but open separately into the vagina, which at least for part of its course is double. During the very short period in which the embryo is contained in the uterus, its nourishment seems to be derived from the umbilical vesicle, the allantoic vessels not reaching the surface of the chorion to form a true placenta. The mammæ vary much in number, but are always abdominal in position, have long teats, and in most of the species are more or less enclosed in a fold of the integument forming a pouch or marsupium, though in some this is entirely wanting, and the newly-born, blind, naked, and helpless young, attached by their mouths to the teat, are merely concealed and protected by the hairy covering of the mother's abdomen. In this stage of their existence they are fed by milk injected into their stomach by the contraction of the muscles covering the mammary gland, the respiratory organs being modified temporarily, much as they are permanently in the *Cetacea*,—the elongated upper part of the larynx projecting into the posterior nares, and so maintaining a free communication between the lungs and the external surface independently of the mouth and gullet, thus averting the danger of suffocation while the milk is passing down the latter passage.

The existing species of Marsupials are, with the exception of one family (the *Didelphidæ*), limited in geographical distribution to the Australian region, forming the chief mammalian fauna of Australia, New Guinea, and some of the adjacent islands. The *Didelphidæ* are almost purely neotropical, one or two species ranging northwards into the Nearctic region. Fossil remains of members of this family have also been found in Europe in strata of the Eocene and early Miocene period.

In dividing the Marsupials into minor groups, it may be observed that one of the most obvious distinctive characters among them is derived from the form and arrangement of the teeth. In certain species, as the Opossums, Dasyures, and Thylacines, the incisors are numerous, small, and subequal in size and the canines large, as in the typical placental Carnivores (fig. 24; compare with that of Lion, vol. xiv. p. 680). To these the term "polyprotodont" is applied, and they are all more or less carnivorous in their habits. In others the central incisors are very prominent, and the lateral incisors and canines absent or subordinate in function (fig. 25). These are called "diprotodont," and they are all wholly or in great part vegetable feeders.

[1] Except in *Belideus breviceps* (Forbes, *Proc. Zool. Soc.*, 1881, p. 188).

In one group of these, the Wombats, there are but two incisors above and the same number below; but all the others, including the Kangaroos, Koalas, and Phalangers,

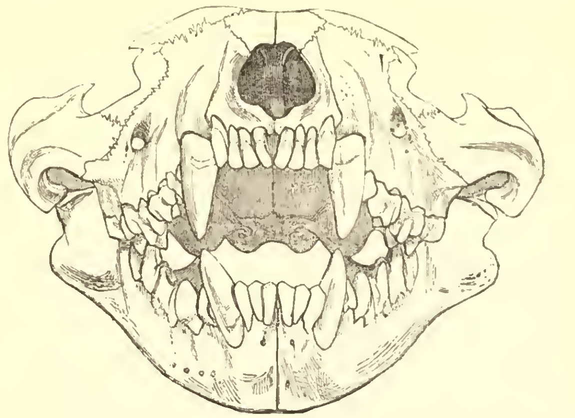

Fig. 24.—Front View of Skull of *Dasyurus ursinus*, showing polyprotodont and carnivorous dentition (*Proc. Geol. Soc.*, 1868, p. 313).

have two incisors below and as many as six above, three on each side, but of these the first or central pair is the most fully developed.

Though this division is extremely convenient, a difficulty in accepting it as marking a radical separation of the order into two primary stocks is caused by the *Peramelidæ*, which combine a polyprotodont form of dentition with a peculiar structure of the hind feet, so exactly resembling that of some of the best-marked diprotodonts, as the Kangaroos, that it is difficult to believe that it can have been developed independently. Taking various combinations of characters into consideration, the existing Marsupials readily group themselves into six very natural families, the characters of which can be thus defined :—

Fig. 25.—Front View of Skull of Koala (*Phascolarctos cinereus*), showing diprotodont and herbivorous dentition (*Proc. Geol. Soc.*, 1868, p. 313).

A. Teeth rooted.

a. Polyprotodont. — Incisors numerous, small, subequal. Canines larger than the incisors. Molars with sharp tubercles.

α. Incisors $\frac{5}{4}$. Hind feet with the four outer toes subequal, distinct, and a well-developed opposable hallux. 1. *Didelphidæ.*

β. Incisors $\frac{4}{3}$. Hind feet with four outer toes distinct, subequal. Hallux small or rudimentary; rarely opposable. 2. *Dasyuridæ.*

γ. Incisors $\frac{4}{3}$. Hind feet long, narrow. Fourth toe larger than all the others. Hallux rudimentary or absent. Second and third toes very slender and united in a common integument (syndactylous). 3. *Peramelidæ.*

b. Diprotodont.—Incisors $\frac{3}{1}$. Central upper and lower incisors large and cutting. Canines absent or small. Molars with bluntly tuberculated or transversely ridged crowns. Hind feet syndactylous.

α. Hind limbs disproportionately large, with feet as in *Peramelidæ.* 4. *Macropodidæ.*

β. Hind limbs not disproportionately large. Feet broad, with four subequal outer toes, and a large opposable hallux. 5. *Phalangistidæ.*

B. All the teeth with persistent pulps. Incisors $\frac{2}{2}$, large, scalpriform, with enamel on the outer surface only. No canines. Hind feet with four subequal outer toes; partially syndactylous and with rudimentary hallux. 6. *Phascolomyidæ.*

Family DIDELPHIDÆ.

Dentition: $i\,\frac{5}{4}$, $c\,\frac{1}{1}$, $p\,\frac{3}{3}$, $m\,\frac{4}{4}$; total 50. Incisors very small and pointed. Canines large. Premolars with compressed pointed crowns. Molars with numerous sharp cusps. The third premolar preceded by a deciduous multicuspidate molar, which remains in place until the animal is nearly adult. Limbs of moderate development, each with five complete and distinct toes, all of which are provided with short, compressed, curved, sharp claws of nearly equal size, except the first toe of the hind foot or hallux, which is large, widely separable from the others, to which it is opposed in climbing, and terminates in a dilated rounded extremity, without a nail. Tail generally long, partially naked and prehensile. Stomach simple. Cæcum of small or moderate size. Pouch in some complete, in others represented by two lateral folds of the abdominal integument, partially covering the teats, while in some all trace of it is absent. Vertebræ: C 7, D 13, L 6, S 2, C 19–35.

The *Didelphidæ*, or true Opossums, differ from all other Marsupials in their habitat, being peculiar to the American continent. They are mostly carnivorous or insectivorous in their diet, and arboreal in habits. One slightly aberrant form, with webbed hind feet, and aquatic mode of life, constitutes the genus *Chironectes.* The other numerous species are commonly included in the genus *Didelphys.* See OPOSSUM.

Family DASYURIDÆ.

Dentition: $i\,\frac{4}{3}$, $c\,\frac{1}{1}$, p and m numerous, variable. Incisors small; canines well developed; molars with pointed cusps. Limbs equal. Fore feet with five subequal toes with claws. Hind feet with the four outer toes well-developed, and distinct from each other and bearing claws; the first (or hallux) clawless, generally rudimentary, sometimes entirely wanting. Stomach simple. No cæcum. Predatory, carnivorous or insectivorous animals, inhabitants of Australia, Tasmania, and the southern parts of New Guinea and some of the adjacent islands. The aberrant genus *Myrmecobius,* though clearly a member of this family, is so sharply distinguished from all the others as to render a division into two subfamilies necessary.

Subfamily **Dasyurinæ**.—This comprises the more typical *Dasyuridæ,* in which the premolars and molars never exceed the normal number of seven on each side of each jaw, and in which the tongue is not specially extensile.

Thylacinus.—Dentition: $i\,\frac{4}{3}$, $c\,\frac{1}{1}$, $p\,\frac{3}{3}$, $m\,\frac{4}{4}=46$. Incisors small, vertical, the outer one in the upper jaw larger than the others. Summit of the lower incisors, before they are worn, with a deep transverse groove, dividing it into an anterior and a posterior cusp. Canines long, strong, and conical. Premolars with compressed crowns, increasing in size from before backwards. True molars in general characters resembling those of *Dasyurus,* but of more simple form, the cusps being not so distinct nor sharply pointed. Milk molar very small, and shed before the animal leaves the mother's pouch. General form very Dog-like. Head elongated. Muzzle pointed. Ears moderate, erect, triangular. Fur short and closely applied to the skin. Tail of moderate length, thick at the base and tapering towards the apex, clothed with short hair. Hallux (including the metacarpal bone) wanting. Vertebræ: C 7, D 13, L 6, S 2, C 23. Marsupial bones represented only by small unossified fibro-cartilages.

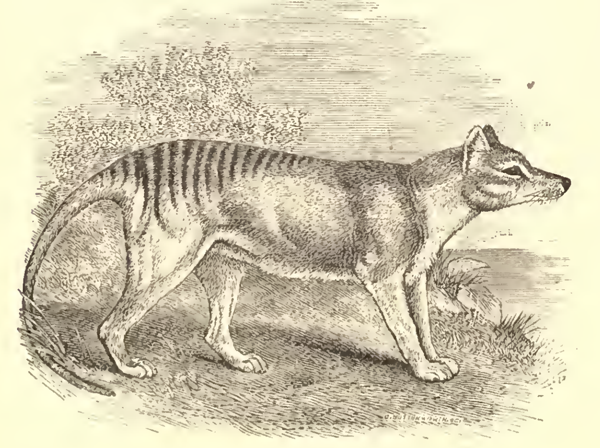

FIG. 26.—Thylacine (*Thylacinus cynocephalus*).

The only known species of this genus, *T. cynocephalus,* though smaller than a common Wolf, is the largest predaceous Marsupial at present existing. It is now entirely confined to the island of Tasmania, although fragments of bones and teeth found in caves afford evidence that a closely allied species once inhabited the Australian mainland. The general colour of the Thylacine is grey-brown, but it has a series of transverse black bands on the hinder part of the back and loins, whence the name of "Tiger" frequently applied to it by the colonists. It is also called "Wolf," and sometimes, though less appropriately, "Hyæna." Owing to the havoc it commits among the sheepfolds, it has been nearly exterminated in all the more settled parts of Tasmania, but still finds shelter in the almost impenetrable rocky glens of the more mountainous regions of the island. The female produces four young at a time.

Dasyurus.—Dentition: $i\,\frac{4}{3}$, $c\,\frac{1}{1}$, $p\,\frac{2}{2}$, $m\,\frac{4}{4}$; total 42. Upper incisors nearly equal, and placed vertically. In the smaller species the first is slightly longer, narrower, and separated from the rest. Lower incisors nearly vertical in the larger, but sloping forwards and upwards in the smaller species. Canines large and sharply pointed. Premolars, in the typical forms, with compressed and sharp-pointed crowns, and slightly developed anterior and posterior accessory basal cusps. True molars with numerous sharp-pointed cusps. In the upper jaw the first three with crowns having a triangular free surface, the fourth small, simple, narrow, and placed transversely. In the lower jaw the molars more compressed, with longer cusps; the fourth not notably smaller than the others. Ears of moderate size, prominent, and obtusely pointed. Hallux rudimentary, clawless, or absent; its metatarsal bone always present. Tail generally long and well clothed with hair. Vertebræ: C 7, D 13, L 6, S 2, C 18–20. The true Dasyures are mostly inhabitants of the Australian continent and Tasmania, where in the economy of nature they take the place of the smaller predaceous *Carnivora,* the Cats, Civets, and Weasels of other parts of the world. They hide themselves in the daytime in holes among rocks or in hollow trees, but prowl about at night in search of the small living mammals and birds which constitute their prey. The species are not numerous, and divide themselves into two sections. (1) *Dasyurus* proper includes *D. maculatus,* about the size of a common Cat, inhabiting Tasmania and the southern part of Australia; *D. viverrinus* or *maugei,* Tasmania and Victoria; *D. geoffroyi,* South Australia; *D. hallucatus,* North Australia; *D. albopunctatus,* New Guinea. (2) *Sarcophilus* contains one species, *D. ursinus,* differing from the others in being a larger and heavier animal, with a disproportionally large and broad head. Its teeth are relatively larger and more massive, and hence more crowded in the jaws; the premolars especially are scarcely compressed but rather conical; the lower molars want a cusp placed near the middle of the inner border, found developed in different degrees in all the species of the first section. This animal is peculiar to Tasmania, where it is commonly known by the name of "Devil." Its prevailing colour is black, its size about that of an English Badger, and its disposition remarkably savage and voracious.

Phascogale.—This genus (more properly *Phascologale*) comprises a considerable number of small Marsupials, none of them exceeding a common Rat in size, differing from the true Dasyures in possessing an additional premolar,—the dentition being $i\,\frac{4}{3}$, $c\,\frac{1}{1}$, $p\,\frac{3}{3}$, $m\,\frac{4}{4}$; total 46,—and having the teeth generally developed upon an insectivorous rather than a carnivorous pattern, the upper middle incisors being larger and inclined forwards, the canines relatively smaller, and the molars with broad crowns, armed with prickly tubercles. The muzzle is pointed. Ears moderately rounded and nearly naked. Fore feet with five subequal toes, with compressed, slightly curved pointed claws. Hind feet with the four outer toes subequal, with claws similar to those in the fore feet; the hallux almost always distinct and partially opposable, though small and nailless, sometimes absent. The food of these animals is almost entirely insects, which some pursue among the branches of trees, while others are purely terrestrial. They are found throughout Australia, and also in New Guinea and the Aru and some of the adjacent islands. Variations in the details of the dentition and of the structure of the hind limbs, and in the length and arrangement of the hairy covering of the tail, have given rise to several subdivisions which will probably be accepted as generic by most zoologists, although further investigations are required before their limits can be very satisfactorily defined.

P. cristicauda, a species with a thick compressed tail ornamented upon its apical half with a crest of black hair, differs from the others by the very reduced size of the third premolar in the upper and its complete absence in the lower jaw, thus forming an interesting transition in dentition towards *Dasyurus.* It constitutes the genus *Chætocercus* of Krefft. Another very aberrant form, *P. lanigera,* distinguished by the great elongation of the fore arm and hind foot, and the complete absence of hallux, is *Antechinomys* of the same author. It is an elegant little terrestrial mouse-like animal, with large oval ears and long tail with the terminal part bushy. *Antichinus* and *Podabrus* are names proposed for other divisions of the group.

Subfamily **Myrmecobiinæ**.—Molars and premolars exceeding the normal number of seven on each side. Tongue long and extensile.

Myrmecobius.—Dentition : $i\,\frac{4}{3}$, $c\,\frac{1}{1}$, $p\,\frac{3}{3}$, $m\,\frac{5}{5}$ or $\frac{6}{6}$; total 52 or 54, being the largest number of teeth in any existing Marsupial. The distinction between the molars and premolars is not certain, as it is not founded on a knowledge of the succession of the teeth, but on their form. The teeth are all small and (except the four posterior inferior molars) separated from each other by an interval. Head elongated, but broad behind. Muzzle long and pointed. Ears of moderate size, ovate, and rather pointed. Fore feet with five toes, all having strong, pointed, compressed claws, the second, third, and fourth nearly equal, the fifth somewhat and the first considerably shorter. Hind feet with no trace of hallux externally, but the metatarsal bone is present. Tail long, clothed with long hairs. Fur rather harsh and bristly. Female without any trace of a pouch, the young when attached to the nipples being concealed only by the long hair of the abdomen. Vertebræ : C 7, D 13, L 6, S 3, C 23.

Fig. 27.—*Myrmecobius fasciatus*. From Gould.

Of this singular genus but one species is known, *M. fasciatus*, found in western and southern Australia. It is about the size of an English squirrel, to which animal its long bushy tail gives it some resemblance; but it lives entirely on the ground, especially in sterile, sandy districts, feeding on ants. Its prevailing colour is chestnut-red, but the hinder part of the back is elegantly marked with broad, white, transverse bands on a dark ground.

Family PERAMELIDÆ.

Dentition : $i\,\frac{5}{3}$, $c\,\frac{1}{1}$, $p\,\frac{3}{3}$, $m\,\frac{4}{4}$; total 48. Upper incisors small, with short, broad crowns. Lower incisors moderate, narrow, proclivous. Canines well developed. Premolars compressed, pointed. Molars with quadrate tuberculated crowns. Third premolar preceded by a very minute molariform tooth, which remains in place until the animal is nearly full grown. Fore feet with two or three of the middle toes of nearly equal size, and provided with strong, sharp, slightly curved claws; the other toes rudimentary. Hind feet long and narrow; the hallux rudimentary or absent; the second and third toes very slender, and united in a common integument; the fourth very large, with a stout elongated conical claw; the fifth smaller than the fourth (see fig. 29). The ungual phalanges of the large toes of both feet cleft at their extremities (as in *Manis* among the *Edentata*, but in no other Marsupials). Head elongated. Muzzle long, narrow, and pointed. Stomach simple. Cæcum of moderate size. Pouch complete, generally opening backwards. Alone among Marsupials they have no clavicles.

The *Peramelidæ* form a very distinct family, in some respects intermediate between the sarcophagous *Dasyuridæ* and the phytophagous *Macropodidæ*. In dentition they resemble the former, but they agree with the latter in the peculiar structure of the hind feet. In the construction of the fore feet they differ from all other Marsupials. They may be divided into three genera.

Perameles.—Anterior and posterior extremities not differing greatly in development. Fore feet with three middle toes well developed, the third slightly larger than the second, the fourth somewhat shorter, provided with long, strong, slightly curved, pointed claws. First and fifth toes very short and without claws. Hind feet with hallux of one or two phalanges, forming a distinct tubercle visible externally ; the second and third toes very slender,

Fig. 28.—*Perameles gunnii*. From Gould.

of equal length, joined as far as the ungual phalanx, but with distinct claws ; the fifth intermediate in length between these and the largely developed fourth toe. Ears of moderate or small size, ovate, pointed. Tail rather short, clothed with short adpressed hairs. Fur short and harsh. Pouch opening backwards. Vertebræ: C 7, D 13, L 6, S 1, C 17.

The animals of this genus, commonly called "Bandicoots" in Australia, are all small, and live entirely on the ground, making nests composed of dried leaves, grass, and sticks in hollow places. They are rather mixed feeders; but insects, worms, roots, and bulbs constitute their ordinary diet. The various species are widely distributed over Australia, Tasmania, New Guinea, and several of the adjacent islands, as Aru, Kei, and New Ireland. The best known are—*P. fasciata*, *gunnii* (fig. 28), *myosurus*, *nasuta*, *obesula*, and *macrura* from Australia, and *P. dorcyana*, *saffrayana* and *longicauda* from New Guinea.

Macrotis.—Molar teeth curved, and with longer crowns and shorter roots than in the last. Hinder extremities proportionally longer, and hallux represented only by a small metatarsal bone. Muzzle much elongated and narrow. Fur soft and silky. Ears very large, long, and pointed. Tail long, its apical half clothed on the dorsal surface with long hairs. Pouch opening forwards. Vertebræ: C 7, D 13, L 6, S 2, C 23.

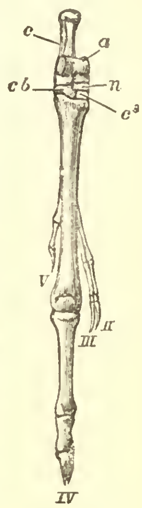

Fig. 29.—Skeleton of Hind Foot of *Chœropus castanotis*. *c*, os calcis; *a*, astragalus ; *cb*, cuboid ; *n*, navicular; *c*³, ectocuneiform; II, and III, the conjoined second and third digits; IV, the large and only functional digit; V, the rudimentary fifth digit. Compare this foot with that of the Kangaroo, vol. xiii. p. 839.

But one species is known, *M. lagotis*, from western Australia. It is the largest member of the family, being about the size of the common Rabbit, to which animal it bears sufficient superficial resemblance to have acquired the name of "Native Rabbit" from the colonists. It burrows in the ground, but in other respects resembles the Bandicoots in its habits.

Chœropus.—Dentition generally resembling that of *Perameles*, but the canines are less developed, and in the upper jaw two-rooted. Limbs very slender; posterior nearly twice the length of the anterior. Fore feet with the functional toes reduced to two, the second and third, of equal length, with closely united metacarpals and short, sharp, slightly curved, compressed claws. First toe represented by a minute rudiment of a metacarpal bone ; the fourth by a metacarpal and two small phalanges without a claw, and not reaching the middle of the metacarpal of the third ; fifth entirely absent. Hind foot long and narrow, mainly composed of the strongly developed fourth toe, terminating in a conical pointed nail, with a strong pad behind it ; the hallux represented by a rudimentary metatarsal ; the remaining toes completely developed, and with claws, but exceedingly slender; the united second and third reaching a little way beyond the metatarso-phalangeal articulation of the fourth; the fifth somewhat shorter. Tail not quite so long as the body, and covered with short hairs. Ears large and pointed, and folded down when the animal is at rest. Fur soft and loose. Pouch opening backwards. Vertebræ: C 7, D 13, L 6, S 1, C 20.

The only known species of this genus, chiefly remarkable for the singular construction of its limbs, is an animal about the size of a small Rat, found in the interior of the Australian continent. Its general habits and food appear to resemble those of the other

Fig. 30.—*Chœropus castanotis.* From Gould.

Peramelidæ. It was first described as *C. ecaudatus* by Ogilby from a mutilated specimen, but the specific name was afterwards changed by Gray to *castanotis.*

Family Macropodidæ.

The general characters of this family, and an account of the animals composing it, will be found in the article Kangaroo, vol. xiii. p. 838 *sq.*

Family Phalangistidæ.

Dentition (except in the aberrant genus *Tarsipes*): $i\,\frac{3}{1}$, the first above strong, curved, and cutting, the other two generally somewhat smaller; the single lower incisor large, more or less proclivous; $c\,\frac{1}{1 \text{ or } 0}$, upper small or moderate, conical and harp-pointed; lower absent or quite rudimentary; $p\frac{2-3}{1-3}$, variable; $m\,\frac{4}{4}$ or $\frac{3}{3}$, with four obtuse tubercles. Limbs subequal. Fore feet with five distinct, subequal toes with claws. Hind feet, short and broad, with five well-developed toes; the hallux large, nailless and opposable; the second and third slender and united by a common integument as far as the claws. Stomach simple. Cæcum present (except in *Tarsipes*), and usually large. Pouch complete. Animals of small or moderate size and arboreal habits, feeding on vegetable or mixed diet, inhabiting Australia and the Papuan Islands. Excluding *Phascolarctos* and especially *Tarsipes*, they form a very natural family. The latter is, however, evidently a modified form of the same general type, chiefly aberrant in the characters of its alimentary organs, which are adapted for a peculiar mode of subsistence. It may constitute a distinct subfamily.

Subfamily **Tarsipedinæ.**—Teeth almost rudimentary and variable in number. Tongue long, slender, pointed, and very extensile. Cæcum absent.

Tarsipes.—This is named from some supposed resemblance of its foot to that of the Lemurine genus *Tarsius*; but it must be remarked that it has none of the peculiar elongation of the calcaneum and scaphoid so characteristic of that genus. Head with elongated and slender muzzle. Mouth opening small. The two lower incisors are long, very slender, sharp-pointed, and horizontally placed. All the other teeth are simple, conical, minute, and placed at considerable and irregular intervals apart in the jaws, the number appearing to vary in different individuals and even on different sides of the two individuals. The formula in a specimen in the Museum of the Royal College of Surgeons is $i\,\frac{2-2}{1-1}$, $c\,\frac{1-1}{0-0}$, p and $m\frac{3-4}{2-3}$; total 20. Rami of the mandible extremely slender, nearly straight, and without coronoid process or inflected angle. Fore feet with five well-developed toes, with small, flat, scale-like nails, not reaching to the extremity of the digits. Hind feet rather long and slender compared with that of the *Phalangistinæ*, with well-developed opposable and nailless hallux; second and third digits syndactylous, with sharp compressed curved claws; the fourth and fifth free, and with small flat nails. Ears of moderate size and rounded. Tail longer than the body and head, scantily clothed with short hairs, prehensile. Vertebræ: C 7, D 13, L 5, S 3, C 24.

Of this singular genus but one species, *T. rostratus* (fig. 31), is known, about the size of a common Mouse. It inhabits western Australia, lives in trees and bushes, uses its tail in climbing, and feeds on honey, which it procures by inserting its long tongue into the blossoms of *Melaleucæ*, &c. One kept in confinement by Mr Gould was also observed to eat flies.

Fig. 31.—*Tarsipes rostratus.* From Gould.

Subfamily **Phalangistinæ.**

Teeth normal. Rudimentary lower canines present. Tongue of ordinary structure. No cheek pouches. Stomach and ascending colon simple. Cæcum long, simple. Tail well-developed.

A numerous group, varying in size from that of a Mouse to a large Cat, arboreal in their habits, and abundantly distributed throughout the Australian region. One section is distinguished by the possession of a flying membrane, or fold of skin, extending on each side of the body between the fore and hind legs, forming when the limbs are extended a kind of parachute, as in the Flying Squirrels, and also by a non-prehensile tail. This includes the genera *Petaurus*, *Belideus*, and *Acrobata*. The remainder have no such membrane, and have the tail more or less prehensile, the under surface at least of the apical portion being bare. These are the typical Phalangers, or "Opossums" as they are commonly called in Australia (genus *Phalangista*), and their various modifications, as *Cuscus*, *Pseudochirus*, and *Dactylopsila*. These will be more fully described in the article Phalanger.

Subfamily **Phascolarctinæ.**—Teeth normal; no rudimentary lower canines. Tongue of ordinary structure. Distinct cheek pouches. Stomach with a special gland near the cardiac orifice. Cæcum very long, and (with the upper portion of the colon) dilated and provided with numerous longitudinal folds of mucous membrane. In many anatomical characters, especially the possession of a special gastric gland, this group resembles the *Phascolomyidæ*, to which it obviously forms a transition.[1]

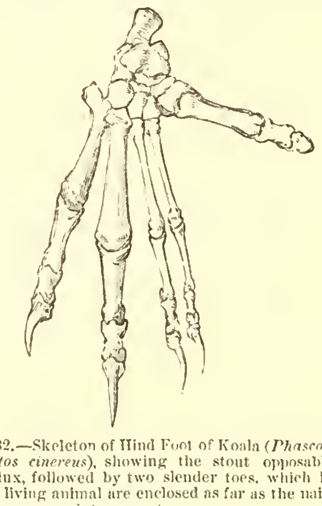

Fig. 32.—Skeleton of Hind Foot of Koala (*Phascolarctos cinereus*), showing the stout opposable hallux, followed by two slender toes, which in the living animal are enclosed as far as the nails in a common integument.

Phascolarctos.—Dentition: $i\,\frac{3}{1}$, $c\,\frac{1}{0}$, $p\,\frac{1}{1}$, $m\,\frac{4}{4}$; total 30. Upper incisors crowded together, cylindroidal, the first much larger than the others, with a bevelled cutting edge (fig. 25). Canine very small; a considerable interval between it and the premolar, which is as long from before backwards but not so broad as the true molars, and has a cutting edge, with a smaller parallel inner ridge. The molars slightly diminishing in size from the first to the fourth, with square crowns, each bearing four pyramidal cusps. The lower incisors are semiproclivous, com-

[1] *Cf.* W A Forbes, "Anatomy of the Koala," *Proc. Zool. Soc.*, 1881, p. 180.

pressed and tapering, bevelled at the ends. Premolars and molars in continuous series, as in the upper jaw. Fore feet with the two inner toes slightly separated from and opposable to the remaining three, all with strong, curved, and much compressed claws. Hind foot with the hallux placed very far back, large and broad, the second and third (united) toes considerably smaller than the other two; the fourth the largest. No external tail. Fur dense and woolly. Ears of moderate size, thickly clothed with long hairs. Vertebræ: C 7, D 11, L 8, S 2, C 8. Ribs eleven pairs, a rare exception to the usual number (13) in the *Marsupialia*.

There is but one species, the Koala or Native Bear of the Australian colonists (*P. cinereus*), found in the south-eastern parts of the Australian continent. It is about 2 feet in length, and of an ash-grey colour, an excellent climber, and residing generally in lofty *Eucalyptus* trees, on the buds and tender shoots of which it feeds, though occasionally descending to the ground in the night.

Kindred Fossil Forms.

Here may be noticed several genera of extinct Marsupials, the remains of which have been found in the post-Tertiary deposits of Australia, which agree with the *Macropodidæ* and the *Phalangistidæ* in having $\frac{3}{1}$ incisors, those of the lower jaw very large and proclivous. As the whole of their structure, especially that of the hind feet, is not yet known, their precise affinities cannot be determined.

Diprotodon.—Dentition: $i\,\frac{3}{1}$, $c\,\frac{0}{0}$, $p\,\frac{1}{1}$, $m\,\frac{4}{4}$; total 28. The first upper incisor very large and scalpriform. True molars with prominent transverse ridges, as in *Macropus*, but wanting the longitudinal connecting ridge. Anterior and posterior limbs less disproportionate than in tho Kangaroos. *D. australis* is a gigantic animal compared with all existing Marsupials, surpassing a Rhinoceros in bulk.

Nototherium.—Dental formula as in the last, from which it differs chiefly in the incisor teeth, especially those of the lower jaw, being much smaller. The skull is short, with the zygomatic arches extremely broad. *N. mitchelli* and *inerme*, both animals of great size, though inferior to *Diprotodon*.

Thylacoleo.—Dentition of adult: $i\,\frac{3}{1}$, $c\,\frac{1}{0}$, $p\,\frac{3}{1}$, $m\,\frac{1}{2}$; total 24. First upper incisor much larger than the others; canine and first two premolars rudimentary. In the lower jaw there are also one or two small and early deciduous premolars; posterior premolars of both jaws formed on the same type as that of *Hypsiprymnus*, but relatively much larger; true molars rudimentary, tubercular. One species, *T. carnifex*. This animal presents a most anomalous condition of dentition, the functional teeth being reduced to one pair

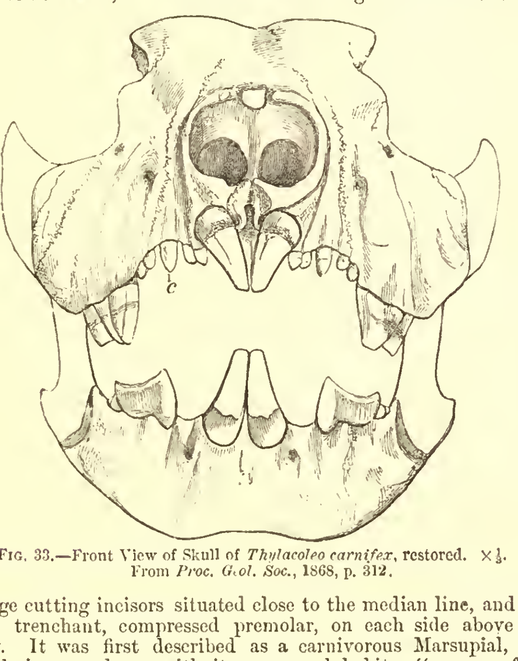

FIG. 33.—Front View of Skull of *Thylacoleo carnifex*, restored. ×½. From *Proc. Geol. Soc.*, 1868, p. 312.

of large cutting incisors situated close to the median line, and one great, trenchant, compressed premolar, on each side above and below. It was first described as a carnivorous Marsupial, and named, in accordance with its presumed habits, "as one of the fellest and most destructive of predatory beasts;" but, as its affinities are certainly with the *Phalangistidæ* and *Macropodidæ*, and its dentition completely unlike that of any known predaceous animal, this view has been called in question.[1]

[1] The lowest Eocene formation of New Mexico has recently yielded an animal (*Ptilodus mediævus*) having a mandibular dentition allied to that of *Thylacoleo*, and which goes some way to bridge over the gap, both in structure and time, between this and the Mesozoic *Plagiaulacidæ* (see Cope in *American Naturalist*, June 1882).

Family PHASCOLOMYIDÆ.

Dentition: $c\,\frac{1}{1}$, $i\,\frac{0}{0}$, $p\,\frac{1}{1}$, $m\,\frac{4}{4} = 24$. All the teeth with persistent pulps. The incisors large, scalpriform, with enamel only on the front surface, as in the *Rodentia*. The molars strongly curved, forming from the base to the summit about a quarter of a circle, the concavity being directed outwards in the upper and inwards in the lower teeth. The first of the series (generally called "premolar," though it appears to have no milk predecessor) single-lobed; the other four composed of two lobes, each subtriangular in section. Limbs equal, stout, and short. Fore feet with five distinct toes, each furnished with a long, strong, and slightly curved nail, the first and fifth considerably shorter than the other three. Hind feet with a very short nailless hallux, the second, third, and fourth toes partially united by integuments, of nearly equal length, the fifth distinct and rather shorter; all four provided with long and curved nails. In the skeleton of the foot, the second and third toes are distinctly more slender than the fourth, showing a slight tendency towards the peculiar character so marked in the last three families. Tail rudimentary. Stomach simple, provided with a special gland situated near the cardiac orifice. Cæcum very short, wide, and with a peculiar vermiform appendage.

The species of this family are few, and all contained in one genus, *Phascolomys*, with two well-marked sections, one containing the Common and Broad-nosed Wombats, *P. wombat* and *platyrhinus*, the other the Hairy-nosed Wombat, *P. latifrons*. They are all terrestrial and burrowing animals, generally slow in their movements, and harmless in disposition; they feed on roots and other vegetable substances, and inhabit the southern parts of the Australian continent, Tasmania, and the islands of Bass's Straits. See WOMBAT.

Bibliography of Marsupialia.—G. R. Waterhouse, *Nat. Hist. of the Mammalia*, vol. i. "Marsupiata," 1846; J. Gould, *Mammals of Australia*, 1863; R. Owen, article "Marsupialia," in *Cyclop. of Anatomy and Physiology*, and various memoirs "On Extinct Mammals of Australia" in *Philosophical Transactions*; W. H. Flower, "On the Development and Succession of the Teeth in the Marsupialia," *Phil. Trans.*, 1867.

SUBCLASS EUTHERIA OR MONODELPHIA.

The remaining mammals are included in the EUTHERIA, PLACENTALIA, or MONODELPHIA, the leading characters of which have been given at p. 372. Their affinities with one another are so complex that it is impossible to arrange them satisfactorily in any serial order. The *Edentata* may be taken first as standing in some respects apart from all the others. The *Sirenia* and *Cetacea* are also somewhat isolated, having undergone most remarkable modifications from the normal mammalian type. The *Primates* must be placed at the head of the series. The position of the others is quite arbitrary, as none of the hitherto proposed associations of the orders into larger groups stand the test of critical investigation, and palæontological researches have already gone far to show that they are all modifications of a common heterodont, diphyodont, pentadactyle form.

ORDER EDENTATA.

The name assigned to this group (which some zoologists think ought rather to be ranked as a subclass than an order) by Cuvier is often objected to as inappropriate, for though some of the members are edentulous, others have very numerous teeth; and the Linnæan name *Bruta* is occasionally substituted. But that term is quite as objectionable, especially as the group to which Linnæus applied it is by no means equivalent to the order as now understood, as the names of the genera contained in it, viz., *Elephas*, *Trichechus*, *Bradypus*, *Myrmecophaga*, *Manis*, and *Dasypus*, will indicate. It contained, in fact, all the animals then known which are comprised in the modern orders of *Proboscidea*, *Sirenia*, and *Edentata*, together with the Walrus, one of the *Carnivora*. If retained at all, it should rather belong to the *Proboscidea*, as *Elephas* stands first in the list of genera, and was probably in the mind of Linnæus when he assigned the name to the group. Cuvier's order included the *Ornithorhynchus* and *Echidna*, the structure of which was then imperfectly known, and which are now by common consent removed to an altogether different section of the class, but otherwise its limits are those now adopted. The name *Edentata* is so generally used, and its meaning so well understood, that it would be very undesirable to change it now; in fact similar reasons might be assigned for ceasing to use nearly all the other current ordinal designations, for it might be equally well objected that all the *Carnivora* are not flesheaters, many of the *Marsupialia* have not pouches, and so forth.

If the teeth are not always absent, they invariably exhibit certain imperfections, which are indeed almost the only common characters which bind together the various extinct and existing members of the order. These are—that they are homodont and, with the remarkable exception of the genus *Tatusia*, monophyodont; they are never rooted but have persistent pulps; they are always deficient in one of the constituents which enter into the formation of the complete mammalian tooth, the enamel, and are never present either in the upper or lower jaw in the fore part of the mouth, the situation occupied by the incisors of other mammals.[1]

There is so great a difference in structure and habits between some of the existing animals assigned to this order that, beyond the negative characters just mentioned, there seems little to connect them. The Sloths and Anteaters, for instance, in mode of life, general conformation of limbs, structure of digestive organs, &c., appear at first sight almost as widely separated as any mammals. Palæontology has, however, thrown great light upon their relations, and proved their real affinities. Perfectly intermediate forms have been discovered in the great Ground Sloths of America, which have the dentition and general form of the head of the Sloths, combined with the limbs and trunk of the Anteaters. It is highly probable that the existing members of the order are very much differentiated representatives of a large group, the greater number of which are now extinct, and which have become so without ever attaining a high grade of organization. The great diversity of structure of the existing families, the high degree of specialization to which many have attained, the paucity of species and even of individuals, their limited area of distribution, and their small size compared with known ancestral forms, all show that this is an ancient and a waning group, the members of which seem still to hold their own either by the remoteness and seclusion of their dwelling-places, by their remarkable adaptation of structure to special conditions of life, or by aid of the peculiar defensive armature with which they are invested. Their former history can, however, only be thus surmised, rather than read, at present; for, though we have ample evidence of the abundance and superior magnitude of certain forms in the most recent or post-Tertiary geological age, and in one part of the world, beyond this time, *i.e.*, in the true Tertiary period, and in other parts of the world than America, the remains of animals of this order hitherto discovered are only fragmentary, giving a most imperfect idea of their actual structure, and affording no indications which serve to connect them with any other branch of the class.

The existing members of the order readily group themselves into five distinct families, the limits of which are perfectly clear. These are (1) *Bradypodidæ*, or Sloths; (2) *Myrmecophagidæ*, or Anteaters; (3) *Dasypodidæ*, or Armadillos; (4) *Manidæ*, Pangolins or Scaly Anteaters; and (5) *Orycteropodidæ*, Aard-varks or African Anteaters. The geographical distribution of these families coincides with their structural distinction, the first three being inhabitants of the New and the last two of the Old World. It has been usual to arrange these families into two large groups or suborders:—(1) the *Phyllophaga*, leaf-eaters, also called *Tardigrada*, containing the *Bradypodidæ* alone; and (2) the *Entomophaga*, insect-eaters, or *Vermilingua*, containing all the other families, from which sometimes the *Orycteropodidæ* are separated as a third suborder under the name of *Effodientia*. Such an arrangement is, however, an artificial one, founded on superficial resemblance. The bonds which unite the *Manidæ* to the *Myrmecophagidæ* are mainly to be found in the structure of the mouth, especially the extensile character of the tongue, the great development of the submaxillary glands, and the absence of teeth. These characters are exactly analogous to those found in the *Echidna* among Monotremes, the Woodpeckers among Birds, and the Chamæleon among Reptiles,—the fact probably being that in countries where Termites and similar insects flourish various distinct forms of vertebrates have become modified in special relation to this abundance of nutritious food, which could only be made available by a peculiar structure of the alimentary organs. A close study of the more essential portions of the anatomy of these animals[2] leads to the belief that all the American Edentates at present known, however diversified in form and habits, belong to a common stock. The *Bradypodidæ*, *Megatheriidæ*, and *Myrmecophagidæ* are closely allied, the modifications seen in the existing families relating only to food and manner of life. The ancestral forms may have been omnivorous, and gradually separated into the purely vegetable and purely animal feeders; from the former are developed the modern Sloths, from the latter the Anteaters. The Armadillos (*Dasypodidæ*) are another modification of the same type, retaining some generalized characters, as those of the alimentary organs, but in other respects, as their defensive armature, remarkably specialized. The two Old-World families *Manidæ* and *Orycteropodidæ* are so essentially distinct, both from the American families and from each other, that it may even be considered doubtful whether they are derived from the same primary branch of mammals, or whether they may not be offsets of some other branch, the remaining members of which have been lost to knowledge.

Family BRADYPODIDÆ.

Externally clothed with long, coarse, crisp hair. Head short and rounded. External ears inconspicuous. Teeth $\frac{5}{4}$ in each jaw, subcylindrical, of persistent growth, consisting of a central axis of vaso-dentine, with a thin investment of hard dentine, with a thick outer coating of cement; without (as far as is yet known) any succession. Fore limbs greatly longer than the hind limbs. All the extremities terminating in narrow, curved feet; the digits never exceeding three in number, encased for nearly their whole length in a common integument, and armed with long strong claws. Tail rudimentary. Stomach complex. No cæcum. Placenta deciduate, dome-like, composed of an aggregation of numerous discoidal lobes. Strictly arboreal in habits, vegetable feeders, and limited geographically to the forest regions of South and Central America. Two genera, *Bradypus* and *Cholœpus*. See SLOTH.

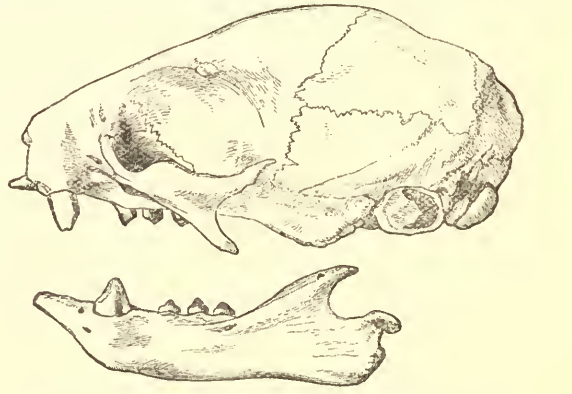

FIG. 34.—Skull of Two-toed Sloth (*Cholœpus didactylus*). From *Proc. Zool. Soc.*, 1871, p. 432.

Family MEGATHERIIDÆ.

The members of this family are all extinct. Their characters, so far as is known from the well-preserved remains of many species found abundantly in deposits of Pleistocene age in

[1] In some few Armadillos the suture between the premaxilla and maxilla passes behind the first upper tooth, but in all the other known members of the order all the teeth are implanted in the maxilla.

[2] See *Proceedings of the Zoological Society* of London, 1882, p. 358.

both North and South America, were intermediate between those of the existing *Bradypodidæ* and the *Myrmecophagidæ*, combining the head and dentition of the former with the structure of the vertebral column, limbs, and tail of the latter. Almost all the known species are of comparatively gigantic size, the smallest, *Cœlodon escrivanensis*, exceeding the largest existing Anteater, and the Megatherium being larger than a Rhinoceros. The dentition is usually $\frac{5}{4}$ on each

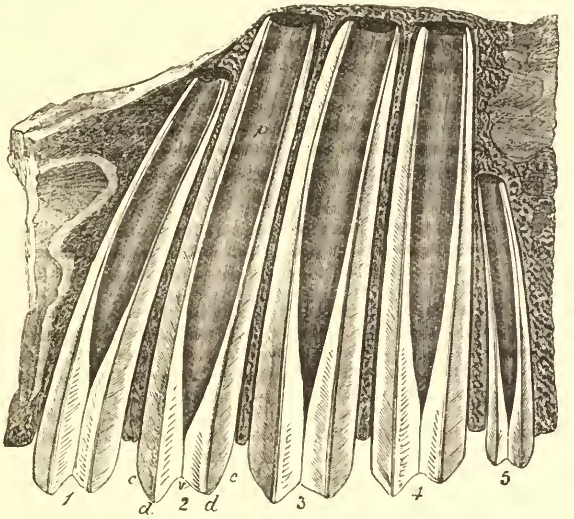

FIG. 35.—Section of Upper Molar Teeth of *Megatherium*. ×½. From Owen.

side, as in the Sloths, but in *Cœlodon* $\frac{4}{3}$. This genus, and in a still more marked degree *Megatherium*, differ from all the others in the details of the structure of the teeth. They are very deeply implanted, of prismatic form (quadrate in transverse section); and the component tissues—hard dentine (fig. 35, *d*), softer vaso-dentine (*v*), and cementum (*c*)—are so arranged that, as the tooth wears, the surface always presents a pair of transverse ridges, thus producing a triturating apparatus comparable to the "bilophodont" molar of *Dinotherium*, *Tapirus*, *Manatus*, *Macropus*, and others, though produced in a different manner. In all the other genera the teeth are more or less cylindrical, though sometimes laterally compressed or even longitudinally grooved on the sides, and on the grinding surface the prominent ridge of hard dentine follows the external contour, and is surrounded only by a thin layer of cementum, as in the existing Sloths. The genera of which the remains are best known are *Mylodon* (fig. 37), *Lestodon*, *Scelidotherium*, *Gryphotherium*, and *Megalonyx*. In the last-named the anterior tooth of both upper and lower jaws is large and removed by a considerable interval from the others. The osteological characters of these genera have been fully described in the works of Cuvier, Owen, Burmeister, Leidy, Gervais, Reinhardt, and others.

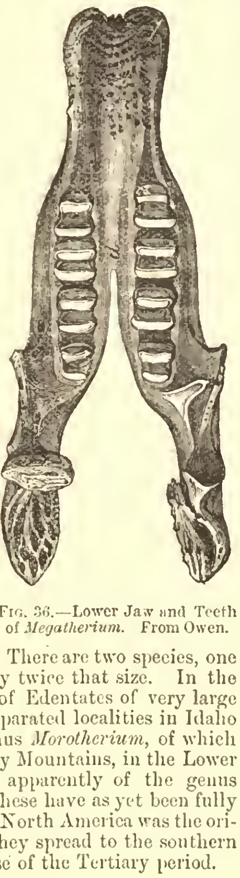

FIG. 36.—Lower Jaw and Teeth of *Megatherium*. From Owen.

No Eocene Edentates have yet been found in America. In the Miocene of the Pacific coast of North America some remains have been discovered, assigned by Marsh to the genus *Moropus*, the type of a distinct family, the *Moropidæ*. There are two species, one about as large as a Tapir, and one nearly twice that size. In the Lower Pliocene, well-preserved remains of Edentates of very large size have been found at several widely separated localities in Idaho and California. These belong to the genus *Morotherium*, of which two species are known. East of the Rocky Mountains, in the Lower Pliocene of Nebraska, a large species apparently of the genus *Moropus* has been discovered. None of these have as yet been fully described or figured. Marsh believes that North America was the original home of the Edentates, and that they spread to the southern portion of the continent towards the close of the Tertiary period.

Family MYRMECOPHAGIDÆ.

Externally clothed with hair. No teeth. Head elongated. Mouth tubular, with a small terminal aperture, through which the long, vermiform tongue, covered with the viscid secretion of the enormous submaxillary glands, is rapidly protruded in feeding, and withdrawn again with the adhering particles of aliment, which are then sucked into the pharynx. In the manus, the third toe is greatly developed, and has a long falcate claw; the others are reduced or suppressed. The pes has four or five subequal digits with claws. Posterior dorsal and lumbar vertebræ with additional interlocking zygapophyses. Tail long, sometimes prehensile. Placenta dome-like or discoidal. The animals of this family are the "Anteaters" *par excellence*. They feed exclusively on animal substances, mostly insects. One species is terrestrial, the others arboreal; none burrow in the ground. They are all inhabitants of the Neotropical region.

Myrmecophaga.—Skull greatly elongated and narrow, its upper surface smooth and cylindriform. Anteriorly the face is produced into a long, tubular rostrum, rounded above and flattened below, and with terminal nares, and composed of the mesethmoid ossified for more than half its length, the vomer, the maxillæ, and the long and narrow nasal bones, the premaxillæ being extremely short and confined to the margin of the anterior nares. The zygomatic arch is incomplete, the styliform malar only articulating with the maxilla in front, and not reaching to the very short zygomatic process of the squamosal. The lacrymal foramen is in front of the margin of the orbit. There are no post-orbital processes to the frontals or any other demarcation between the orbits and the temporal fossæ. Palate ex-

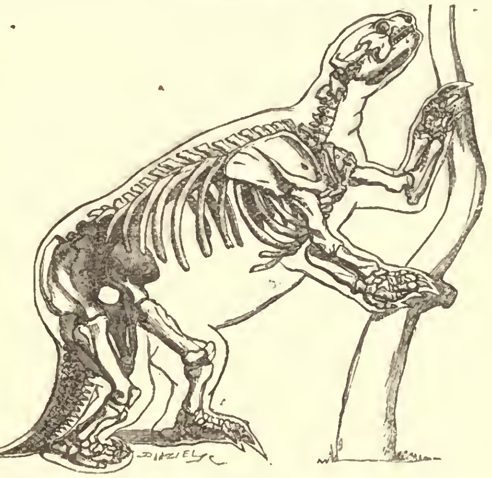

FIG. 37.—Skeleton of *Mylodon robustus* (Pleistocene, South America). From Owen.

tremely elongated, and produced backwards as far as the level of the external auditory meatus by the meeting in the middle line of the largely developed pterygoids. The glenoid fossa a shallow oval facet, with its long diameter from before backwards. Mandible very long and slender, with an exceedingly short symphysis, no distinct coronoid process, and a slightly elevated, elongated, flattened, condylar articular surface. Vertebræ: C 7, D 15–16, L 3–2, S 6, C 31. Clavicles rudimentary. In the manus, the first digit is very slender, the second also slender, with compressed phalanges of nearly equal length. The third digit is immensely developed; though its proximal phalanx is extremely short, its ungual phalanx is so long that the entire length of the digit exceeds that of the second. The fourth has a long and rather slender metacarpal, and three phalanges diminishing in size, the ungual phalanx being very small. The fifth has the metacarpal nearly as long, but not so stout as the fourth, and followed by two small phalanges, the last rudimentary and conical. Claws are developed upon all but the fifth. In walking the toes are kept strongly flexed, and have their points turned upwards and inwards, the weight being supported upon a callous pad over the end of the fifth digit, and by the dorsal surfaces of the third and fourth digits. The hind feet are short and rather broad, with five subequal claws, the fourth rather longest, the first shortest; the whole sole is placed on the ground in walking. Body rather compressed, clothed with long, coarse hair. Tail about as long as the body, and covered with very long hair; not prehensile. Ears small, oval, erect. Eyes very small. Stomach consisting of a subglobular, thin-walled, cardiac portion, and a muscular pyloric gizzard with dense epithelial lining. No ileo-colic valve, and a short wide ill-defined cæcum. Mammæ two, pectoral.

There is one species, *M. jubata*, the Great Anteater, or Ant Bear, measuring 4 feet in length without the tail, and upwards of 2 feet in height at the shoulder. Its prevailing colour is grey, with a broad black band, bordered with white, commencing on the chest, and passing obliquely over the shoulder, diminishing gradually in breadth as it approaches the loins, where it ends in a point.

It is extensively distributed in the tropical parts of South and Central America, frequenting low swampy savannas, along the banks of rivers, and the depths of the humid forests, but is nowhere abundant. Its food consists mainly of termites, to obtain which it opens their nests with its powerful sharp anterior claws, and as the insects swarm to the damaged part of their dwelling, it draws them into its mouth by means of its long, flexible, rapidly-moving tongue covered with glutinous saliva. The Great Anteater is quite terrestrial in its habits, being never known to climb trees, nor does it burrow underground like the Armadillos. Though generally an inoffensive animal, when attacked it can defend itself vigorously and effectively with its sabre-like anterior claws. The female bears but a single young at a birth.

Tamandua.—This genus closely resembles the last in anatomical structure, but the head is much less elongated, the fur is short and bristly, the tail, tapering, prehensile, with the under side throughout and the whole of the terminal portion naked and scaly. The stomach is similar to that of *Myrmecophaga*, but with the muscular pyloric gizzard not quite so strongly developed. There is a distinct

FIG. 38.—Tamandua Anteater (*Tamandua tetradactyla*). From *Proc. Zool. Soc.*, 1871, pl. xliii.

ileo-colic valve and short globular cæcum. The fore foot has a very large claw on the third toe, moderate-sized claws on the second and fourth, a very minute one on the first, and none on the fifth, which is entirely concealed within the skin. The hind foot has five subequal claws. Vertebræ: C 7, D 17, L 2, S 5, C 37. There are very rudimentary clavicles.

The Tamandua (*T. tetradactyla*) is much smaller than the Great Anteater, and differs essentially from it in its habits, being mainly arboreal. It is an inhabitant of the dense primeval forests of South and Central America. As different individuals vary much in their coloration, it is possible that there may be more than one species. The usual colour is yellowish-white, with a broad black lateral band, covering nearly the whole of the side of the body.

Cycloturus.—The skull is much shorter even than in *Tamandua*, and is arched considerably in the longitudinal direction. It differs from that of the other members of the family mainly in the long canal for the posterior nares not being closed by bone below, as the greater part of the palatines and the pterygoids do not meet in the middle line. The mandible has a prominent, narrow, recurved coronoid and a well-developed angular process; it is strongly decurved in front. Vertebræ: C 7, D 16, L 2, S 4, C 40. Ribs remarkably broad and flat. Clavicles well developed. Manus remarkably modified. The third digit is greatly developed at the expense of all the others; it has a stout short metacarpal and but two phalanges, of which the most distal is large, compressed, pointed, and much curved, and bears a very strong hook-like claw. The second digit has the same number of phalanges, and bears a claw, but is very much more slender than the third. The fourth is represented only by the metacarpal, and one nailless phalanx, the first and fifth only by very rudimentary metacarpals. The pes is also completely modified into a climbing organ. The hallux is rudimentary, consisting of a metatarsal and one phalanx, concealed beneath the skin, but the other four toes are subequal and much curved, with long pointed compressed claws. The tuber calcanei is directed towards the plantar surface, and parallel with it and extending to about double its length is a greatly elongated sesamoid ossicle. These together support a prominent calcarine cushion to which the nails are opposed in climbing. Stomach pyriform, with muscular walls, but no distinct gizzard-like portion, as in the foregoing genera. The commencement of the colon provided with two small cæca, resembling those of many Birds, narrow at the base, and rather dilated at their terminal blind ends, and communicating with the general cavity by very minute apertures. Tail longer than the body, tapering, bare on the under surface, and very prehensile. Fur soft and silky.

This genus has also but one species certainly known, the Little or Two-toed Anteater (*C. didactylus*), an animal not larger than a Rat, of a general yellowish colour, and exclusively arboreal in its habits. It is a native of the hottest parts of South and Central America.

Family DASYPODIDÆ.

The greater part of the skin strongly ossified. On the back and sides the union of numerous quadrate or polygonal scutes forms a hard shield, usually consisting of an anterior (scapular) and posterior (pelvic) solid portion (which overhang on each side the parts of the body they respectively cover, forming chambers into which the limbs are withdrawn), and a variable number of rings between, connected by soft flexible skin so as to allow of curvature of the body. The top of the head has also a similar shield (cephalic), and the tail is usually encased in bony rings or plates. The outer or exposed surfaces of the limbs are protected by irregular bony scutes, not united at their margins; but the skin of the inner surface of the limbs and under side of the body is soft and more or less clothed with hair. Hairs also in many species project through apertures between the bony scutes of the back. The ossified dermal plates are everywhere covered by a layer of horny epidermis. Teeth numerous, simple, of persistent growth, and usually monophyodont, but in one genus (*Tatusia*) a succession of teeth has been observed. Zygomatic arch of skull complete. Cervical vertebræ with extremely short, broad, and depressed bodies. The atlas free, but the second and third, and often several of the others, ankylosed together both by their bodies and arches. Lumbar vertebræ with accessory zygomatic processes, and very large metapophyses, supporting the bony carapace. Clavicles well developed. A third trochanter on the femur. Tibia and fibula ankylosed at their distal extremities. Fore feet with strongly developed, curved claws, adapted for digging and scratching, three, four, or five in number. Hind feet plantigrade, with five toes, all provided with nails. Tongue long, pointed, and extensile, though to a less degree than in the Anteaters. Submaxillary glands largely developed. Stomach simple. Placenta discoidal, deciduate.

The animals of this family are commonly called Armadillos, a word of Spanish origin, having reference to their armour-like covering. The existing species are all of small or moderate size. They are mostly, though not universally, nocturnal in their habits. They are omnivorous, feeding on roots, insects, worms, reptiles, and carrion. They are harmless and inoffensive creatures, offering no resistance when caught, their principal means of escape from their enemies being the extraordinary rapidity with which they can burrow in the ground, and the tenacity with which they retain their hold in their subterranean retreats. Notwithstanding the shortness of their limbs they can run with great rapidity. Most of the species are esteemed good eating by the natives of the countries in which they live. They are all inhabitants of the open plains or the forests of the tropical and temperate parts of South America, with the exception of one species (*Tatusia peba*), which ranges as far north as Texas. Of the existing genera, *Chlamydophorus* stands apart from the rest in the formation of its external covering; but in all other respects *Tatusia* is the most aberrant form, exhibiting a different type of structure of the fore feet, which in all the others shows modifications, though in very varying degrees, of the same type.

Subfamily **Chlamydophorinæ.**—In most anatomical characters, especially the structure of the fore foot, this little group resembles the *Dasypodinæ*, but it differs remarkably from all other known Armadillos, living or extinct, in the peculiar modification of the dermal armour.

Chlamydophorus.—Teeth $\frac{8}{8-9}$, subcylindrical, somewhat compressed, moderate in size, smaller at each end (especially in front) than at the middle of the series. Skull broad and rounded behind, pointed in front. Muzzle subcylindrical and depressed. A conspicuous rounded, rough prominence on the frontal bone, just before each orbit. Tympanic prolonged into a tubular auditory meatus, curving upwards round the base of the zygoma. Vertebræ: C 7, D 11, L 3, S 10, C 15. Upper part of head and trunk covered with four-sided horny plates (with very small thin ossifications beneath), forming a shield, free, and overhanging the sides of the trunk, and attached only along the middle line of the back. The plates are arranged in a series of distinct transverse bands, about twenty in number between the occiput and the posterior truncated end, and not divided into solid thoracic and pelvic shields with movable bands between. The hinder end of the body is abruptly truncated and covered by a vertically-placed, strong, solid, bony shield, of an oval (transversely extended) form, covered by thin epidermic plates. This shield is firmly ankylosed by five bony processes to the hinder part of the pelvis. Through a notch in the middle of its lower border the tail passes out. The latter is rather short, cylindrical in its proximal half, and expanded and depressed or spatulate in its terminal portion, and covered with horny plates. The dorsal surfaces of the fore and hind feet are also covered with horny plates. The remainder of the limbs and under surface and sides of the body beneath the overlapping lateral parts of the dorsal shield are clothed with rather long, very soft silky hair. Eyes and ears very small, and concealed by the hair. Extremities short. Feet large, each with five well-developed claws, those on the fore feet very long, stout, and subcompressed, the structure of the digits being essentially the same as those of *Xenurus* and *Priodon.* Nipples two, pectoral. Visceral anatomy closely resembling that of *Dasypus*, the cæcum being broad, short, and bifid.

C. truncatus.—The Pichiciago, a small burrowing animal, about 5 inches long, inhabits the sandy plains of the western part of the Argentine Republic, especially the vicinity of Mendoza. Its horny covering is of a pinkish colour, and its silky hair snow white. It is rare, and its habits but little known. A second species, *C. retusa*, from Bolivia, has been described by Burmeister. It is of rather larger size, and has the dorsal shield attached to the skin of the back, as far as its edge, instead of only along the median line.

Subfamily **Dasypodinæ.**—Fore feet usually with all five digits developed and with nails, though the first and fifth may be suppressed. The first and second long and slender, with the normal number and relative length of phalanges. The others stout, with short broad metacarpals, and with phalanges greatly reduced in length and generally in number by coalescence. The ungual phalanx of the third very large, that of the others gradually diminishing to the fifth. *Dasypus*, as now restricted, has the most normal form of manus, but the modifications so markedly developed in all the others (and culminating in *Tolypeutes*) are foreshadowed, as it were, in it. Ears wide apart. Mammæ one pair, pectoral.

Dasypus.—Teeth $\frac{9}{10}$ or $\frac{8}{9}$, of which the anterior in the upper jaw is usually implanted in the premaxillary bone. The series of teeth extends posteriorly some distance behind the anterior root of the zygoma, almost level with the hinder edge of the palate. They are large, subcylindrical, slightly compressed, diminishing in size towards each end of the series; the anterior two in the mandible much smaller, and more compressed than the others. Cranial portion of the skull broad and depressed. Facial portion triangular, broad in front and much depressed. Auditory bulla completely ossified, perforated on the inner side by the carotid canal, and continued externally into an elongated bony meatus auditorius, with its aperture directed upwards and backwards. (In all the remaining genera of *Dasypodinæ* the tympanic bone is a mere half ring, loosely attached to the cranium.) Mandible with a high ascending ramus, broad transversely-placed condyle, and high slender coronoid process. Vertebræ: C 7, D 11–12, L 3, S 8, C 17–18. Head broad and flat above. Muzzle obtusely pointed. Ears of moderate size or rather small, placed laterally, far apart. Body broad and depressed. Carapace with six or seven movable bands between the scapular and pelvic shields. Tail shorter than the body, tapering, covered with plates forming distinct rings near the base. Fore feet with five toes; the first much more slender than the others, and with a smaller ungual phalanx and nail; the second, though the longest, also slender. The third, fourth, and fifth gradually diminishing in length, all armed with very strong, slightly curved, compressed claws, sloping away from an elevated rounded inner border to a sharp, outer, and inferior edge. The hind foot is rather short, with all five toes armed with stout, compressed, slightly curved, obtusely pointed claws,—the third the longest, the second nearly equal to it, the fourth the next, the first and fifth shorter and nearly equal.

To this genus belongs one of the best-known species of the group, the Six-banded Armadillo or Encoubert (*D. sexcinctus*) of Brazil and Paraguay. A very similar species, *D. villosus*, the Hairy Armadillo, replaces it south of the Rio Plata. There are also two very small species, *D. vellerosus* and *D. minutus*, from the Argentine Republic and North Patagonia. The latter differs from the other three in having no tooth implanted in the premaxillary bone.

Xenurus.—Teeth $\frac{9}{9}$ or $\frac{8}{8}$, of moderate size and subcylindrical. The most posterior placed a little way behind the anterior root of the zygoma, but far from the hinder margin of the palate. Cranium somewhat elongated, much constricted behind the orbits, and immediately in front of the constriction considerably dilated. Mandible slender; coronoid process very small and sharp-pointed, sometimes obsolete. Vertebræ: C 7, D 12–13, L 5, S 10, C 18. Head broad behind. Ears rather large and rounded, wide apart. Movable bands of carapace 12–13. Tail considerably shorter than the body, and slender, covered with nearly naked skin, with but a few small, scattered, dermal bony plates, chiefly on the under surface and near the apex. On the fore feet the first and second toes are long and slender, with small claws and the normal number of phalanges; the other toes have but two phalanges; the third has an immense falcate claw; the fourth and fifth similar but smaller claws. The hind feet are comparatively small, with five toes, with small, triangular, blunt nails; the third longest, the first shortest. The best known species of this genus, the Tatouay or Cabassou, *X. unicinctus*, is, after *Priodon gigas*, the largest of the group. It is found, though not abundantly, in Surinam, Brazil, and Paraguay. Others, *X. hispidus* and *lugubris*, have been described, but little is as yet known of them.

Priodon.—Teeth variable in number, and generally differing on the two sides of each jaw, usually from 20 to 25 on each side above and below, so that as many as 100 may be present altogether, but as life advances the anterior teeth fall out, and all traces of their alveoli disappear. The series extends as far back as the hinder edge of the anterior root of the zygoma. They are all very small; in the anterior half of each series they are strongly compressed, having flat sides and a straight free edge; the posterior teeth are more cylindrical, with flat, truncated, free surfaces. Vertebræ: C 7, D 12, L 3, S 10, C 23. Head small, elongated, conical. Ears moderate, ovate. Carapace with 12–13 movable bands. Tail nearly equal to the body in length, gradually tapering, closely covered with quadrangular scales, arranged in a quincunx pattern. Fore feet with five toes, formed on the same plan as those of *Xenurus*, but with the claw of the third of still greater size, and that of the others, especially the fifth, proportionately reduced. Hind foot short and rounded, with five very short toes, with short, broad, flat obtuse nails. The only known species, the Great Armadillo (*P. gigas*), is by far the largest of existing members of the family, measuring rather more than 3 feet from the tip of the nose to the root of the tail, the tail being about 20 inches long. It inhabits the forests of Surinam and Brazil. The powerful falcate claws of its fore feet enable it to dig with great facility. Its food consists chiefly of termites and other insects, but it is said to attack and uproot newly-made graves for the purpose of devouring the flesh of the bodies contained in them.

Tolypeutes.—Teeth $\frac{9}{9}$ or $\frac{8}{9}$, rather large in proportion to the size of the skull, the hinder end of the series reaching nearly to the posterior margin of the palate. Vertebræ: C 7, D 11, L 3, S 12, C 13. Ears placed low on the sides of the head, rather large, broadly ovate. Carapace with its scapular and pelvic shields very free at the sides of the body, forming large chambers into which the limbs can be readily withdrawn. Only three movable bands. Tail short, conical, covered with large bony tubercles. The fore feet formed on the same type as the last, but the peculiarities carried out to a still greater extent. The claw of the third toe is very long and falcate, the first and fifth greatly reduced and sometimes wanting. On the hind foot the three middle toes have broad, flat, subequal nails, forming together a kind of tripartite hoof; the first and fifth much shorter and with more compressed nails.

The Armadillos of this genus have the power of rolling themselves up into a perfect ball, the shield on the top of the head and the tuberculated dorsal surface of the tail exactly fitting into and filling up the apertures left by the notches at either end of the carapace. This appears to be their usual means of defence when frightened or surprised, as they do not burrow like the other species. They run very quickly, with a very peculiar gait, only the tips of the claws of the fore feet touching the ground. Three species are described:—*T. tricinctus*, the Apar; *T. conurus*, the Matico; and *T. muriei.*

Subfamily **Tatusiinæ.**—This contains but one genus, *Tatusia.*—Teeth $\frac{8}{8}$ or $\frac{7}{7}$, very small, subcylindrical. The first and second subcompressed, the last considerably smaller than the others. They present the remarkable peculiarity (unique among Edentates, so far as

FIG. 39.—*Glyptodon clavipes* (Pleistocene, South America). From Owen.

is yet known) of all being, with the exception of the last, preceded by two-rooted milk teeth, which are not changed until the animal has nearly attained its full size. Vertebræ: C 7, D 9–11, L 5, S 8, C 20–27. Head narrow, with a long, narrow, subcylindrical, obliquely-truncated snout. Ears rather large, ovate, and erect, placed close together on the occiput. Carapace with seven to nine distinct movable bands. Body generally elongated and narrow. Tail moderate or long, gradually tapering; its dermal plates forming very distinct rings for the greater part of its length. Fore feet with four visible toes, and a concealed clawless rudiment of the fifth. Claws all long, slightly curved, and very slender, the third and fourth subequal and alike, the first and fourth much shorter. Hind feet with five toes, all armed with strong, slightly-curved, conical, obtusely-pointed nails. The third longest, then the second and fourth; the first and fifth much shorter than the others.

This genus differs from all the other Armadillos in having a pair of inguinal mammæ, in addition to the usual pectoral pair, and in producing a large number (four to ten) of young at a birth, all the others having usually but one or two.

The Peba Armadillo, *T. septemcincta*, is a well-known species, having an extensive range from Texas to Paraguay. It is replaced in the more southern regions of South America by a smaller species, with shorter tail, the Mulita (*T. hybrida*), so called from the resemblance of its head and ears to those of a mule. *T. kappleri* is a large species or variety from Surinam.[1]

Fossil remains of *Dasypodidæ* have been found by Lund and others in the caves of Brazil in deposits of Pleistocene age. Some are attributable to existing genera, but others are assigned to distinct modifications of the type called *Euryodon*, *Chlamydotherium*, *Eutatus*, &c. In the same region, but still more abundantly in the fluviatile deposits which cover the country in the neighbourhood of Buenos Ayres, are found the remains of one of the most remarkable forms of mammals yet discovered, the Glyptodons, or *Hoplophoridæ* (fig. 39). They differ from the existing *Dasypodidæ* in their large size, and in having the carapace composed of a solid piece (formed by the union of a multitude of bony dermal scutes) without any movable rings, and in having also a ventral piece or plastron. The facial portion of the skull is very short. A long process of the maxillary bone descends from the anterior part of the zygomatic arch. The ascending ramus of the mandible is remarkably high. The teeth are $\frac{8}{8}$ in all known species, all much alike, having two deep grooves or flutings on each side, so as to divide them into three nearly distinct lobes (fig. 40). The vertebral column is almost entirely ankylosed into a solid tube, but there is a complex joint at the base of the neck, to allow the head being retracted within the carapace. The limbs are very strong, and the feet short and broad, resembling externally those of an elephant or tortoise. Many species of the family have been described and figured, especially by Burmeister (in the *Annales del Museo publico de Buenos Aires*), by whom five genera are recognized, which are thus characterized:—

FIG. 40.—Teeth of Glyptodon. From Owen.

I. Four toes only on the posterior feet.
 A. Four toes on the anterior feet, the pollex being absent.
  a. Cuirass thin but inflexible.
   1. *Hoplophorus*:—*H. euphractus*, *H. ornatus*, *H. elegans*, *H. pumilio*.
  b. The cuirass stronger, with clefts between the scutes at the lower antero-lateral border, allowing of a certain amount of flexibility.
   2. *Panochthus*:—*P. tuberculatus*, *P. bullifer*.
 B. Both pollex and fifth digit of the manus absent.
   3. *Dœdicurus*:—*D. giganteus*.

II. Five perfect toes on the posterior feet, and four on the anterior, the fifth digit of which is absent.
 A. Tail elongated, with the rings of the base smooth, and the cuirassed apex cylindrical or tubular.
   4. *Glyptodon*:—*G. clavipes*, *G. reticulatus*.
 B. Tail short, the rings tuberculated, the point round and short.
   5. *Schistopleurum*:—*S. elongatum*, *S. asperum*, *S. læve*.

Family MANIDÆ.

Covered externally (except the under surface of the body and inside of the limbs) with large imbricated horny scales, with scattered hairs growing in the intervals. No teeth. Tongue long, vermiform, and protractile. No accessory articular processes to the lumbar vertebræ, but the anterior zygapophyses largely developed and very concave, completely embracing the semicylindrical surfaces of the posterior zygapophyses. Limbs short, with five complete digits on each foot. Scaphoid and lunar bone of carpus united. Uterus bicornuate. Placenta diffused and non-deciduate. The species are mainly terrestrial and fossorial, though one is partially arboreal. All belong to the Ethiopian and Oriental regions of the Old World.

Manis.—Skull somewhat of the form of an elongated cone, with the small end turned forwards; very smooth and free from crests and ridges. No distinction between the orbits and temporal fossæ. The zygomatic arch usually incomplete, owing to the absence of the malar bone. No distinct lacrymal bone. Palate long and narrow. The pterygoids extend backwards as far as the tympanics, but do not meet in the middle line below. Tympanic ankylosed to the surrounding bones, and more or less bullate, but not produced into a tubular auditory meatus. Rami of mandible very slender and straight, without any angle or coronoid process. From near the anterior extremity of the upper edge a sharp, conical, tooth-like process projects upwards and outwards. No clavicles. No third trochanter to the femur. Ungual phalanges bifid at their terminations. Caudal vertebræ with very long strong transverse processes and numerous chevron bones. Tongue long, vermiform, flattened towards the tip. The retractor or sterno-glossal muscles arise from the hinder extremity of the immensely prolonged ensiform cartilage of the sternum. Stomach with thick, muscular walls and lining membrane, and with a special gland near the middle of the great curvature, consisting of a mass of complex secreting follicles, the ducts of which terminate in a common orifice. No cæcum. A gall-bladder. Head small, depressed, narrow, pointed in front, with a very small mouth-opening. Eyes and pinna of ear very small. Body elongated, narrow. Tail more or less elongated, convex above, flat underneath. The whole of the upper surface of the head, the upper surface and sides of the body, the whole of the tail, and the outer sides of the extremities covered with large, overlapping, horny scales, with usually a few stiff hairs growing between and projecting beyond them. The sides and under surface of the head, the under surface of the body, and the inner sides of the limbs without scales but with a rather scanty covering of hair. Limbs short. In walking the dorsal surface and outer sides of the phalanges of the two outer digits of the front feet alone rest on the ground, the points of the nails turning upwards and inwards. The third toe the longest, with a powerful compressed curved claw, the second and fourth with similar but smaller claws, that of the pollex often almost rudimentary. Hind feet plantigrade, with hallux very short, and four other toes subequal, with moderate, curved, subcompressed nails.

The animals of this genus, called Pangolins or Scaly Anteaters, are all of small or moderate size, terrestrial and burrowing, and feed mainly on termites. One small African species climbs trees. They can roll themselves up in a ball when in danger. Their peculiar elongated form, short limbs, long, gradually-tapering tail, and scaly covering give them on a superficial inspection more the appearance of reptiles than of mammals. The species are not numerous, but may be grouped into three sections. (1) *Manis* proper. Tail considerably exceeding in length both head and body. Scales not covering the dorsal surface of the manus. On fore feet the first toe exceedingly small, but with a distinct short nail; second, fourth, and fifth subequal, with moderate compressed claws; third greatly exceeding the others, with a much larger falcate claw. Two species, both from West Africa: *M. longicaudata* (vertebræ: C 7, D 13, L 5, S 3, C 46), and *M. tricuspis* (vertebræ: C 7, D 13, L 6, S 3, C 44). (2) All the others have the scaly covering of the fore limbs extending to the claws, and the tail not exceeding the length of the head and body. On the fore feet the first and fifth toes are equal and very small, the second and fourth equal and longer, the third longest, but not so disproportionately so as in the other section. The tails of most of these are broad at the base and taper towards the extremity. They constitute the genus *Pholidotus* of Gray, and include *M. gigantea*, West Africa, the largest species of the group, of which the head and body measure 2 feet 6 inches, and the tail the same. Vertebræ: C 7, D 13, L 6, S 4, C 28. *M. pentadactyla*, *M. aurita*, and *M. javanica*, all of the Oriental region. (3) One very distinct species, *M. temminckii*, from South and East Africa, with the tail nearly as broad as the body for the whole of its length, and rounded at the end, constitutes the genus *Smutsia* of Gray.

Family ORYCTEROPODIDÆ.

External surface scantily covered with bristle-like hairs. Teeth numerous, and of peculiar and complex structure, being traversed by a number of parallel vertical pulp-canals. Lumbar vertebræ with no accessory zygapophyses. Femur with a third trochanter. Fore feet without pollex, but all the other digits well developed, with strong moderate-sized nails, suited to digging, the plantar surfaces of which rest on the ground in walking. Hind feet with five subequal toes. Mouth elongated and tubular. Tongue subvermiform. Placenta broadly zonular. Feed on animal substances. Terrestrial and fossorial in habits. Limited to the Ethiopian region.

Orycteropus.—The total number of teeth appears to be from

[1] A single imperfect skin, brought from the province of Ceara in Brazil, indicates a very remarkable form of Armadillo, named by A. Milne-Edwards *Scleropleura brunetti* (*Ann. Sc. Nat.*, xvi. p. 8, 1872). The dermal plates are said to be much less developed than in other members of the family, and confined to the sides, all the median portion of the back being clothed with a flexible hairy skin. The head is broad and short, the ears small and far apart. The tail is long, and almost entirely devoid of scutes. The feet are unknown.

eight to ten in each side of the upper, and eight in the lower jaw; but they are never all in place at one time, as the small anterior teeth are shed before the series is completed behind. In the adult they number usually five on each side above and below, of which the first two are simple and compressed, the next two larger and longitudinally grooved at the sides, the most posterior simple and cylindrical. The structure of all these teeth is quite peculiar among mammals, though resembling that of some fishes. Their summits are rounded before they are worn; their bases do not taper to a root, but are evenly truncated and continually growing. Each tooth is made up of an aggregation of parallel dental systems, having a slender pulp cavity in the centre, from which the dentinal tubes radiate outwards, and being closely packed together each system assumes a polygonal outline as seen in transverse section. No evidence of any vertical succession of teeth has been discovered. Skull moderately elongated. The facial portion subcylindrical and slightly tapering. The zygoma complete and slender. The palate ends posteriorly in the thickened transverse border of the palatines, and is not continued back by the pterygoids. The tympanic is annular, and not ankylosed to the surrounding bones. The mandible is slender anteriorly, but rises high posteriorly, with a slender recurved coronoid, and an ascending pointed process on the hinder edge below the condyle, which is small, oval, and looks forwards as much as upwards. Vertebræ: C 7, D 13, L 8, S 6, C 25. The large number of lumbar vertebræ is peculiar among Edentates. Tongue less vermiform than in *Myrmecophaga*, being thick and fleshy at the base, and gradually tapering to the apex. The salivary apparatus is developed much in the same manner as in that genus, but the duct of the submaxillary gland has no reservoir. The stomach consists of a large subglobular cardiac portion, with a very thick, soft, and corrugated lining membrane, and a smaller muscular, pyloric part, with a comparatively thin and smooth lining. There is a very distinct ileo-cæcal valve, and a considerable-sized cæcum; also a gall-bladder. No pollex to the fore foot. All the other usual toes well developed, with strong, subcompressed nails, flatter on the hind foot. Head elongated, with a tubular snout, terminal nostrils, and small mouth-opening. Ears large, pointed, erect. Tail nearly as long as the body, cylindrical, very thick at the base, tapering to the extremity.

The best known species is the Cape Anteater (*O. capensis*), or "Aard-Vark" (Earth Pig) of the Dutch colonists, from South Africa, an animal not altogether unlike a Pig in size and general appearance. It lives in burrows in the ground, and feeds chiefly on ants and other insects. A second species, or well-marked local variety, *O. æthiopicus*, inhabits the north-eastern parts of Africa.

Extinct Edentata of the Old World.

Certain remains, chiefly of bones of the limbs, found in France and Greece, and assigned to genera called *Macotherium* and *Ancylotherium*, united provisionally in the family *Macrotheriidæ*, indicate the existence of animals of large size inhabiting Europe during the Middle Tertiary epoch, the characters of which appear to indicate a generalized Edentate form or something intermediate between the *Edentata* and *Ungulata*. In the structure of the phalanges they most resembled the *Manidæ*, but there is some evidence that they possessed teeth. Some fragments from the Eocene of Paris are still more doubtfully assigned by Gervais to the order.

Bibliography of Edentata.—No general work on the order has been published but that of Rapp (*Anat. Untersuchungen über die Edentaten*, 2d ed., 1852), now nearly out of date. Among numerous memoirs on special groups the following may be cited:—*Myrmecophagidæ*:—R. Owen, "Anatomy of Great Anteater," *Trans. Zool. Soc.*, vol. iv.; G. Pouchet, *Mém. sur le Grand Fourmilier*, 1871; W. A. Forbes, "Anat. of Great Anteater," *Proc. Zool. Soc.*, 1882, p. 287. *Megatheriidæ*:—R. Owen, *Extinct Gigantic Sloth* (*Mylodon Robustus*), 1842; Id., "On the Megatherium," *Philos. Trans.*, 1851–56; J. Leidy, "Extinct Sloth-tribe of North America," *Smithsonian Contrib. to Knowledge*, vii., 1855; H. Burmeister, *Description de la République Argentine*, t. iii. Mammifères, 1879,—which contains full references to various memoirs by Owen, Gervais, Reinhardt, and others. *Glyptodontidæ*:—Owen, *Catalogue of Fossil Mammals, Mus. Roy. Coll. Surgeons*, 1845; T. H. Huxley, "Osteol. of Glyptodon," *Phil. Trans.*, 1865; H. Burmeister, *Annales del Museo Publico de Buenos Ayres*, and *Descript. de la République Argentine*, 1879. *Dasypodidæ*:—J. Murie, "Anatomy of *Tolypeutes*," *Trans. Linn. Soc.*, vol. xxx., 1874; A. H. Garrod, *Proc. Zool. Soc.*, 1878. For placentation of Edentates see W. Turner, *Trans. Roy. Soc. Edin.*, xxvii. (1873) p. 72, and *Jour. Anat. and Physiol.*, vols. viii. and x.; A. Milne-Edwards, *Ann. Sciences Nat.* [6] viii. p. 1; and for brain, P. Gervais, "Formes cérébrales des Edentés," *Nouv. Arch. du Muséum*, tom. v.; W. Turner, *Jour. Anatomy*, i. 313 (1867).

Order SIRENIA.

The purely aquatic habits and Fish-like form of the animals of this order caused them to be formerly confounded with the *Cetacea*, but a more intimate knowledge of their structure has shown that they really belong to a widely different type of the class.

The head is rounded and not disproportionate in size as compared with the trunk, from which it is scarcely separated by any externally visible constriction or neck. Nostrils valvular, separate, and placed above the fore part of the obtuse, truncated muzzle. Eyes very small, with imperfectly formed eyelids, capable, however, of contraction, and with a well-developed nictitating membrane. Ear without any pinna. Mouth of small or moderate size, with tumid lips beset with stiff bristles. General form of the body depressed fusiform. No dorsal fin. Tail flattened and horizontally expanded. Fore limbs paddle-shaped, the digits being enveloped in a common cutaneous covering, though sometimes rudiments of nails are present. No trace of hind limbs. External surface covered with a tough, finely wrinkled, or very rugous skin, naked, or with fine hairs sparsely scattered over it.

The skeleton is remarkable for the massiveness and density of most of the bones of which it is composed, especially the skull and ribs, which must add to the specific gravity of these slow-moving animals, and aid in keeping them to the bottom of the shallow waters in which they dwell, while feeding on aquatic vegetables. The skull presents many peculiarities, among which may be indicated the large size and backward position of the anterior narial aperture, a further modification of that met with in the Tapirs among Ungulates, and presenting some approach to that so characteristic of the *Cetacea*. The nasal bones are generally absent in the recent forms, or are only found in a most rudimentary condition, attached to the edge of the frontals, far away from the middle line; but in some at least of the extinct species these bones, though small in size, are normal in situation and relations. In very few other respects does the skull present any resemblance to that of the *Cetacea*. In the spinal column none of the vertebræ are united together to form a sacrum, and the flat ends of the bodies do not ossify separately, so as to form disk-like epiphyses in the young state, as in nearly all other mammals. The anterior caudal vertebræ have well-developed chevron bones. In one genus (*Manatus*) there are only six cervical vertebræ. There are no clavicles. The humerus has a small but distinct trochlear articulation at the elbow-joint. The two bones of the forearm are about equally developed, and generally ankylosed together at both extremities. The carpus is short and broad, and the digits five in number, with moderately elongated and flattened phalanges, which are never increased in number beyond the limit usual in the *Mammalia*. The pelvis is extremely rudimentary, consisting of a pair of bones suspended at some distance from the vertebral column. In no existing species is there any trace of a hind limb, but in the extinct *Halitherium* an acetabular depression and rudimentary femur have been discovered.

Two kinds of teeth, incisors and molars, separated by a wide interval, are generally present. The former may be developed into tusks in the upper jaw, or may be quite rudimentary. The molars vary much in character. In one genus (*Rytina*) no teeth of any kind are present, at least in the adult. In all, the anterior part of the palate, and a corresponding surface on the prolonged symphysis of the lower jaw, are covered with rough horny plates of peculiar structure, which doubtless assist in mastication. The tongue is small and fixed in position, with a surface resembling that of the plates just spoken of. The salivary glands are largely developed. The stomach is compound, being divided by a valvular constriction into two principal cavities, the first of which is provided with a singular glandular pouch near the cardiac end, and the second usually with a pair of elongated, conical, cæcal sacs or diverticula. The intestinal canal is long, and with very muscular walls. There is a cæcum, either simple, conical, and with extremely thick walls, as in *Halicore*, or bifid, as in *Manatus*. The apex of the heart is deeply cleft between the ventricles. The principal arteries form very extensive and complex *retia mirabilia*. The lungs are remarkably long and narrow, as, owing to the very oblique position of the diaphragm, the thoracic cavity extends far back over the abdomen. The epiglottis and arytenoid cartilages of the larynx do not form a tubular prolongation as in the *Cetacea*. The brain is of comparatively small size, and the convolutions on the surface of the cerebrum few and shallow. The kidneys are simple. Testes abdominal. The uterus is bicornuate. The placenta (in the Dugong) is non-deciduate and diffuse, the villi being scattered generally over the surface of the chorion except at the poles. The umbilical vesicle disappears early. The mammæ are two, and pectoral or rather post-axillary in position.

The *Sirenia* pass their whole life in the water, being denizens of shallow bays, estuaries, lagoons, and large rivers, but unlike the *Cetacea* are not met with in the high seas, far away from the shore. Their food consists entirely of aquatic plants, either marine algæ or freshwater grasses, upon which they browse beneath the surface, as the terrestrial herbivorous mammals do upon the green pastures on shore. They are generally gregarious, slow and inactive in their movements, mild, inoffensive, and apparently unintelligent in disposition. Though occasionally found stranded by the tide or waves, there is no satisfactory evidence that they voluntarily leave the water to bask or feed on the shore. The habit of the Dugong of raising its round head out of water, and carrying its young under the fore fin, seems to have given rise, among the imaginative early voyagers in the Indian Ocean, to the legendary beings, half human and half fish, in allusion to which the name *Sirenia* was bestowed by Illiger on the order, though certainly the face of a Dugong, when closely inspected, does not bear the slightest resemblance to that of the mermaid of romance. The species now existing are very few, and there is reason to believe that the time is not far distant when they will all become extinct. One species, *Rhytina stelleri*, of the North Pacific, was totally exterminated through the agency of man during the last century; and the others, being valuable for their flesh as food, for their hides, and especially for the oil obtained from the thick layer of fat which lies immediately beneath their skin, rapidly diminish in numbers as civilized populations occupy the regions forming their natural habitat. The surviving species are confined to the tropical regions of the shores of both sides of the Atlantic and the great rivers which empty themselves into that ocean, and to the coasts of the Indian Ocean from the Red Sea to North Australia. In the Miocene and early Pliocene epoch Sirenians abounded in the seas of Europe, and their remains have been found in deposits of corresponding periods of North America. Evidence has also been discovered of the existence of an animal of the group in the seas at the bottom of which the Eocene nummulitic limestone mountain ranges of Egypt were deposited.

The existing genera present such well-marked distinguishing characters that, if they alone were known, they might be placed in separate families; but, as in so many similar cases, our knowledge of the extinct forms, imperfect as it is, goes far to bridge over the distinction between them.

Manatus.—Incisors $\frac{2}{2}$, rudimentary, concealed beneath the horny oral plates, and disappearing before maturity. Molars $\frac{11}{11}$, but rarely more than $\frac{6}{6}$ present at one time; the anterior teeth falling before the posterior come into use; similar in characters from beginning to end of the series; with square, enamelled crowns, the grinding surface raised into tuberculated transverse ridges. The upper teeth with two ridges and three roots, the lower teeth with an additional (posterior) ridge or talon and two roots. The cervical vertebræ present the remarkable anomaly of being reduced to six in number, the usual vertebral formula being C 6, D 15–18, L and C 25–29. Rostrum of the skull, formed by the union of the premaxillæ in front of the anterior narial aperture, shorter than the length of the aperture and scarcely deflected from the basi-cranial axis. Tail entire, rounded or shovel-shaped. Rudimentary nails on the fore limbs. Cæcum bifid. Habitat the shores of, and the great rivers which empty themselves into, the Atlantic within the tropics. The American and African forms are generally considered to be distinct species (*M. australis* and *M. senegalensis*), though they differ but little from each other in anatomical characters and in habits. They are rather fluviatile than marine, ascending large rivers almost to their sources. See MANATEE.

Halicore.—In the upper jaw a pair of large, nearly straight, tusk-like incisors, directed downwards and forwards, partially coated with enamel. In the male they have persistent pulps, and bevelled cutting edges, which project a short distance from the mouth, but in the female, though they remain through life in the alveolar cavity, they are not exserted, and, the pulp cavity being filled with osteodentine, they soon cease to grow (as in the female Narwhal). In the young there is also a second small deciduous incisor on each side above. At this age there are also beneath the horny plate which covers the anterior portion of the mandible four pairs of slender conical teeth lodged in wide alveolar depressions. These become absorbed before the animal reaches maturity. The molars are usually $\frac{5}{5}$, sometimes $\frac{6}{6}$, altogether, but not all in place at once, as the first falls before the last rises above the gum; they are more or less cylindrical in section, except the last, which is compressed and grooved laterally, without distinction into crown and root, increasing in size from before backwards, with persistent pulps and no enamel. The summits of the crowns are tuberculated before wearing, afterwards flattened or slightly concave. Skull with rostrum formed by the union of the premaxillæ in front of the narial aperture, longer than the aperture itself, bending downwards at a right angle with the basi-cranial axis, and enclosing the sockets of the large incisor tusks. Anterior part of the lower jaw bent down in a corresponding manner. Vertebræ: C 7, D 18–19, L and C 30. Tail broadly notched in the middle line, and with two pointed lateral lobes. No nails on the fore limbs. Cæcum single.

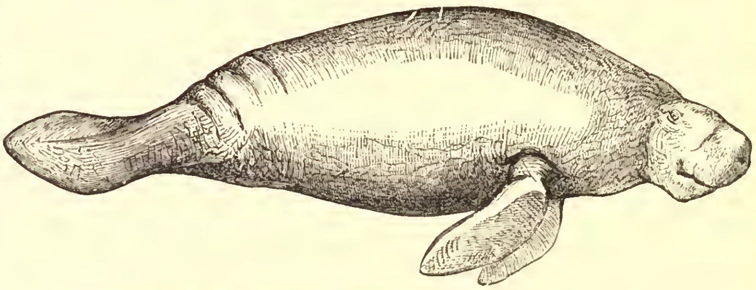

FIG. 41.—American Manatee (*Manatus australis*), from life. *Proc. Zool. Soc.*, 1881, p. 457.

The Dugongs are more distinctly marine in their habits than the Manatees, feeding chiefly on sea-water algæ. They inhabit the shallow bays and creeks of the Red Sea, east coast of Africa, Ceylon, islands of the Bay of Bengal and the Indo-Malayan Archipelago (including the Philippines), and the north coast of Australia, ranging from Barrow Reefs on the west to Moreton Bay on the east. Though the distinctive characters are not very obvious, they have been divided into three species, according to the localities which they respectively inhabit:—*H. tabernaculi* from the Red Sea, *H. dugong* from the Indian seas, and *H. australis* from Australia. The last-named has lately been the object of a regular "fishery," chiefly on account of its oil, which is peculiarly clear, limpid, and free from disagreeable smell, and is said to have the same medical properties as cod-liver oil. Although often stated in books to attain the length of 20 feet when adult, there does not appear to be any evidence from actual specimens in museums that Dugongs ever reach half that size, 8 feet being the common length of adult animals.

Rhytina.—No teeth, their place being supplied functionally by the dense, strongly-ridged, horny oral plates. Premaxillary rostrum about as long as the anterior narial aperture, and moderately deflected. Vertebræ: C 7, D 19, L and C 34–37. Head very small in proportion to the body. Tail with two lateral pointed lobes. Pectoral limbs small and truncated. Skin naked and covered with a very thick, hard, rugged bark-like epidermis. Stomach without cæcal appendages to the pyloric cavity. Cæcum simple.

Only one species of this genus is known, *R. stelleri*, the Northern Sea-cow, by far the largest animal of the order, attaining the length of 20 to 25 feet. It was formerly an inhabitant of the shores of two small islands in the North Pacific, Behring's and the adjacent Copper Island, on the former of which it was discovered by the ill-fated navigator whose name the island bears, when, with his accomplished companion, the German naturalist Steller, he was wrecked upon it in 1741. Twenty-seven years afterwards (1768), as is commonly supposed, the last of the race was killed,[1] and its very existence would have been unknown to science but for the interesting account of its anatomy and habits left by Steller, and the few more or less perfect skeletons which have recently rewarded the researches carried on in the frozen soil of the islands around which it dwelt. There is no evidence at present of its having inhabited any other coasts than those of the islands just named, though it can hardly be supposed that its range was always so restricted. When first discovered it was extremely numerous in the shallow bays round Behring's Island, finding abundant nutriment in the large laminariæ growing in the sea. Its extirpation is entirely due to the Russian hunters and traders who followed upon the track of the explorers, and who, upon Steller's suggestion, lived upon the flesh of the great Sea-cows. Its restricted distribution, large size, inactive habits, fearlessness of man, and even its affectionate disposition towards its own kind when wounded or in distress, all contributed to accelerate its final extinction.

Extinct Sirenia.

The Miocene and early Pliocene seas of Europe abounded in Sirenians, to which the generic name of *Halitherium* was given by Kaup. They had large tusk-like incisors in the upper jaw, as in the existing Dugongs, though not so greatly developed. Their molar teeth were $\frac{5}{5}$ or $\frac{6}{6}$, anteriorly simple and single-rooted, posteriorly those above with three and those below with two roots, and with enamelled and tuberculated or ridged crowns, in all which respects they more resemble those of the Manatee than of the Dugong. The anterior molars were deciduous. Some species at least had nasal bones, short, broad, but normal in position, whereas in all the existing genera these bones are quite rudimentary. Another and still more important evidence of conformity to the general mammalian type is the better development of the pelvic bone, and the presence of a small styliform femur articulated to the acetabulum, although no traces of any other part of the limb have been discovered. These ancient Sirenians were thus, in dental, cranial, and other osteological characters, less specialized than are either of the existing species, and, if the intermediate links could be discovered, might well be looked upon as ancestral forms from which the latter have been derived, but at present the transitional conditions have not been detected. So far as is yet known, when changes in the physical conditions of the European seas rendered them unfitted to be the habitation of Sirenians, the Halitherium type still prevailed. If the existing Dugongs and Manatees are descended from it, their evolution must have taken place during the Pliocene and Pleistocene epochs, the one in seas to the east, the other to the west of the African continent, which has long formed a barrier to their intercommunication. Halitherium remains have been found in many parts of Germany, especially near Darmstadt, also in France, Italy, Belgium, Malta, the isthmus of Suez, &c. Until lately none were known from England, probably owing to the absence of beds of an age corresponding to those in which they are found on the European continent; but recently a skull and several teeth have been detected among the rolled debris of Miocene formations, out of which the Red Crag of Suffolk is partially composed. The species are not yet satisfactorily characterized. Some of them appear to have attained a larger size than the existing Manatee or Dugong. One of these from the Pliocene of Italy and France, having but $\frac{5}{5}$ molar teeth, has been separated generically under the name of *Felsinotherium* by Capellini, by whom it has been fully described. A portion of a skull found in Belgium has been named *Crassitherium* by Van Beneden; and some compressed teeth, somewhat similar to but larger than those of the Dugong, discovered in the department of Lot-et-Garonne, France, gave origin to the genus *Rytiodus* of E. Lartet. Of this more complete remains have recently been described by Delfortrie. The rostrum is more elongated than in *Halitherium*, but the skull is otherwise very similar, as are the molar teeth. The incisors are very large, exserted, strongly compressed, almost sabre-like, rounded on the upper or anterior surface, sharp below, concave on the external and convex on the inner side, and transversely striated.

Pachyacanthus of Brandt, from the Vienna basin, is also, according to Van Beneden, another form of *Sirenia*, of which, however, the skull is not known. In various Miocene and perhaps Eocene marine formations of the United States of America remains of Sirenians have been found, but mostly in such a fragmentary condition that they afford at present little evidence of the early history of the group in that country. A more satisfactory discovery is that of a nearly complete skull and some bones from a limestone Tertiary formation in Jamaica. It is of smaller size than the Manatee, and as far as the teeth are concerned, of a still more generalized character than *Halitherium*, the dentition being apparently $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{5}{5}$, $m\ \frac{3}{3} = 48$. The incisors are small, not developed into tusks; the canines (wanting in all existing Sirenians) are rather larger than the incisors, judging by the sockets; and the molars are bilophodont, and covered with enamel. It has been described by Professor Owen under the name of *Prorastomus sirenoides*. Unfortunately we have no knowledge of the geological antiquity of the formation in which it was embedded. Lastly must be mentioned the *Eotherium egyptiacum*, Owen, founded on the cast of a brain, with a small quantity of surrounding bone, discovered in the nummulitic limestone of Eocene age of the Mokattam Hills, near Cairo. The brain is narrower than in *Manatus*, and resembles that of *Halitherium*. This is of interest as the most ancient known evidence of any Sirenian whose age has been geologically determined.

The few facts as yet collected relating to the former history of the *Sirenia* leave us as much in the dark as to the origin and affinities of this peculiar group of animals as we were when we only knew the living members. They lend no countenance to their association with the *Cetacea*, and on the other hand their supposed affinity with the *Ungulata*, so much favoured by modern zoologists, receives no very material support from them.

Bibliography of Sirenia.—J. F. Brandt, *Symbolæ Sirenologicæ*, St Petersburg, 3 fasciculi, 1846-61-68,—an exhaustive account of the anatomy, affinities, and literature of the group, with copious illustrations of the osteology of *Rhytina*. *Anatomy of Dugong*:—Everard Home, *Phil. Trans.*, 1820, p. 315; Owen, *Proc. Zool. Soc.*, 1838, p. 29. *Manatee*:—Vrolik, *Bijdr. tot de Dierkunde*, 1851; Murie, *Trans. Zool. Soc. Order CETACEA.

This is perhaps the most distinctly circumscribed and natural of all the larger groups into which the class is divided.

The external form is Fish-like, the body being fusiform, passing anteriorly into the head without any distinct constriction or neck, and posteriorly tapering off gradually towards the extremity of the tail, which is provided with a pair of lateral, pointed expansions of skin supported by dense fibrous tissue, called "flukes," forming together a horizontally placed triangular propelling organ, notched in the middle line behind.

The head is generally large, in some species attaining to even more than one-third of the entire length of the animal, and the aperture of the mouth is always wide, and bounded by stiff immobile lips. The fore limbs are reduced to the condition of flattened ovoid paddles, encased in a continuous integument, showing no external sign of division into fore arm and manus, or of separate digits, and without any trace of nails. There are no signs of hind limbs visible externally. The general surface of the skin is smooth and glistening, and devoid of hair, although in many species there are a few fine bristles in the neighbourhood of the mouth, which may persist through life or be present only in the young state. Immediately beneath the skin, and intimately connected with it, is a thick layer of fat, held together by a dense mesh of areolar tissue, constituting the "blubber," which serves the purpose of the hairy covering of other mammals in retaining the heat of the body. In nearly all species a compressed median dorsal tegumentary fin is present. The eye is small, and is not provided with a nictitating membrane or true lacrymal apparatus. The external auditory meatus is a very minute aperture in the skin situated at a short distance behind the eye, and there is no vestige of a pinna. The nostrils open separately or by a single crescentic valvular aperture, not at the extremity of the snout, but near the vertex.

The bones generally are spongy in texture, the cavities being filled with oil. In the vertebral column, the cervical region is remarkably short and immobile, and the vertebræ, originally always seven in number, are in many species more or less fused together into a solid mass. The odontoid process of the axis, when that bone is free, is usually very obtuse, or even obsolete. None of the vertebræ are united

[1] Nordenskiöld, during his recent voyage in the "Vega," obtained some information from natives of Behring's Island which led him to believe that a few individuals may have survived to a much later date, even to 1854.

together to form a sacrum. The lumbar and caudal vertebræ are numerous and large, and, as their arches are not connected by any articular processes (zygapophyses), they are capable of a very free motion in all directions. The epiphyses at the ends of the vertebral bodies are very distinct flattened disks, not uniting until after the animal has attained its full dimensions.[1] There are largely developed chevron bones, the presence of which indicates the distinction between the caudal and lumbar vertebræ.

The skull is modified in a very peculiar manner. The brain-case is short, broad, and high, almost spherical in fact. The supra-occipital bone rises upwards and forwards from the foramen magnum, to meet the frontals at the vertex, completely excluding the parietals from the upper region of the cranium. The frontals are expanded laterally to form the roof of the orbits. The anterior narial aperture opens upwards, and has in front of it a

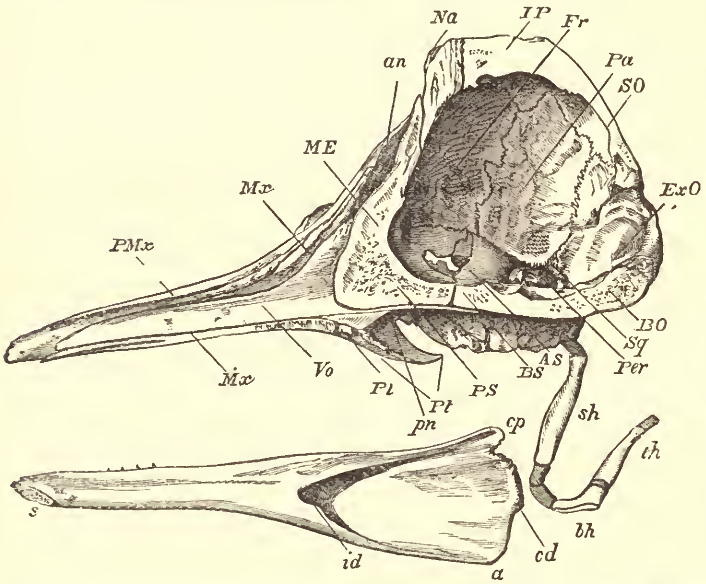

FIG. 42.—A Section of the Skull of a Young Dolphin (*Globicephalus melas*). ×⅛. *PMx*, premaxilla; *Mx*, maxilla; *ME*, ossified portion of the mesethmoid; *an*, anterior nares; *Na*, nasal; *IP*, inter-parietal; *Fr*, frontal; *Pa*, parietal; *SO*, supra-occipital; *ExO*, ex-occipital; *BO*, basi-occipital; *Sq*, squamosal; *Per*, periotic; *AS*, alisphenoid; *PS*, presphenoid; *Pt*, pterygoid; *pn*, posterior nares; *Pl*, palatine; *Vo*, Vomer; *s*, symphysis of mandible; *id*, inferior dental canal; *cp*, coronoid process of mandible; *cd*, condyle; *a*, angle; *sh*, stylo-hyal; *bh*, basi-hyal; *th*, thyro-hyal. From *Osteology of Mammalia*.

more or less horizontally prolonged rostrum, formed of the maxillæ, premaxillæ, vomer, and mesethmoid cartilage, extending forwards to form the upper jaw or roof of the mouth.

There are no clavicles. The humerus is freely movable on the scapula at the shoulder-joint, but beyond this the articulations of the limb are imperfect, flattened ends of the bones coming in contact with each other, with fibrous tissue interposed, allowing of scarcely any motion. The radius and ulna are distinct, and about equally developed, and much flattened, as are all the bones of the manus. There are four, or more commonly five, digits, and the number of the phalanges of the second and third digits always exceeds the normal number in mammals, sometimes very considerably; they present the exceptional character of having epiphyses at both ends.[2] The pelvis is represented by a pair of small styliform bones placed longitudinally, suspended below and at some distance from the vertebral column at the commencement of the caudal region. These appear to represent the ischia, as the crura of the corpora cavernosa are attached to them. In some species, to the outer surface of these are fixed other small bones or cartilages, the rudiments of the hind limb.

Teeth are generally present, but exceedingly variable in number. In the existing species, they are of simple, uniform character, all having conical or compressed crowns and single roots, and are never preceded by milk teeth. They are therefore homodont and monophyodont. In one group, the Mystacocetes, the teeth are absent (except in the fœtal condition), and the palate is provided with numerous transversely placed horny laminæ or "baleen." The salivary glands are rudimentary or absent. The stomach is multilocular. The intestinal canal simple, and only in some species provided with a small cæcum. The liver is very little fissured, and there is no gall-bladder. The vascular system is greatly complicated by arterial and venous plexuses, or *retia mirabilia*. The larynx is of peculiar shape, the arytenoid cartilages and the epiglottis being much elongated, and together forming a tubular prolongation, which projects into the posterior nares, and when embraced by the soft palate forms a continuous passage between the nostrils and the trachea, as in the Ungulates, but in a more perfect manner. The brain is large relatively to the size of the animal, very round in form, and with its surface divided by sulci into very numerous and complex convolutions. The kidneys are deeply lobulated. The testes are abdominal. There are no vesiculæ seminales, nor os penis. The uterus is bicornuate, the placenta non-deciduate and diffuse. The mammæ are two in number, and the nipples placed in depressions on each side of the vulva. The principal ducts of the gland are dilated during lactation into large reservoirs, into which the milk collects, and from which it is injected by the action of a compressor muscle into the mouth of the young animal, by which means the process of sucking under water is greatly facilitated and expedited.

The animals of the order *Cetacea* abound in all known seas, and some species are inhabitants of the larger rivers of South America and Asia. Their organization necessitates their passing their life entirely in the water, as on land they are absolutely helpless. They have, however, to rise very frequently to the surface for the purpose of respiration; and, in relation to the constant upward and downward movement in the water thus necessitated, their principal instrument of motion, the tail, is expanded horizontally, quite unlike that of a Fish, whose movements are mainly in straightforward or lateral directions. The position of the respiratory orifice or nostril on the highest part of the head is very important for this mode of life, as it is the only part of the body the exposure of which above the surface is absolutely necessary. Of the numerous erroneous ideas connected with natural history, few are so widespread and still so firmly believed, notwithstanding repeated expositions of its falsity, as that the *Cetacea* spout out through their blowholes water taken in at the mouth. The fact is, the "spouting," or more properly "blowing," of the Whale is nothing more than the ordinary act of expiration, which, taking place at longer intervals than inland animals, is performed with a greater amount of emphasis. The moment the animal rises to the surface it forcibly expels from its lungs the air taken in at the last inspiration, which of course is highly charged with watery vapour in consequence of the natural respiratory changes. This, rapidly condensing in the cold atmosphere in which the phenomenon is generally observed, forms a column of steam or spray, which has been erroneously taken for

[1] This is an important distinction from the *Sirenia*, but a character common to nearly all other mammals. It is doubtful whether there is any foundation for the statement that these epiphyses remain ununited for an exceptionally long period in the *Cetacea*.

[2] A character repeated in some of the Seals.

water. It also often happens, especially when the surface of the ocean is agitated into waves, that the animal commences its expiratory puff before the orifice has quite cleared the top of the water, some of which may thus be driven upwards with the blast, tending to complete the illusion. In hunting Whales the harpoon often pierces the lungs or air passages of the unfortunate victim, and then fountains of blood may be forced high in the air through the blowholes, as commonly depicted in scenes of Arctic adventure; but this is nothing more (allowance being made for the Whale's peculiar mode of breathing) than what always follows severe wounds of the respiratory organs of other mammals.

All the *Cetacea* are predaceous, subsisting on living animal food of some kind. One genus alone (*Orca*) eats other warm-blooded animals, as seals, and even members of its own order, both large and small. Many feed on fish, others on small floating crustaceans, pteropods, and medusæ, while the principal staple of the food of many is constituted by the various species of cephalopods, *Loligo* and other *Teuthidæ*, which must abound in some seas in vast numbers, as they form almost the entire support of some of the largest members of the order. In size the *Cetacea* vary much, some of the smaller Dolphins scarcely exceeding 4 feet in length, while others are the most colossal of all animals. It is true that most statements of their bulk found in general and even zoological literature are greatly exaggerated, but even when reduced to their actual dimensions (which will be mentioned under the respective genera) some of the existing Whales exceed in size that of any animal living either at present or in former times of which we have any certain evidence. With some exceptions, the *Cetacea* generally are timid inoffensive animals, active in their movements, and very affectionate in their disposition towards one another, especially the mother towards the young, of which there is usually but one, or at most two, at a time. They are generally gregarious, swimming in herds or "schools" (so termed by the whalers) sometimes amounting to many thousands in number; though some species have hitherto only been met with either singly or in pairs.

Relations of the different Cetacea to each other and to other Mammals.—As before said, the *Cetacea* form a perfectly well-defined group, sharply separated from all other mammals, and with no outlying or doubtful forms at present known. Among the existing members of the order, there are two very distinct types, the Toothed Whales or *Odontoceti* and the Baleen Whales or *Mystacoceti*, which present as many marked distinguishing structural characters as are found between many other divisions of the *Mammalia* which are reckoned as orders. The extinct *Zeuglodon*, so far as its characters are known, does not fall into either of these groups, but is in some respects an annectant form, and therefore must be placed, provisionally at least, in a third group by itself.

The Mystacocetes appear at first sight to be the most specialized and aberrant of the existing *Cetacea*, as indicated by the absence of teeth, the presence of baleen, and the form and size of the mouth; but, as we see in other groups, dental characters, and all such as relate to the prehension of food generally, are essentially adaptive and consequently plastic or prone to variation, and hence cannot well be relied upon as tests of affinity. In another character, also adaptive, the laxity of the connexion of the ribs with the vertebral column and with the sternum, and the reduction of that bone in size, allowing great freedom of expansion of the thoracic cavity for prolonged immersion beneath the water, the Mystacocetes have passed beyond the Odontocetes in specialization. On the other hand, the greater symmetry of the skull, the more anterior position of the external nostrils and their double external orifice, the form of the nasal bones, the presence of a distinctly developed olfactory organ, the mode of attachment of the periotic bone to the cranium, the presence of a cæcum and the regular arrangement of the alimentary canal, the more normal characters of the manus and the better development of the muscles attached to it, and the presence, in many species at least, of parts representing not only the bones but the muscles and ligaments of a hind limb,[1] all show less deviation from the ordinary mammalian type than is presented by the Odontocetes. Taking all these characters into consideration, it does not appear reasonable to suppose that either type has been derived from the other, at all events in the form in which we see it now, but rather that they are parallel groups, both modified in different fashions from common ancestors.

Among the Mystacocetes, in the especially distinguishing characters of the division, the *Balænopteræ* are less specialized than the *Balænæ*, which in the greater size of the head, the length and compression of the rostrum, the development of the baleen, and shortness of the cervical region are exaggerated forms of the type, and yet they retain more fully some primitive characters, as the better development of the hind limb, the pentadactylous manus, and the absence of a dorsal fin. Both forms are found distinct in a fossil state as far back as the early Pliocene age, but generally represented by smaller species than those now existing. The Mystacocetes of the Miocene seas were, so far as we know at present, only *Balænopteræ*, some of which (*Cetotherium*) were, in the elongated flattened form of the nasal bones, the greater distance between the occipital and frontal bone at the top of the head, and the greater length of the cervical vertebræ, more generalized than those now existing. In the shape of the mandible also, Van Beneden, to whose researches we are chiefly indebted for a knowledge of these forms, discerns some approximation to the Odontocetes.

Among the last-named group there are several distinct types, of which that represented by *Platanista*, although in some respects singularly modified, has been considered to present on the whole approximations towards the more normal and general type of mammalian structure. It is therefore interesting to find a similar form well represented among the earliest fossil remains of Cetaceans in Europe. Almost all the other members of the suborder range themselves under the two principal heads of Ziphioids (or Physeteroids) and Delphinoids. The former is an ancient and once abounding type, of which the Sperm Whale (*Physeter*) is a highly specialized form. Among the latter, *Globicephalus* is a modified form as regards the structure of its anterior extremity, and *Monodon* as regards its dentition, while *Delphinus* with its various minor subdivisions may be regarded as the dominating type of Cetaceans at the present day, abundant in slightly differentiated species and abundant in individuals. They are in this respect to the rest of the order much as the hollow-horned Ruminants are to the Ungulates.

The earliest Cetaceans of whose organization we have anything like complete evidence are the Zeuglodons of the Eocene period,[2] which approach in the structure of skull and teeth to a more generalized mammalian type than either of the existing suborders. The smallness of the cerebral cavity compared with the jaws and the rest of the skull they share with the primitive forms of many other types. The forward

[1] These have recently been described in detail by Professor Struthers in the *Journal of Anatomy and Physiology*, 1881.

[2] The cervical vertebra of *Palæocetus*, supposed to be from the Cambridge Greensand, and a single caudal vertebra lately found in the Upper Eocene at Roydon in Hampshire, may for the present be omitted from consideration, as too inconclusive in the nature of the evidence they afford as to the history of the group.

position of the narial aperture and the length and flatness of the nasal bones, which distinguish them from all existing forms, we must also suppose to be a character at one time common to all Cetaceans, though now retained (but to a less degree) only by the Mystacocetes. Even *Squalodon*, which in its heterodont dentition so much resembles *Zeuglodon* as to have been placed by some zoologists in the same genus, entirely differs from it, and conforms with the ordinary Dolphins in its essential cranial characters.

The origin of the *Cetacea* is at present involved in much obscurity. They present no signs of closer affinity to any of the lower classes of vertebrates than do many other members of their own class. Indeed in all that essentially distinguishes a mammal from the oviparous vertebrates, whether in the osseous, nervous, reproductive, or any other system, they are as truly mammalian as any other group. Any supposed marks of inferiority, as absence of limb structure, of hairy covering, of lacrymal apparatus, &c., are obviously modifications (or degradations, as they may be termed) in adaptation to their special mode of life. The characters of the teeth of *Zeuglodon* and other extinct forms, and also of the fœtal Mystacocetes, clearly indicate that they have been derived from mammals in which the heterodont type of dentition was fully established. The steps by which a land mammal may have been modified into a purely aquatic one are clearly indicated by the stages which still survive among the *Carnivora*, in the *Otariæ*, and in the true Seals. A further change in the same direction would produce an animal somewhat resembling a Dolphin, and it has been thought that this may have been the route by which the Cetacean form has been developed. There are, however, great difficulties in the way of this view. If the hind limbs had ever been developed into the very efficient aquatic propelling organs they present in the Seals, it is not easy to imagine how they could have become completely atrophied and their function transferred to the tail. It is more likely that the Whales were derived from animals with long tails, which were used in swimming, eventually with such effect that the hind limbs became no longer necessary. The powerful tail, with its lateral cutaneous flanges, of an American species of Otter (*Pteronura sandbachii*) may give an idea of this member in the primitive Cetaceans. But the structure of the *Cetacea* is, in so many essential characters, so unlike that of the *Carnivora* that the probabilities are against these orders being nearly related. Even in the skull of the Zeuglodon, which has been cited as presenting a great resemblance to that of a Seal, quite as many likenesses may be traced to one of the primitive Pig-like Ungulates (except in the purely adaptive character of the form of the teeth), while the elongated larynx,[1] complex stomach, simple liver, reproductive organs both male and female, and fœtal membranes of the existing *Cetacea* are far more like those of that group than of the *Carnivora*. Indeed it appears probable that the old popular idea which affixed the name of "Sea-Hog"[2] to the Porpoise contains a larger element of truth than the speculations of many accomplished zoologists of modern times. The fact that *Platanista*, which, as mentioned above, appears to retain more of the primitive characteristics of the group than any other existing form, and also the somewhat related *Inia* from South America, are both to the present day exclusively fluviatile, may point to the freshwater origin of the whole group, in which case their otherwise rather inexplicable absence from the seas of the Cretaceous period would be accounted for.

[1] There is much resemblance in the larynx of the Hippopotamus, but none in that of the Seal, to the same organ in the *Cetacea*.

[2] German, *Meerschwein*, whence the French *Marsouin*. "Porpoise" is said to be derived from "*Porc-poisson*."

Suborder *MYSTACOCETI*,
the Balænoidea, *or Whalebone Whales.*

Teeth never functionally developed, but always disappearing before the close of intra-uterine life. Palate provided with plates of baleen or "whalebone." Skull symmetrical. Nasal bones forming a roof to the anterior nasal passages, which are directed upwards and forwards. Maxilla produced in front of, but not over, the orbital process of the frontal. Lacrymal bones small and distinct from the jugal. Tympanic bone ankylosed with the periotic, which is attached to the base of the cranium by two strong diverging processes. Olfactory organ distinctly developed. Rami of mandible arched outwards, their anterior ends meeting at an angle, and connected by fibrous tissue without any true symphysis. All the ribs at their upper extremity articulating only with the transverse processes of the vertebræ; their capitular processes when present not articulating directly with the bodies of the vertebræ. Sternum composed of a single piece, and articulating only with a single pair of ribs. No ossified sternal ribs. External openings of nostrils distinct from each other, longitudinal. A short conical cæcum.

These animals have, when in the fœtal state, numerous, minute, calcified teeth lying in the dental groove of both upper and lower jaws. They are best developed about the middle of fœtal life, after which period they are absorbed, and no trace of them remains at the time of birth.[3] The baleen or whalebone does not make its appearance until after birth. It consists of a series of flattened horny plates, between three and four hundred in number, on each side of the palate, with a bare interval along the middle line. They are placed transversely to the long axis of the palate, with very short intervals between them. Each plate or blade is somewhat triangular in form, with the base attached to the palate and the apex hanging downwards. The outer edge of the blade is hard and smooth, but the inner edge and apex fray out into long bristly fibres, so that the roof of the whale's mouth looks as if covered with hair, as described by Aristotle. At the inner edge of each principal blade are two or three much smaller or subsidiary blades. The principal blades are longest near the middle of the series, and gradually diminish towards the front and back of the mouth. The horny plates grow from a dense fibrous and highly vascular matrix, which covers the palatal surface of the maxillæ, and which sends out lamellar processes, one of which penetrates the base of each blade. Moreover, the free edge of these processes is covered with very long vascular thread-like papillæ, one of which forms the central axis of each of the hair-like epidermic fibres of which the blade is mainly composed. A tranverse section of fresh whalebone shows that it is made up of numbers of these soft vascular papillæ, circular in outline, each surrounded by concentrically arranged epidermic cells, the whole bound together by other epidermic cells, that constitute the smooth cortical (so-called "enamel") surface of the blade, which, disintegrating at the free edge, allows the individual fibres to become loose and assume the hair-like appearance before spoken of. These fibres differ from hairs in not being formed in depressed follicles in the enderon, but rather resemble the fibres composing the horn of the Rhinoceros. The whalebone in fact consists of nothing more than modified papillæ of the buccal mucous membrane, with an excessive and cornified epithelial development. The blades are supported, and bound together for a certain distance from their base, by a mass of less hardened epithelium, secreted by the surface of the palatal membrane or matrix of the whalebone in the intervals of the lamellar processes. This is the "intermediate substance" of Hunter, the "gum" of the whalers. Baleen varies much in colour in different species. In some it is almost jet black, in others slate colour, horn colour, yellow, or even creamy-white. In some the blades are variegated with longitudinal stripes of different hues. It differs also greatly in other respects, being short, thick, coarse, and stiff in some, and greatly elongated and highly elastic in those species in which it has attained its fullest development. Its function is to strain the water from the small marine molluscs, crustaceans, or fish upon which the whales subsist. In feeding they fill the immense mouth with water containing shoals of these small creatures, and then, on their closing the jaws and raising the tongue, so as to diminish the cavity of the mouth, the water streams out through the narrow intervals between the hairy fringe of the whalebone blades, and escapes through the lips, leaving the living prey to be swallowed.[4]

Our knowledge of the different structural modifications at-

[3] These were discovered in the Greenland Whale by Geoffroy St Hilaire, whose observations were confirmed and extended to other genera by Eschricht. They have lately been very fully described in *Balænoptera rostrata* by Julin (*Archives de Biologie*, i., 1880).

[4] For the structure of whalebone, see Hunter, "Observations on the Structure and Economy of Whales," *Phil. Trans.*, 1787; Eschricht and Reinhardt, *On the Greenland Right Whale*, English translation by the Ray Society, 1866, pp. 67–78; and W. Turner, in *Trans. Roy. Soc. Edin.*, 1870.

tained by members of this important group of mammals, though largely increased of late years, is still imperfect. Formerly they were all divided into Right Whales (*Balæna*) and Rorquals or Fin-whales (*Balænoptera*), the latter distinguished by their smaller heads, elongated and slender form, free cervical vertebræ, tetradactylous manus, and the presence of very conspicuous longitudinal furrows or folds in the skin of the throat and chest, and of a small adipose dorsal fin. Recent discoveries have, however, brought to light several forms holding a somewhat intermediate position, and presenting combinations of characters not found in either of the larger known sections. According to our present knowledge the group is naturally divided into five very distinct genera. As these will be more fully described in the article WHALE, it will be sufficient at present to indicate their principal characteristics.

Balæna.—Skin of throat smooth, not furrowed. No dorsal fin. Cervical vertebræ united into a single mass. Pectoral limb short, broad, and pentadactylous. Head very large. Baleen very long and narrow, highly elastic and black. Scapula high, with a distinct coracoid and coronoid process. This genus contains the well-known Greenland Right Whale (*B. mysticetus*) of the Arctic seas, the whalebone and oil of which are so much valued in commerce, and also other whales, distinguished from this by having heads somewhat smaller in proportion to the body, with shorter baleen, and a larger number of vertebræ. These inhabit the temperate seas of both northern and southern hemispheres, and have been divided by zoologists into several species in accordance with their geographical distribution,—*B. biscayensis* of the North Atlantic, *B. japonica* of the North Pacific, *B. australis* of the South Atlantic, and *B. antipodarum* and *novæ-zelandiæ* of the South Pacific; but the differential characters by which they have been separated—external as well as anatomical—are so slight and so liable to individual variation that it is not improbable that when they are better known they will all come to be regarded as forming but a single species.

Neobalæna.—Known chiefly at present by the characters of the skeleton and baleen, which are very different from those of all other whales, but said to combine absence of plications of the throat with the presence of a dorsal fin. The cervical vertebræ are united. The manus small, narrow, and tetradactylous, wanting the pollex. The ribs remarkably expanded and flattened. The scapula very low and broad, with completely developed acromion and coracoid processes. Baleen very long, slender, elastic, and white. A single at present very rare species, *N. marginata*, from the Australian and New Zealand seas, is the smallest of the Whalebone Whales, being not more than 20 feet in length.

Rachianectes.—This combines the small head, elongated form, and narrow pectoral fin of *Balænoptera* with the smooth skin of the throat and absence of the dorsal fin of *Balæna*. The baleen is the shortest and coarsest of any of the group. Its osteology is imperfectly known. One species, *R. glaucus*, the Grey Whale of the North Pacific.

Megaptera.—Head of moderate size. Baleen plates short and broad. Cervical vertebræ free. Scapula with acromion and coracoid process absent or rudimentary. Skin of throat plicated. Dorsal fin low. Pectoral limb tetradactylous, very long and narrow, attaining about one-fourth of the length of the entire animal, the metacarpus and phalanges being greatly developed, and the latter very numerous. Animals of this genus, called "Humpbacks" by the whalers, are found in almost all seas. They have been divided into many species, but no satisfactory characters have yet been pointed out by which these can be distinguished from one another.

Balænoptera.—Head small and flat, and pointed in front. Body long and slender. Skin of throat plicated. A small falcate dorsal fin. Baleen short and coarse. Cervical vertebræ free. Scapula low and broad, with a large acromion and coracoid process. Pectoral limb tetradactylous, small, narrow, and pointed. This genus contains the various species of Rorquals, Fin-whales, Fin-backs, Finners, or Razor-backs, as they are variously called, some of which are found in almost every sea. Among them are the most gigantic of all animals, *B. sibbaldii*, which attains the length of 80 feet, and the small *B. rostrata*, which does not exceed 30. There are certainly four quite distinct modifications of this genus, represented by the two just mentioned, and by *B. musculus* and *B. borealis*, all inhabitants of British seas, but the question whether almost identical forms found in the Southern and Pacific Oceans are to be regarded as specifically identical or as distinct awaits the result of future researches.

SUBORDER *ARCHÆOCETI.*

This group is formed to include certain extinct Cetaceans, which are at present only known by more or less fragmentary portions of their skeleton and teeth, and whose position and affinities are therefore still subject to doubt.

In the anterior part of both jaws the teeth are simple, conical, or slightly compressed, and sharp-pointed. The first three in the upper jaw are distinctly implanted in the premaxillary bone, and so may be reckoned as incisors. The tooth which succeeds, or the canine, is also simple and conical, but it does not exceed the others in size. This is followed by five teeth with two distinct roots, and compressed, pointed crowns, with denticulated cutting edges. The dentition is therefore $i\,\frac{3}{3}$, $c\,\frac{1}{1}$, p and $m\,\frac{5}{5} = 36$, resembling that of some Seals.[1] General form of the skull elongated and much depressed. Brain cavity very small, and the skull between it and the orbits elongated and narrow. Temporal fossæ very large. A strong sagittal crest. Rostrum long and narrow, differing from that of other Cetaceans in the large extent to which the premaxillæ form the sides of the anterior extremity. Nasal bones elongated, flat, and narrow, the opening of the anterior nares being over the middle of the elongated compressed rostrum. All the cervical vertebræ free. The characters of the dorsal vertebræ, and mode of articulation of the ribs, appear to have resembled those of *Platanista* rather than *Balæna*, *Physeter*, or *Delphinus*. Lumbar vertebræ with elongated bodies. Characters of the limbs not known with certainty.[2]

All the known fossil remains belonging to the animals of this group may be referred, provisionally at least, to the genus *Zeuglodon*, so named because the first section of a molar tooth examined was taken from the base of the crown, where it was beginning to divide into the two roots, and looked like two single teeth "linked or yoked together." This name was substituted by Owen for the earlier one *Basilosaurus* of Harlan, with the consent of that author, on the mammalian nature of the animal being demonstrated.[3] The latter name is, however, still generally retained by American zoologists. The remains have hitherto been found chiefly in the Eocene formations of the States of Alabama, Louisiana, Mississippi, and Arkansas, and have been assigned to several species. A portion of a skull is recorded from the Barton Clay (Eocene) of Hampshire, England.

SUBORDER *ODONTOCETI,* *the* DELPHINOIDEA, *or Toothed Whales.*

Calcified teeth always present after birth; generally numerous, but sometimes a very limited number (in a few cases none) are functionally developed. No baleen. Upper surface of the skull more or less asymmetrical. Nasal bones in the form of nodules or flattened plates, applied closely to the frontals, and not forming any part of the roof to the narial passage, which is directed upwards and backwards. Olfactory organ rudimentary or absent. Hinder end of the maxilla expanded and covering the greater part of the orbital plate of the frontal bone. Lacrymal bone either inseparable from the jugal, or, when distinct, very large, and forming part of the roof of the orbit. Tympanic bone not ankylosed with the periotic, which is usually only attached to the rest of the skull by ligament. Rami of mandible nearly straight, much expanded in height posteriorly, with a wide funnel-shaped aperture to the dental canal, and coming in contact in front by a flat surface of variable length, but always constituting a true symphysis. Several of the anterior ribs with well-developed capitular processes, which articulate with the bodies of the vertebræ. Sternum almost always composed of several pieces, placed one behind the other, with which several pairs of ribs are always connected by the intervention of well-developed cartilaginous or ossified sternal ribs. External respiratory aperture single, the two nostrils uniting before they reach the surface, usually in the form of a transverse subcrescentic valvular aperture, situated on the top of the head. Manus always pentadactylous, though the first and fifth digits are usually very little developed. No cæcum, except in *Platanista*.

Family PHYSETERIDÆ.

No functional teeth in the upper jaw. Mandibular teeth various, often much reduced in number. Bones of the cranium raised so as to form an elevated prominence or crest behind the nares. Pterygoid bones thick, produced backwards, meeting in the middle line, and not involuted to form the outer wall of the post-palatine air-sinuses, but simply hollowed on their outer side. Transverse processes of the arches of the dorsal vertebræ, to which the tubercles of the ribs are attached, ceasing abruptly near the end of the series, and replaced by processes on the body at a much lower level, and not on a line, or serially homologous with them, but serially homologous anteriorly with the heads of the ribs, and posteriorly with the transverse processes of the lumbar vertebræ. (In some genera, as *Physeter*, the two processes, upper and lower on each side, are both present and well developed in the same vertebra in the region of transition. In others, as *Ziphius* and *Berardius*, they are not both developed on any single vertebra.) Costal cartilages not ossified.

Subfamily **Physeterinæ.**—Numerous teeth in the mandible, which are not set in distinct bony alveoli, but in a long groove

[1] An appearance in one specimen has been described by C. G. Carus as indicating a vertical succession of the teeth, but the evidence upon which this rests is by no means satisfactory, and appears to admit of another explanation.

[2] A mutilated humerus of *Zeuglodon cetoides* has given rise to many conjectures, appearing to some anatomists to indicate Seal-like freedom of motion at the elbow-joint, while to others its characters appear to be truly Cetacean.

[3] See *Trans. Geol. Soc. Lond.*, ser. ii., vol. vi. p. 67.

imperfectly divided by partial septa, and held in place by the strong, fibrous gum which surrounds them. No distinct lacrymal bone. Cranium strikingly asymmetrical in the region of the narial apertures, in consequence of the left opening greatly exceeding the right in size.

Physeter.—Upper teeth apparently of uncertain number, rudimentary and functionless, being embedded in the gum. Lower jaw with from 20 to 25 teeth on each side, stout, conical, recurved, and pointed at the apex until they are worn, without enamel. Upper surface of the cranium concave; its posterior and lateral edges raised into a very high and greatly compressed semicircular crest or wall. Zygomatic processes of malar bones thick and massive. Rostrum greatly elongated, broad at the base and gradually tapering to the apex. Upper edge of the mesethmoid forming a roughened irregular projection between the narial apertures, inclining to the left side. Mandible exceedingly long and narrow, the symphysis being more than half the length of the ramus. Vertebræ: C 7, D 11,

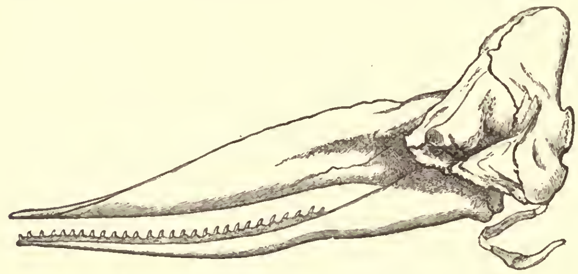

FIG. 43.—Skull of Sperm Whale (*Physeter macrocephalus*).

L 8, C 24; total 50. Atlas free; all the other cervical vertebræ united by their bodies and spines into a single mass. Eleventh pair of ribs rudimentary. Head about one-third the length of the body; very massive, high and truncated, and rather compressed in front; owing its huge size and remarkable form mainly to the great accumulation of a peculiarly modified form of adipose tissue filling the large hollow on the upper surface of the cranium and overlying the rostrum. The single blowhole is longitudinal, slightly sigmoid, and placed at the upper and anterior extremity of the head to the left side of the middle line. The opening of the mouth is on the under side of the head, considerably behind the end of the snout. Pectoral fin short, broad, and truncated. Dorsal fin a mere low protuberance.

There is no certain evidence that more than one species of this genus exists. This is the Cachalot or Sperm Whale, *P. macrocephalus*, one of the most colossal of animals, quite equalling, if not exceeding, the Greenland Whale in bulk. The length of the full-grown male is from 55 to 60 feet, but the female is stated not to reach more than half that size. It feeds chiefly on cephalopods and fish, and is one of the most extensively distributed of Cetaceans, being met with, usually in herds or "schools," in almost all tropical or subtropical seas, but not occurring, except accidentally, in the polar regions. Those that appear occasionally on the British coasts are solitary stragglers, usually, if not always, old males. The oil contained in the great cavity above the skull, when refined, yields "spermaceti," and the thick covering of blubber which everywhere envelops the body produces the valuable "sperm oil" of commerce; hence this animal has long been the subject of a regular chase, by which its numbers have been greatly diminished. The substance called "ambergris," largely used in perfumery, is a concretion formed in the intestine of the Sperm Whale, and is found floating on the surface of the seas which they inhabit. Its genuineness is attested by the presence of the debris of the horny beaks of the cephalopods on which the Whales feed.

Kogia.—Teeth of the upper jaw absent or reduced to a rudimentary pair in front; in lower jaw 9 to 12 on each side, rather long, slender, pointed, and curved, with a coating of enamel. Upper surface of the cranium concave, with thick, raised, posterior and lateral margins, massive and rounded at their anterior terminations above the orbits. Upper edge of the mesethmoid forming a prominent sinuous ridge, constituting a kind of longitudinal septum to the base of the great supra-cranial cavity. Rostrum not longer than the cranial portion of the skull, broad at the base, and rapidly tapering to the apex. Zygomatic process of the malar styliform. Mandible with symphysis less than half the length of the entire ramus. Vertebræ: C 7, D 13 or 14, L and C 30; total 50 or 51. All the cervical vertebræ united by their bodies and arches. External characters not well known, but, judging by the somewhat conflicting accounts of those that have had an opportunity of observing them, the head is about one-sixth of the length of the body, and obtusely pointed in front; the mouth small and placed far below the apex of the snout; the spiracle crescentic, and placed obliquely on the top of the head anteriorly to the eyes, and to the left of the middle line; the pectoral fins are obtusely falcate; and there is a triangular dorsal fin.

The history of this genus is a good illustration of the difficulties in which the study of the *Cetacea* has been involved by the superficial manner in which it has been investigated. The first known example, a skull from the Cape of Good Hope in the Paris Museum, was described by Blainville under the name of *Physeter breviceps*. This was afterwards with good reason generically separated by Gray. Until within a very few years ago only five other individuals had been met with, each of which had been described under a different specific name (viz., *grayi*, *macleayi*, *simus*, *floweri*, and *potsii*), and which are arranged by Gray in two distinct genera. The most careful examination of the description given of these specimens, or of the now numerous osteological remains available, fails to detect any differences beyond those which may be attributed to age or sex; and hence, according to our present knowledge, these six supposed species must all be included under one name, *K. breviceps*, an animal which appears to attain the length of 10 feet when adult, and has been met with at various distant localities in the Southern Ocean, and also off the coast of Madras and in the North Pacific.

Subfamily **Ziphiinæ.**—Teeth of the mandible quite rudimentary and concealed in the gum, except one, or very rarely two, pairs which may be largely developed, especially in the male sex. A distinct lacrymal bone. Externally the mouth is produced into a slender rostrum or beak, from above which the rounded eminence formed by a cushion of fat resting on the cranium in front of the blowhole rises somewhat abruptly. Spiracle or blowhole single, crescentic, median, as in the *Delphinidæ*. Pectoral fin small, ovate, the five digits all moderately well developed. A small obtusely falcate dorsal fin situated considerably behind the middle of the back. Longitudinal grooves on each side of the skin of the throat, diverging posteriorly, and nearly meeting in front. In external characters and habits the animals of this group closely resemble each other. They appear to be almost exclusively feeders on various species of cephalopods, and occur either singly, in pairs, or in small herds. By their dental and osteological characters they are easily separated into four distinct genera.

Hyperoodon.—A small conical pointed tooth at the apex of each ramus of the mandible, concealed by the gum during life. Skull with the upper ends of the premaxillæ rising suddenly behind the nares to the vertex and expanded laterally, their outer edges curving backwards and their anterior surfaces arching forwards and overhanging the nares; the right larger than the left. Nasal bones lying in the hollow between the upper extremities of the premaxillæ, strongly concave in the middle line and in front; their outer edges, especially that of the right, expanded over the front of the inner

FIG. 44.—*Hyperoodon rostratus.* From a specimen taken off the coast of Scotland, 1882.

border of the maxilla. Very high longitudinal crests on the maxillæ at the base of the rostrum, extending backwards almost to the nares, approaching each other in the middle line above; sometimes compressed and sometimes so massive that their inner edges come almost in contact. Anteorbital notch distinct. Mesethmoid but slightly ossified. Vertebræ: C 7, D 9, L 10, C 19; total 45. All the cervical vertebræ united. Upper surface of the head in front of the blowhole very prominent and rounded, rising abruptly from above the small, distinct snout.

Two species are known, *H. rostratus*, the common Hyperoodon or Bottle-nose, and *H. latifrons*, both inhabitants of the North Atlantic, and attaining when adult respectively the length of 24 and 30 feet.

Ziphius.—A single conical tooth of moderate size on each side of the mandible close to the anterior extremity, and directed forwards and upwards. Skull with the premaxillæ immediately in front and at the sides of the nares expanded, hollowed, and with elevated lateral margins, the posterior ends rising to the vertex and curving forwards, the right being considerably more developed than the left; the conjoint nasals forming a strongly pronounced symmetrical eminence at the top of the cranium, projecting forwards over the nares, flat above, most prominent and rounded in the middle line in front, and separated by a notch on each side from the premaxillæ. Anteorbital notch not distinct. Rostrum (seen from above) triangular, gradually tapering from the base to the apex; upper and outer edges of maxillæ at base of rostrum raised into low roughened tuberosities. Mesethmoid cartilage densely ossified in adult age, and coalescing with the surrounding bones of the rostrum. Vertebræ: C 7, D 10, L 10, C 22; total 49. The three anterior cervical vertebræ united, the rest free.

The type of this genus is *Z. cavirostris* of Cuvier, founded upon an imperfect skull picked up in 1804 on the Mediterranean coast of France, and described and figured in the *Ossemens Fossiles* under the impression that it was that of an extinct species. Many other individuals have, however, been subsequently met with in various parts of the world, from the Shetland Islands to New Zealand, all referable to the same genus if not to the same species; although, as is usual in such cases, they have mostly been described under different names. Teeth, apparently of allied forms, are abundantly found in the Suffolk and Antwerp Crags.

Mesoplodon.[1]—A much compressed and pointed tooth in each ramus of the mandible, variously situated, but generally at some distance behind the apex; its point directed upwards, and often somewhat backwards, occasionally developed to a great size. Skull with the region around the nares as in *Hyperoodon*, except that the nasals are narrow and more sunk between the upper ends of the

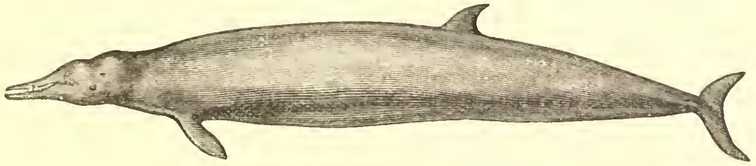

FIG. 45.—*Mesoplodon bidens.* From Reinhardt.

premaxillæ; like those of *Hyperoodon*, they are concave in the middle line in front and above. No maxillary tuberosities. Anteorbital notch not very distinct. Rostrum long and narrow. Mesethmoid in adult age ossified in its entire length, and coalescing with the surrounding bones. Vertebræ: C 7, D 10, L 10 or 11, C 19 or 20; total 46 to 48. Two or three anterior cervicals united, the rest usually free.

Though varying in form, the mandibular teeth of the different members of this genus agree in their essential structure, having a small and pointed enamel-covered crown, composed of true dentine, which, instead of surmounting a root of the ordinary character, is raised upon a solid mass of osteodentine, the continuous growth of which greatly alters the form and general appearance of the organ as age advances, as seen most strikingly in the case of *M. layardi*, where the long, narrow, flat, strap-like teeth, curving inwards at their extremities, actually meet over the rostrum, and must greatly interfere with the movements of the jaw. In one species (*M. grayi*) a row of minute, conical, pointed teeth, like those of ordinary Dolphins, 17 to 19 in number, are present even in the adults, on each side of the middle part of the upper jaw, but embedded by their roots only in the gum, and not in bony alveoli. This fact, with the frequent presence of rudimentary teeth in other species of this and the last genus in both upper and lower jaws, suggests the idea that the Ziphioids are derived from ancestral forms having teeth of normal character in both jaws, but whose dentition

FIG. 46.—Skull of *Mesoplodon densirostris.*

has become greatly specialized. The existing species of this genus are widely distributed in both northern and southern hemispheres, but most frequent in the latter. The best established are *M. bidens*, *M. europæus*, *M. densirostris*, *M. layardi*, *M. grayi*, and *M. hectori*; but there is still much to be learned with regard to their distinctive characters and geographical distribution. They were abundant in the Later Miocene and Pliocene age, as attested by the frequency with which the most imperishable and easily recognized portion of their structure, the long, cylindrical rostrum of the skull, of more than ivory denseness, is found among the rolled and waterworn fragments of animal remains which compose the well-known "bone-bed" at the base of the Red Crags of Suffolk. Numerous generic distinctions have been founded upon slight modifications of the form of these rostra, such as *Choneziphius*, *Placoziphius*, *Belemnoziphius*, &c., but these can only be considered as provisional until further knowledge is obtained of the structure of the animals to which they belonged.

[1] For the very complicated synonymy of this genus, see *Trans. Zool. Soc.*, vol. viii. p. 208.

Berardius.—Two moderate-sized, compressed, pointed teeth on each side of the symphysis of the mandible, with their apices directed forwards, the anterior being the larger of the two and close to the apex. Upper ends of the premaxillæ nearly symmetrical, moderately elevated, very slightly expanded, and not curved forward over the nares. Nasals broad, massive, and rounded, of nearly equal size, forming the vertex of the skull, flattened in front, most prominent in the middle line. Anteorbital notch distinct. Rostrum long and narrow. Mesethmoid only partially ossified. Small rugous eminences on the outer edge of the upper surface of the maxillæ at base of rostrum. Vertebræ: C 7, D 10, L 12, C 19; total 48. The three anterior cervicals ankylosed, the rest free and well developed.

The only known species, *B. arnouxi*, attains the length of 30 feet, and has hitherto only been met with in the seas around New Zealand.

Family SQUALODONTIDÆ.

Numerous extinct forms, chiefly known by teeth and fragments of crania, may be provisionally placed here, until more of their osteological characters shall be brought to light. They differ from all existing Cetaceans in having the teeth distinctly differentiated into groups, as in the *Archæoceti*, the posterior molars being two-rooted. The cranium, has, however, none of the distinguishing characteristics of the Zeuglodons, but essentially resembles that of the *Odontoceti*, especially in the position of the anterior nares and form of the nasal bones.

The best-known are associated in the genus *Squalodon*. Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, simple teeth of the molar series (premolars?) $\frac{4}{4}$, two-rooted molars $\frac{7}{7} = \frac{15}{15}$; total 60. The double-rooted molars differ from those of *Zeuglodon* in having the denticulations of the crown confined to the posterior border, or at all events much less developed on the front edge. Very little is known of the structure of these animals, beyond the skull and teeth, fragments of which have been found widely distributed throughout the marine Miocene and Early Pliocene formations of Europe, especially in the Vienna basin, many parts of France, and the Antwerp and Suffolk Crags. They have also been found in formations of corresponding age in North America and South Australia.

Family PLATANISTIDÆ.

Under this heading may be placed three very singular genera, which, though differing considerably from each other, have several points in common, and do not altogether come under the definition either of the *Physeteridæ* or the *Delphinidæ*, especially in the important character of the mode of articulation of the ribs with the dorsal vertebræ, as the tubercular and capitular articulations, distinct at the commencement of the series, gradually blend together, as they do in most ordinary mammals. The cervical vertebræ are all free. The lacrymal bone is not distinct from the malar. The jaws are long and narrow, with numerous teeth in both. The symphysis of the mandible exceeds half the length of the whole ramus. Externally the head is divided from the body by a slightly constricted neck. Pectoral limbs broad and truncated. Dorsal fin small or obsolete. Fluviatile or estuarine. There are three distinct genera, which might almost be made the types of families, but it is probably more convenient to keep them together.

Platanista.—Teeth about $\frac{30}{30}$ on each side, set near together, rather large, cylindrical, and sharp-pointed in the young; in old animals acquiring a large laterally compressed base, which in the posterior part of the series becomes irregularly divided into roots. As the conical enamel-covered crown wears away, the teeth of the young and old animals have a totally different appearance. The rostrum and dentigerous portion of the mandible are so narrow that

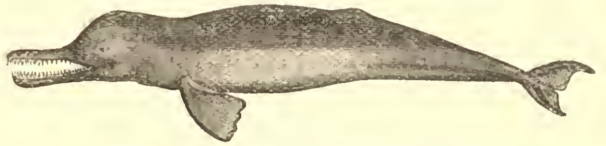

FIG. 47.—*Platanista gangetica.* From Anderson.

the teeth of the two sides are almost in contact. Maxillæ supporting very large, incurved, compressed bony crests, which overarch the nares and base of the rostrum, and almost meet in the middle line above. Orbits very small and eyes rudimentary, without crystalline lens. External respiratory aperture longitudinal, linear. Vertebræ: C 7, D 11, L 8, C 25; total 51. A small cæcum. No pelvic bones. Dorsal fin represented by a low ridge.

One species, *P. gangetica*, entirely fluviatile, being extensively distributed throughout nearly the whole of the river systems, not only of the Ganges, but of the Brahmaputra and Indus, ascending as high as there is water enough to swim in, but never passing out to sea. It is quite blind, and feeds on small fish and *Crustacea*, groping for them with its long snout in the muddy water at the bottom of the rivers. It attains the length of 8 feet.

Inia.—Teeth variable, from 26 to 33 on each side of each jaw; those at the posterior part with a distinct tubercle at the inner side of the base of the crown. Vertebræ: C 7, D 13, L 3, C 18; total 41. Transverse processes of lumbar vertebræ very broad. Sternum short and broad, and consisting of a single segment only. Dorsal fin a mere ridge. The long cylindrical rostrum externally furnished with scattered, stout, and crisp hairs. One species only is known, *I. geoffrensis*, about 8 feet in length, inhabiting the upper Amazon and its tributary streams.

Pontoporia.—Teeth 50 to 60 on each side of each jaw, with a cingulum at the base of the crown. Jaws very long and slender. Vertebræ: C 7, D 10, L 5, C 19; total 41. Transverse processes of the lumbar vertebræ extremely broad. Sternum elongated, composed of two segments, with four sternal ribs attached. Dorsal fin rather small, triangular, pointed. External respiratory aperture transverse,

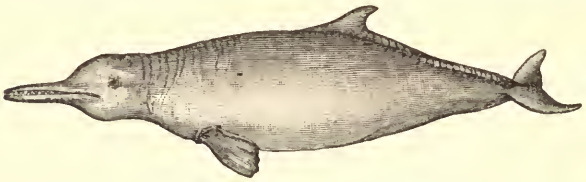

FIG. 48.—*Pontoporia blainvillii.* From Burmeister.

crescentic. This genus connects the last two forms with the true *Delphinidæ.* The only species, *P. blainvillii*, is one of the smallest of the whole order, not exceeding 5 feet in length. It has only been met with at the mouth of the Rio de la Plata, near Buenos Ayres, and there is at present no evidence that it ascends into the fresh waters of the river.

Family DELPHINIDÆ.

Teeth usually numerous in both jaws. Pterygoid bones short, thin, each involuted to form with a process of the palate bone the outer wall of the post-palatine air-sinus. Symphysis of mandible short, or moderate, never exceeding one-third of the length of the ramus. Lacrymal bone not distinct from the jugal. Transverse processes of the dorsal vertebræ gradually transferred from the arches to the bodies of the vertebræ without any sudden break, and becoming posteriorly continuous serially with the transverse processes of the lumbar vertebræ. Anterior ribs attached to the transverse process by the tubercle, and to the body of the vertebra by the head; the latter attachment lost in the posterior ribs. Sternal ribs firmly ossified. External respiratory aperture transverse, crescentic, with the horns of the crescent pointing forwards.

A very large group, closely united in essential characters but presenting great modifications in details. The different types are mostly so connected by intermediate or osculant forms that there are great difficulties in grouping them into natural subfamilies. Even the formation of well-defined genera is by no means satisfactory in all cases.

Monodon.—Besides some irregular rudimentary teeth, the entire dentition is reduced to a single pair of teeth which lie horizontally in the maxilla, and which in the female remain permanently concealed within the alveolus, so that this sex is practically toothless, while in the male (see fig. 49) the right tooth usually remains similarly concealed and abortive and the left is immensely developed, attaining a length equal to more than half that of the entire animal, projecting horizontally from the head in the form of a cylindrical, or slightly tapering, pointed tusk, without enamel, and with the surface marked by spiral grooves and ridges, running in a sinistral direction. (When, as occasionally happens, both tusks are developed, the spiral grooves have the same direction in each.) Vertebræ: C 7, D 11, L 6, C 26; total 50. Cervical region comparatively long, and all the vertebræ distinct, or with irregular unions towards the middle of the series, the atlas and axis being usually free. Manus small, short, and broad; second and third digits nearly equal, fourth slightly shorter. No dorsal fin.

One species, *M. monoceros*, the Narwhal or Sea-unicorn, so called on account of the remarkable single, horn-like tusk of the male, which often grows to a length of 7 or 8 feet. It inhabits the Arctic Ocean, where it is tolerably abundant and gregarious, feeding on various species of cephalopods, small fish, and crustaceans. It is rarely seen south of 65° N. lat.

Delphinapterus.—This genus is closely allied to the last in external form, as well as anatomical structure, differing only in the very different character of the dentition. Teeth from $\frac{8}{8}$ to $\frac{10}{10}$, occupying the anterior three-fourths of the rostrum and corresponding portion of the mandible, rather small, conical, and pointed when unworn, but usually become obliquely truncated, separated by intervals considerably wider than the diameter of the tooth, and implanted obliquely, the crowns inclining forwards especially in the upper jaw. Skull rather narrow and elongated, depressed. Premaxillæ convex in front of the nares. Rostrum about equal in length to the cranial portion of the skull, triangular, broad at the base, and gradually contracting towards the apex, when it is somewhat curved downwards. Vertebræ: C 7, D 11, L 9, C 23; total 50. Cervical vertebræ free. Manus broad, short, and rounded, all the digits being tolerably well developed, except the first. Anterior part of head rounded; no distinct snout. No dorsal fin, but a low ridge in its place.

One species, *D. leucas* (fig. 50), the Beluga, or White Whale, so called from its pure white colour, about 12 feet long, abundant in the Arctic seas, and extending as far south on the American coast as the river St Lawrence, which it ascends for a considerable distance. On rare occasions it has been seen on the coast of Scotland.

In all the remaining genera of *Delphinidæ* the cervical region of the vertebral column is very short, and the first two, and usually more, of the vertebræ are firmly united.

Phocæna.—Teeth $\frac{18}{18}$ to $\frac{25}{25}$, small, occupying nearly the whole length of the rostrum, with compressed, spade-shaped crowns, separated from the root by a constricted neck. Rostrum rather shorter than the cranium proper, broad at the base and tapering towards the apex. Premaxillæ raised into tuberosities in front of the nares. The frontal bones forming a somewhat square, elevated protuberance in the middle line of the skull behind the nares, rising altogether above the flattened nasals. Symphysis of mandible very short. Vertebræ: C 7, D 13, L 14, C 30; total 64 (subject to slight individual modifications). First to sixth cervical vertebræ, and sometimes the seventh also, coalesced. Manus of moderate size, oval, slightly falcate; second and third digits nearly equal in length; fourth and fifth well developed, but shorter. Head short, moderately rounded in front of the blowhole. Dorsal fin (in the typical species) near the middle of the back, triangular; its height considerably less than the length of the base; its anterior edge frequently furnished with one or more rows of conical horny tubercles.

The common Porpoise or Porpus, *P. communis*, is the best known of British Cetaceans (see PORPOISE). A species from Japan, *P. melas*, closely allied in osteological and dental characters, but which wants the dorsal fin, constitutes the genus *Neomeris* of Gray. It is entirely black in colour, and has but $\frac{18}{18}$ teeth, rather larger proportionally than those of *P. communis*, but of similar form.

Orcella.—Teeth $\frac{12}{12}$ to $\frac{14}{14}$, small, conical, pointed, rather closely set, and occupying nearly the whole length of the rostrum. Skull sub-globular, high. Rostrum nearly equal in length to the cranial portion of the skull, tapering. Manus of moderate size, not elongated, but somewhat pointed. All the bones of the digits broader than long, except the proximal phalanges of the index and third fingers. Head globular in front. Dorsal fin rather small, placed behind the middle of the body. Two species, both of small size—*O. brevirostris*, from the Bay of Bengal, and *O. fluminalis*, from the Irrawaddy river, from 300 to 900 miles from the sea. Our present knowledge of the anatomy, geographical distribution, and habits of these interesting Cetaceans is almost entirely due to the researches of Dr J. Anderson.[1]

FIG. 49.—Upper Surface of the Skull of Male Narwhal (*Monodon monoceros*), with the whole of both teeth exposed by removal of the upper wall of their alveolar cavities.

Orca.—Teeth about $\frac{12}{12}$, occupying nearly the whole length of the rostrum, very large and stout, with conical recurved crowns, and large roots, expanded laterally and flattened, or rather hollowed, on the anterior and posterior surfaces. Rostrum about equal in length to the cranial part of the skull, broad and flattened above, rounded in front; premaxillæ broad and rather concave in front of the

[1] *Anatomical and Zoological Researches, comprising an Account of the Zoological Results of the two Expeditions to Western Yunnan, in* 1868 *and* 1875 (1878).

nares, contracted at the middle of the rostrum, and expanding again towards the apex. Vertebræ: C 7, D 11–12, L 10, C 23; total 51 or 52. Bodies of the first and second and sometimes the third cervical vertebræ united; the rest free. Pectoral fin very large, ovate, nearly as broad as long. All the phalanges and metacarpals broader than long. General form of body robust. Face short and rounded. Dorsal fin near the middle of the back, very high and pointed.

The animals composing this genus are met with in almost all seas from Greenland to Tasmania, but the number of species is still very uncertain. They are readily known, when swimming in the water, by the high, erect, falcate dorsal fin, whence their common German name of *Schwert-fisch* (Sword-fish). By English sailors they are generally known as "Grampuses" or "Killers." They are

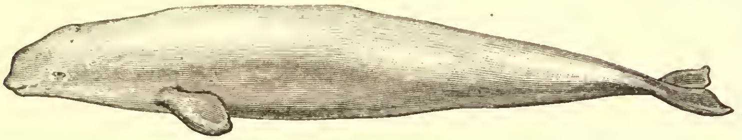

FIG. 50.—Beluga or White Whale (*Delphinapterus leucas*). From a specimen taken in the river St Lawrence, and exhibited in London, 1877.

distinguished from all their allies by their great strength and ferocity, being the only Cetaceans which habitually prey on warm-blooded animals, for, though fish form part of their food, they also attack and devour Seals, and various species of their own order, not only the smaller Porpoises and Dolphins, but even full-sized Whales, which last they combine in packs to hunt down and destroy, as Wolves do the larger Ruminants.

Pseudorca.—Teeth about $\frac{10}{10}$. Cranial and dental characters generally like those of *Orca*, except that the roots of the teeth are cylindrical. Vertebræ: C 7, D 10, L 9, C 24; total 50. First to sixth or seventh cervical vertebræ united. Bodies of the lumbar vertebræ distinguished from those of the preceding genera by being

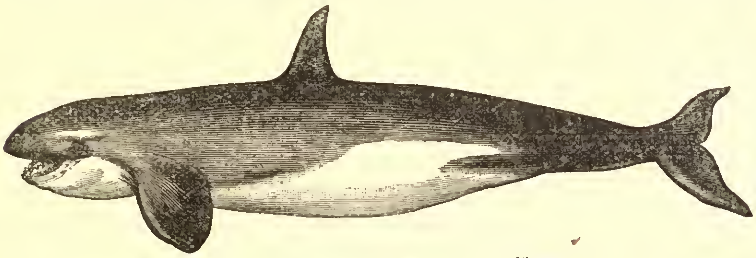

FIG. 51.—Grampus (*Orca gladiator*). From Hunter.

more elongated, the length being to the width as 3 to 2. Pectoral fin of moderate size, narrow, and pointed. Dorsal fin situated near the middle of the back, of moderate size, falcate. Head in front of the blowhole high, and compressed anteriorly, the snout truncated.

This genus was first known by the discovery of a skull in a subfossil state in a fen in Lincolnshire, named by Professor Owen *Phocæna crassidens*. Animals of apparently the same species were afterwards met with in small herds on the Danish coast, and fully described by Reinhardt. Others subsequently received from Tasmania were supposed at first to indicate a different species, but comparison of a larger series of specimens from these extremely distant localities fails to establish any characteristic difference, and indicates an immense range of distribution for a species apparently so rare. Its length is about 14 feet, and its colour entirely black.

Globiocephalus.—Teeth $\frac{8-12}{8-12}$, confined to the anterior half of the rostrum and corresponding part of the mandible, small, conical, curved, sharp-pointed when unworn, sometimes deciduous in old age. Skull broad and depressed. Rostrum and cranial portion about equal in length. Upper surface of rostrum broad and flat. Premaxillæ strongly concave in front of the nares, as wide at the middle of the rostrum as at the base or wider, and very nearly or completely concealing the maxillæ in the anterior half of this region. Vertebræ: C 7, D 11, L 12–14, C 28–29; total 58 or 59. Bodies of the anterior five or six cervical vertebræ united. Length of the bodies of the lumbar and anterior caudal vertebræ about equal to their width. Pectoral limb very long and narrow, the second digit the longest, and having as many as 12 or 13 phalanges, the third shorter (with 9 phalanges), the first, fourth, and fifth very short. Fore part of the head very round, in consequence of the great development of a cushion of fat, placed on the rostrum of the skull in front of the blowhole. Dorsal fin low and triangular, the length of its base considerably exceeding its vertical height.

The type of this well-marked genus is *G. melas*, the Pilot Whale, Ca'ing Whale, or Grindhval of the Faroe islanders, which attains the length of 20 feet, and is of nearly uniform black colour, except the middle of the under surface, which is lighter. They are extremely gregarious, and, unlike the Killers, are mild and inoffensive in disposition, feeding principally on cephalopods. Their eminently sociable character constantly leads to their destruction, as when attacked they instinctively rush together and blindly follow the leaders of the herd. In this way many hundreds at a time are frequently driven ashore and killed, when a herd enters one of the bays or fiords of the Faroe Islands or north of Scotland. Animals of this well-marked genus are found in nearly all seas, and their specific distinctions are not yet made out. Specimens from the Australian coasts, where they are generally called "Blackfish," are quite indistinguishable, either by external or osteological characters, from those of the North Atlantic.

Grampus.—Teeth none in the upper jaw; in the mandible few (3 to 7 on each side), and confined to the region of the symphysis. Vertebræ: C 7, D 12, L 19, C 30; total 68. General external characters much as in *Globiocephalus*, but the fore part of the head less rounded, and the pectoral fin less elongated.

But one species, *G. griseus*, is certainly known, about 13 feet long, and remarkable for its great variability of colour. It has been found, though rarely, in the North Atlantic and Mediterranean. A skull from the Cape of Good Hope, which differs slightly from that of the above, has been described under the name of *G. richardsoni*.

Delphinus.—Teeth very numerous in both jaws, more than $\frac{20}{20}$, occupying nearly the whole length of the rostrum, small, close-set, conical, pointed, slightly curved. Rostrum more or less elongated, and pointed in front, usually considerably longer than the cranial portion of the skull. Vertebræ: C 7, D 12–14, L and C variable; total 51 to 90. Pectoral fin of moderate size, narrow, pointed, somewhat falcate. First digit rudimentary, the second longest, third nearly equal, fourth and fifth extremely short. Externally the head shows a distinct beak or pointed snout, marked off from the antenarial adipose elevation by a V-shaped groove. Dorsal fin rather large, triangular or falcate, rarely wanting.

This is a large and heterogeneous genus, which probably ought to be divided, but, until more is known of the structure of many of the species than is at present attainable from the scanty materials in our collections, it is impossible to frame a system of subdivision upon a scientific basis. It seems preferable therefore, instead of introducing new names into zoology for groups founded upon trifling differences in the length or width of the rostrum of the skull or the number of the teeth, which may or may not be correlated with other more important structural modifications, to keep provisionally at least the Linnæan term *Delphinus* for what remains of the family, after eliminating the well-characterized genera previously described.

The true Dolphins, Bottle-noses, or, as they are more commonly called by seafaring people, "Porpoises," are found in considerable abundance in all seas, and some species are habitually inhabitants of large rivers, as the Amazon. They are all among the smaller members of the order, none exceeding 10 feet in length. Their food is chiefly fish, for the capture of which their long narrow beaks, armed with numerous sharp-pointed teeth, are well adapted, but some appear also to devour crustaceans and molluscs. They are mostly gregarious, and the agility and grace of their movements in the water are constant themes of admiration to the spectators of the scene when a "school of Porpoises" is observed playing round the bows of a vessel at sea. The type of the genus

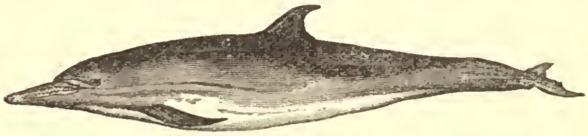

FIG. 52.—Common Dolphin (*Delphinus delphis*). From Reinhardt.

is the Common Dolphin of the Mediterranean (*D. delphis*, fig. 52), also found in the Atlantic, and of which a closely allied if not identical form is met with in the Australian seas (*D. forsteri*) and in the North Pacific (*D. bairdii*). The Tursio (*D. tursio*) is another British species of larger size and heavier build, with larger and less numerous teeth; this and several allied forms probably constitute a natural subgroup. The White-beaked and White-sided Dolphins (*D. albirostris* and *leucopleurus*) of the North Atlantic, and several others from the South and Pacific Seas, with comparatively broad and short rostrum to the skull and very numerous (80 to 90) vertebræ, constitute the genus *Lagenorhynchus* of Gray. Others, with long narrow rostrum, are associated under the name of *Steno*, one of which from the Chinese seas (*D. sinensis*) has but 51 vertebræ. This last is of a pure milk-white colour, but most of the species are variegated with glossy black, various shades of grey, and white, the latter chiefly on the under parts of the body. One species (*D. peronii*) from the South Seas is remarkable for the absence of dorsal fin. It constitutes the genus *Leucorhamphus* of Lilljeborg, and *Delphinapterus* of other authors; this last name, however, was originally bestowed on the Beluga, and should be retained for it.

Bibliography of Cetacea.—D. F. Eschricht, *Untersuchungen über die Nordischen Wallthiere*, 1849, contains a copious bibliography of the group up to the date of publication. Since that time numerous monographs on special families and genera have been published, and a large illustrated general work, *Ostéographie des Cétacés*, by P. J. Van Beneden and P. Gervais, 1868-79. See also J. F. Brandt, "Untersuchungen über die Fossilen und Subfossilen Cetaceen Europa's," in *Mém. de l'Acad. Imp. de St. Pétersbourg*, 7th ser. t. xx., 1873; and C. M. Scammon, *Marine Mammals of the N. W. Coast of North America*, 1874.

Order INSECTIVORA.

Terrestrial, rarely arboreal or natatorial, diphyodont, heterodont, placental mammals of small size, with plantigrade or semiplantigrade, generally pentadactyle, unguiculate feet; with clavicles (except in *Potamogale*); with more than two incisors in the mandible, and with enamel-coated molars having tuberculated crowns and well-developed roots. The body is clothed with fur, or protected by an armature of spines; the testes are inguinal or placed near the kidneys, and are not received into a scrotum, the penis is pendent or suspended from the wall of the abdomen; the uterus is two-horned and with or without a distinct corpus uteri, the placenta discoidal and deciduate; and the smooth cerebral hemispheres do not extend backwards over the cerebellum.

Representatives of this order are found throughout the temperate and tropical parts of both hemispheres (except South America and Australia), and exhibit much variety both in organization and in habit. The greater number are cursorial, but some (*Talpa*, *Chrysochloris*, *Oryzorictes*) are fossorial, some (*Potamogale*, *Nectogale*, *Myogale*) natatorial, and some (*Tupaiidæ*) arboreal, while the species of one genus (*Galeopithecus*) glide through the air like Flying Squirrels; to the great majority, however, the term insectivorous is applicable, the aberrant *Galeopithecus* being alone phytophagous also, while *Potamogale* is said to feed on fish, and the different species of Moles live chiefly on worms. Notwithstanding the homogeneous nature of their food, much variety prevails in the form and number of their teeth, as will be seen when we come to consider the classification of the species. In many the division into incisors, canines, premolars, and molars may be readily traced, but in others, forming the great majority of the species, such as the Shrews, this is accomplished with difficulty. The dentition of the *Insectivora* may, however, be considered typical, since from it may be derived, by modification, that of any known species of diphyodont placental *Mammalia*. This typical dentition is especially noticeable in the genus *Gymnura*, where the dental formula is—$i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $pm\ \frac{4}{4}$, $m\ \frac{3}{3}$; total 44 teeth. So also, in their general organization, these animals appear to have departed so little from what must have been the original mammalian type that, were it not for the apparently advanced character of their placentation, they might easily be considered the scarcely modified descendants of the ancestors of all other orders of diphyodont placental mammals. Their study, therefore, affords the best introduction to that of this division especially.

In most *Insectivora* the cranial cavity is of small relative size, and in none is the brain case elevated to any considerable extent above the face-line. The facial part of the skull is generally much produced, and the premaxillary and nasal bones well developed. The zygomatic arch is usually slender or deficient, the latter being the case in most of the species, and post-orbital processes of the frontals are found only in *Galeopithecidæ*, *Tupaiidæ*, and *Macroscelidæ*. The number of dorsal vertebræ varies from 13 in *Tupaia* to 19 in *Centetes*, of lumbar from 3 in *Chrysochloris* to 6 in *Talpa* and *Sorex*, and of caudal from the rudimentary vertebræ of *Centetes* to the 40 or more well-developed ones of *Microgale*. Not less variable are the characters of the vertebræ: the spinous processes may be very long in one species and short in another, though belonging to the same genus; in the *Soricidæ* and in *Myogale* the neural arches of the cervical vertebræ are very slender; in *Soricidæ* also and in *Gymnura* the four anterior vertebræ develop large single hypapophyses, and in *Galeopithecus* the body of each supports posteriorly a pair of hypapophysial tubercles. In *Erinaceus*, *Myogale*, and *Talpa* small oval ossicles are found on the inferior surfaces of the lumbar interspaces. In *Erinaceus*, owing to the thickness of the cord in the cervical region and its abrupt termination, the diameter of the neural canal in the cervical and first two dorsal vertebræ greatly exceeds that of any of the succeeding vertebræ. The sternum is variable, but generally narrow, bilobate in front, and divided into segments. The shoulder-girdle presents remarkable adaptive modifications, most expressed in *Talpa* (see MOLE), having relation to the use of the fore limbs in burrowing; in the Golden Moles (*Chrysochloris*), however (*vide infra*), the forearm and manus alone become specially modified. In *Galeopithecus* and *Macroscelides* the forearm bones are distally united; in all other known *Insectivora* the radius and ulna are distinct. The manus has generally five digits, but in *Rhynchocyon* and in one species of *Oryzorictes* the pollex is wanting. In the true Moles (see MOLE) it is extremely modified. The femur has, in most species, a prominent ridge below the greater trochanter presenting the characters of a third trochanter. In *Galeopithecus*, *Tupaia*, *Centetes*, *Hemicentetes*, *Ericulus*, and *Solenodon* the tibia and fibula are distinct, in all other genera more or less united together. The pes consists usually of five digits (rarely four by reduction of the hallux), and in some, as in the leaping species (*Macroscelides*, *Rhynchocyon*), the tarsal bones are greatly elongated. The form of the pelvis, and especially that of the symphysis pubis, varies within certain limits, which have been proposed by Leche as a basis for the classification of the families. Thus in *Galeopithecidæ*, *Tupaiidæ*, and *Macroscelidæ* there is a long symphysis, as in Rodents; in *Erinaceidæ*, *Centetidæ*, and *Potamogalidæ* it is short; and in *Soricidæ*, *Talpidæ*, and *Chrysochloridæ* there is none.

Space does not admit of even attempting a sketch of the interesting modifications of the muscular system, which will be found fully described in the present writer's *Monograph*, referred to in the bibliography. As to the nervous system, it may be noticed that the brain throughout the species presents a low type of organization: in none do the cerebral hemispheres present any trace of convolutions, nor do they extend backwards so as to cover the cerebellum; the olfactory lobes are large and project in front; and the corpus callosum is short and thin. In the Hedgehogs (*Erinaceus*) the spinal column ends abruptly opposite the third or fourth dorsal vertebra in a slender filament; the dorsal and lumbar nerves, given off in front of this point, are carried backwards in two compressed bundles occupying the suddenly narrowed spinal canal as far as the sacrum.

Owing to the similarity in the character of the food, the truly insectivorous species, forming more than nine-tenths of the order, present little variety in the structure of the digestive organs. Except in *Galeopithecus* (*vide infra*) the stomach is a simple, thin-walled sac; in some, as in *Centetes* and allied genera, the pyloric and œsophageal openings are very close together; the intestinal canal has much the same calibre throughout, and varies from three (in the Shrews) to twelve times (in the Hedgehogs) the length of the head and body. In the arboreal genera, *Galeopithecus* and *Tupaia*, and in the allied *Macroscelidæ*, all of which probably feed on vegetable substances as well, most of the species possess a cæcum. The liver is deeply divided into lobes, the right and left lateral being cut off by deep fissures; both the caudate and Spigelian lobes are generally well developed, and the gall-bladder, usually large and globular, is placed on the middle of the posterior surface of the right central lobe.

In most of the species (*Soricidæ*, *Centetidæ*, *Chrysochloridæ*) the penis is capable of being more or less completely retracted within the fold of integument surrounding the anus; in some (*Galeopithecidæ*, *Talpidæ*) it is pendent in front of the anus, while in others (*Macroscelidæ*, *Erinaceidæ*, *Solenodontidæ*) it is carried forwards and suspended from the abdominal wall. In *Centetinæ* and *Chrysochloris* the testes lie immediately behind the kidneys, in others more or less within the pelvis. During the rut they become greatly enlarged, forming protrusions in the inguinal region. Except in *Rhynchocyon* the uterine cornua are long and open into a short corpus uteri, which in many species (*Soricidæ*, *Talpidæ*, *Centetidæ*, *Chrysochloridæ*) is not separated from the vagina by a distinct os uteri. With the exception of *Galeopithecus* all *Insectivora* appear to be multiparous, the number of fœtuses varying from two to eight in *Erinaceus*, and from twelve to twenty-one in *Centetes*. The position of the mammary glands and the number of the teats vary greatly. In *Galeopithecus* there are two pairs of axillary teats, in *Solenodon* a single pair post-inguinal, but in most species they range from the thorax to the abdomen, varying from two pairs in *Gymnura* to twelve in *Centetes*. In *Chrysochloris* the thoracic and inguinal teats are lodged in deep cup-shaped depressions.

Odoriferous glands exist in many species. In most Shrews they occur on the sides of the body at a short distance behind the axilla, and their exudation is probably protective, as few carnivorous animals will eat their dead bodies. In both species of *Gymnura* and in *Potamogale* large pouches are situated on either side of the rectum, and discharge their secretions by ducts, opening in the first-named genus in front of and in the latter within the margin of the anus. In *Centetes* racemose glands similarly situated discharge by pores opening at the bottom of deep pits placed at either side of the anus.

The integument is thin, but in many species lined with well-developed muscles, which are probably more developed in the Hedgehogs (*Erinaceidæ*) than in any other mammal; in this family and in *Centetidæ* most of the species are protected by spines implanted in the panniculus carnosus, and more or less replacing the fur of the upper surface of the body.

The *Insectivora* are divisible into two very distinct suborders, of which the first includes a single genus only.

SUBORDER I. *Dermoptera*.

Upper and lower incisors compressed, multicuspidate, the lower deeply pectinate; anterior and posterior limbs connected by a broad integumentary expansion forming a parachute. Family I. *Galeopithecidæ*.

SUBORDER II. *Insectivora Vera*.

Upper and lower incisors conical, unicuspidate or with basal cusps only, the lower not pectinate; limbs free, formed for terrestrial progression.

I. Upper true molars broad, multicuspidate, with more or less well-defined W-shaped crowns.
  A. Symphysis pubis long; intestinal canal generally with a cæcum; cerebral cavity comparatively large.
    a. Orbital ring encircled by bone; metatarsus moderate; arboreal. Family II. *Tupaiidæ*.
    b. Orbital ring not encircled by bone; metatarsus greatly elongated; terrestrial. Family III. *Macroscelidæ*.
  B. Symphysis pubis short or none; intestinal canal without cæcum; cerebral cavity small; skull without post-orbital processes.
    a. First and second upper molars with a central fifth cusp.
      a'. Tympanics annular, not forming bullæ. Family IV. *Erinaceidæ*.
    b. No central fifth cusp; crowns of the upper molars W-shaped.
      a'. Tympanics annular, not forming bullæ; no zygomatic arches. Family V. *Soricidæ*.
      b'. Tympanics forming bullæ; zygomatic arches developed. Family VI. *Talpidæ*.
II. Upper true molars narrow, with V-shaped crowns.
      a'. Tympanics annular, not forming bullæ; zygomatic arches imperfect.
        a''. No clavicles. Family VII. *Potamogalidæ*.
        b''. Clavicles well developed.
          a'''. Skull constricted between the orbits; penis suspended. Family VIII. *Solenodontidæ*.
          b'''. Skull not constricted; penis pendent, retractible. Family IX. *Centetidæ*.
      b'. Tympanics forming bullæ; zygomatic arches well-developed. Family X. *Chrysochloridæ*.

Family GALEOPITHECIDÆ.

The characters of the family are those of the suborder *Dermoptera*, to which may be added that the orbit is nearly surrounded by bone, the zygomatic arches are well developed, the tympanics form bullæ osseæ, the ulna is distally united with the radius, the tibia and fibula are distinct, the pubic symphysis is long, the penis is pendent, the testes are received into inguinal pouches, the mammæ are axillary, the uterus is two-horned, and there is a large cæcum.

Galeopithecus ($i\ \frac{2}{3}$, $c\ \frac{1}{1}$, $pm\ \frac{2}{2}$, $m\ \frac{3}{3}$; second upper incisors and canines with two roots), with two species—*G. volans* and *G. philippinensis*. The former, the Flying Lemur of Linnæus, distinguished from the latter by the form of the upper incisors, has a total length of nearly 2 feet. The long and slender limbs are connected by a broad integumentary expansion extending outwards from the sides

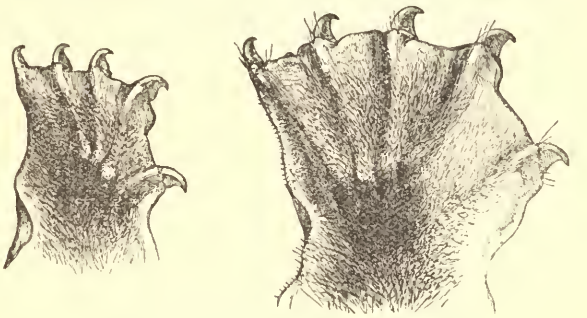

FIG. 53.—Feet of *Galeopithecus philippinensis*.

of the neck and body, and forming also a web between the fingers and toes as far as the base of the claws (fig. 53); the hind limbs are further connected by a similar expansion passing outwards along the back of the feet to the base of the claws, and, inwardly, involving the long tail to the tip, forming a true interfemoral membrane, as in the Bats.

The species of this family live in the forests of the Malay Peninsula, Sumatra, Borneo, and the Philippine Islands, where they feed chiefly on the leaves of trees, and probably also on insects. Their habits are nocturnal, and during the daytime they cling to the trunks or limbs of trees head downwards in a state of repose. With the approach of night their season of activity commences, when they may be occasionally seen gliding from tree to tree supported on their cutaneous parachute, and they have been noticed as capable of traversing in this way a space of 70 yards with a descent of only about one in five.

Galeopithecus was referred by some of the older zoologists and anatomists to the Bats, and by others (and even in lately published works) to the Lemurs, but Professor Peters's view (in which most subsequent writers agree) that it belongs to neither of these orders, and must be considered an aberrant Insectivore, appears to be undoubtedly the correct one. Besides differing from the Bats altogether in the form of the anterior limbs and of the double-rooted outer incisors and canines, it also contrasts strongly with them in the presence of a large sacculated cæcum, and in the great length of the colon, which is so remarkably short in all the *Chiroptera*. From the Lemurs, on the other hand, the form of the brain, the character of the teeth, the structure of the skull, and the deciduate discoidal placenta at once separate it.

Family TUPAIIDÆ.

Arboreal *Insectivora*, with comparatively large brain case, orbits encircled with bone, and well-developed zygomatic arches. The malar bone is perforated; the tympanics form bullæ; the pubic symphysis is long; the tibia and fibula are distinct, the metatarsus but little longer than the tarsus; the molars are broad, with

W-shaped cusps; and the intestinal canal has generally a short cæcum.

The animals included in this family are all arboreal, resembling Squirrels closely both in habits and in external form; they are divided into two genera having the same dental formula ($i\,\frac{2}{3}$, $c\,\frac{1}{1}$, $pm\,\frac{3}{3}$, $m\,\frac{3}{3}$), but distinguished by the form of the skull. *Tupaia*, with nine species, is found in India, Burmah, the Malay Peninsula, Nicobars, Sumatra, Java, and Borneo. The species closely resemble one another, differing chiefly in size and in the colour and length of the fur. Nearly all have long bushy tails, which still further

Fig. 54.—Pentail (*Ptilocercus lowii*). $\times\frac{1}{2}$. From Gray, *Proc. Zool. Soc.*, 1848.

increase their resemblance to Squirrels. Their food consists of insects and fruit, which they usually seek for in the trees, but also occasionally on the ground. When feeding they often sit on their haunches, holding the food, after the manner of Squirrels, between their fore paws. *Ptilocercus* includes a single very interesting species, *Pt. lowii*, inhabiting Borneo, remarkable for its long tail, two-thirds naked, having the terminal third furnished with a double fringe of long hairs. Its habits are probably similar to those of the Tupaias, of which it may be further noticed that they alone among *Insectivora* are day-feeders.

Family Macroscelidæ.

Terrestrial *Insectivora*, with comparatively large brain case, well-developed zygomatic arches, and tympanic bullæ; but the orbits are not encircled by bone, the malar is imperforate, and there are generally no post-orbital processes. The pubic symphysis is long, the tibia and fibula united high up, the metatarsus much longer than the tarsus, the molars broad and quadricuspidate, and the intestinal canal has a large cæcum.

These leaping Insectivores are easily distinguished by the great length of their metatarsal bones. All the species are African, and are divisible into two genera:—

a. $i\,\frac{3}{3}$, $c\,\frac{1}{1}$, $pm\,\frac{3}{3}$, $m\,\frac{3}{3}$ or $\frac{3}{4}$; forearm bones united below. *Macroscelides.*

b. $i\,\frac{1}{3}$ (or $\frac{0}{3}$), $c\,\frac{1}{1}$, $pm\,\frac{3}{3}$, $m\,\frac{3}{3}$; forearm bones separate. *Rhynchocyon.*

Macroscelides includes ten species widely distributed throughout the African continent. All are closely related, resembling one another in general forms, and even in the colour of the fur. They fall into two groups distinguished by the presence or absence of a small lower fourth molar. *M. tetradactylus* (fig. 55), type of the subgenus *Petrodromus*, differs from all in the absence of the hallux. Of *Rhynchocyon* four closely allied species have been described, all from East Africa.

Family Erinaceidæ.

Terrestrial *Insectivora*, with a small brain case, without post-orbital processes, with slender (rarely imperfect) zygomatic arches, with a short pubic symphysis, and with the tibia and fibula united above. The tympanics are annular, not forming bullæ; the intestine has no cæcum; the penis is carried forwards, and suspended from the wall of the abdomen; and the upper true molars have each four principal cusps and a small central fifth cusp very characteristic of the family.

Subfamily I. **Gymnurinæ.**—Caudal vertebræ numerous; palate bones completely ossified; pelvis very narrow; fur without spines.

Gymnura, $i\,\frac{3}{3}$, $c\,\frac{1}{1}$, $pm\,\frac{4}{4}$, $m\,\frac{3}{3}$, with two species, *G. rafflesii* and *G. suilla*, from the Malay Peninsula and Indian Archipelago. The former has the appearance of a large Rat with a long head and projecting mobile snout; the latter, much smaller, with a short tail and small third upper premolar, has long been known under the name of *Hylomys suillus*, and classed with the *Tupaiidæ*. Both species present a very generalized type of dentition, in this respect occupying an almost central position in the order.

Fig. 55.—*Macroscelides* (*Petrodromus*) *tetradactylus*. $\times\frac{1}{2}$. From Peters, *Reise nach Mossambique.*

Subfamily II. **Erinaceinæ.**—Caudal vertebræ rudimentary; palate bones with defects of ossification; pelvis wide; fur with spines.

Erinaceus, $i\,\frac{3}{2}$, $c\,\frac{1}{1}$, $pm\,\frac{3}{2}$, $m\,\frac{3}{3}$, includes nineteen species (familiarly known as Hedgehogs) distributed throughout Europe, Africa, and the greater part of Asia, but they have not been found in Madagascar, Ceylon, Burmah, Siam, the Malay Peninsula and Archipelago, or Australia. All the species resemble one another

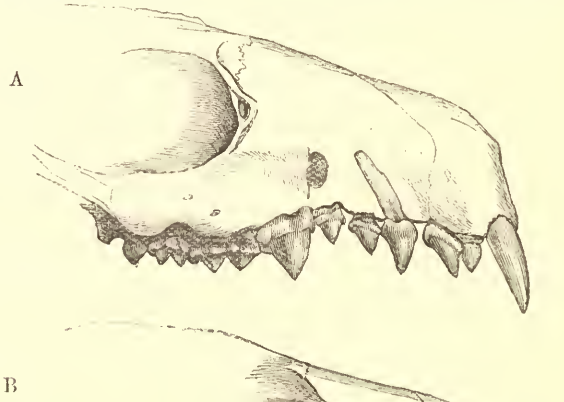

Fig. 56.—Facial parts of Skulls of (A) *Erinaceus europæus* and (B) *E. grayi*, much enlarged. Dobson, *Proc. Zool. Soc.*, 1881.

closely in the armature of spines which invests the upper surface and side of the body; and all possess the power of rolling themselves up into the form of a ball protected on all sides by strong spines, the dorsal integument being brought downwards and inwards over the head and tail, so as to include the limbs also, by the action of special muscles (for description see *Monograph of the*

Insectivora referred to in the bibliography). The common Hedgehog (*E. europæus*) is the most aberrant species, differing from all the rest in the peculiarly shaped and single-rooted third incisors and first upper premolars (fig. 56, A), and in its very coarse harsh fur. The dentition of the long-eared North Indian form, *E. grayi* (fig. 56, B), may be considered characteristic of all the other species, the only important differences being found in the variable size and position of the second upper premolar, which is very small, external, and deciduous in the Indian species *E. micropus* and *pictus*. The former species, limited to South India, is further distinguished by the absence of the malar bone. Of African species, *E. diadematus*, with long frontal spines, is probably the commonest, and *E. albiventris* has been made the type of a separate genus on account of the total absence of the hallux.

Family Soricidæ.

Terrestrial, rarely natatorial, *Insectivora*, with narrow elongated skulls, without post-orbital processes or zygomatic arches. The tympanics are annular, not forming bullæ; there is no symphysis pubis; the intestine has no cæcum; the tibia and fibula are united; and the molars have well-developed W-shaped cusps.

The dentition is very characteristic of the family; in all the upper front incisors are large, with a more or less prominent posterior basal cusp, and between these and the last premolar intervene a variable number of small incisors and premolars, among which the small canine can be distinguished only by its position immediately behind the premaxillary suture. The number of teeth in the mandible is always twelve, and the single pair of incisors are much extended horizontally forwards, the canine is the smallest tooth, and the single premolar is not much larger (see fig. 57).

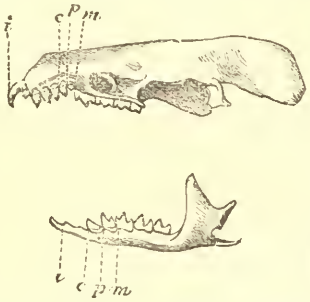

Fig. 57.—Skull and Dentition of *Sorex vermpicis*. Alston, *Proc. Zool. Soc.*, 1877.

The Shrews thus form a very compact family, which includes considerably more than half the known species of *Insectivora*, and of which the geographical distribution is coextensive with that of the order. They have been divided into several genera (so-called) and subgenera, depending chiefly on the number of the upper incisors and premolars, and on the colour of the teeth. The best arrangement appears to be that proposed by M. Alph. Milne-Edwards, as follows:—

A. Terrestrial; feet without a border composed of stiff hairs.
- *a.* Teeth white.
  - *a′*. 26 teeth.
    - *a″*. Tail very short, concealed. 1. *Anourosorex.*
    - *b″*. Tail moderately long. 2. *Diplomesodon.*
  - *b′*. 28–30 teeth. 3. *Crocidura.*
- *b.* Teeth more or less brown or red.
  - *a′*. Tail short; ears small. 4. *Blarina.*
  - *b′*. Tail and ears moderately long. 5. *Sorex.*

B. Amphibious; feet with a border of stiff hairs.
- *a.* Feet not webbed.
  - *a′*. 32 teeth; hairs of tail equal. 6. *Neosorex.*
  - *b′*. 30 teeth; tail fringed along middle edge. 7. *Crossopus.*
- *b.* Feet webbed. 8. *Nectogale.*

Anourosorex includes *A. squamipes*, a Mole-like species, with very short ears and tail, from Tibet. *Diplomesodon*, with one species, *D. pulchellus*, from the Kirghiz steppes, though agreeing in the number of teeth, is Shrew-like in external form. *Crocidura*, 28–30 teeth, with about seventy species divided into four subgenera, comprises the greater number of white-toothed Old-World Shrews, having a round tail thinly clothed with a few hairs of unequal length. *C. aranea* and *C. suaveolens* of the continent of Europe, and *C. indicus*, the Musk-Rat of India, are well-known examples. *Sorex*, the typical genus (see Shrew), also divided into four subgenera, with *Blarina*, includes all the species with brown teeth and angular uniformly hairy tail. *Neosorex* includes the New-World and *Crossopus* (see Shrew) the Old-World amphibious species, having a fringe of stiff hairs along the sides of the feet, and *Nectogale* a very remarkable species from Tibet, *N. elegans* (fig. 58), distinguished from all other Shrews by the webbed condition of the toes, and the presence of adhesive cushions on the under surface of the feet, which enable the animal to hold on to smooth stones at the bottom of rushing torrents.

Family Talpidæ.

Fossorial, rarely natatorial, *Insectivora*, distinguished from the *Soricidæ* by the presence of zygomatic arches and tympanic bullæ osseæ, and by the form of the teeth. The eyes are very small, in some species covered with skin; the ears are short and concealed by the fur; the fore limbs are generally more or less modified for digging; there is no symphysis pubis; the intestine has no cæcum; the tibia and fibula are united; and the unicuspidate upper and lower front incisors are not extended horizontally forwards.

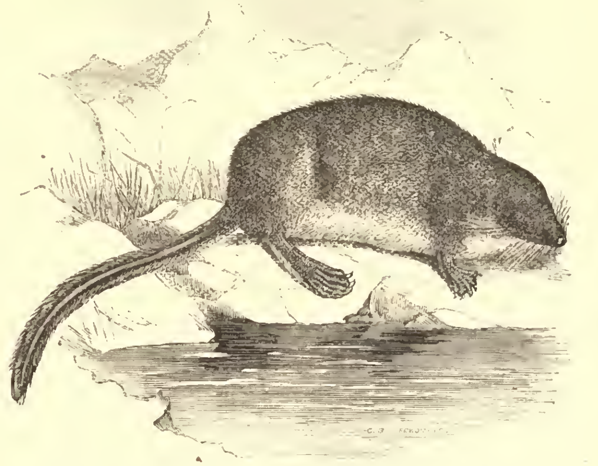

Fig. 58.—*Nectogale elegans*. A. Milne-Edwards, *Mammif. Tibet.*

This family, though thus easily distinguished, is, nevertheless, evidently closely related to the Shrews, with which such intermediate forms as those included in the genera *Urotrichus* and *Uropsilus* connect it. In striking contrast with the Shrews, however, the distribution of the Moles is limited to the temperate regions of Europe, Asia, and North America.

Subfamily I. **Myogalinæ.**—Clavicles and humeri moderately elongated; manus without os falciforme.

a. $i\,\frac{3}{3}$, $c\,\frac{1}{1}$, $pm\,\frac{4}{4}$, $m\,\frac{3}{3}$; feet webbed; natatorial. *Myogale.*
b. $i\,\frac{2}{1}$, $c\,\frac{1}{1}$, $pm\,\frac{3}{3}$, $m\,\frac{3}{3}$; feet narrow; terrestrial. *Uropsilus.*
c. $i\,\frac{2}{1}$, $c\,\frac{1}{1}$, $pm\,\frac{4}{3}$ or $\frac{3}{4}$, $m\,\frac{3}{3}$; feet wide; fossorial. *Urotrichus.*

Myogale includes two very remarkable species, *M. moschata* and *M. pyrenaica*. The former is by far the largest species of the family, its total length being about 16 inches. Its long proboscis-like snout projects far beyond the margin of the upper lip; the toes are webbed as far as the bases of the claws; and the long scaly tail is laterally flattened, forming a powerful instrument of propulsion when swimming. This species inhabits the banks of streams and lakes in south-east Russia, where its food consists of various aquatic insects. *M. pyrenaica*, living in a similar manner in the region of the Pyrenees, is very much smaller, has a round

Fig. 59.—*Myogale moschata*. × ¼.

tail, and a proportionally longer snout. *Urotrichus*, with *pm* $\frac{4}{3}$, and *Neürotrichus* (subg.), with *pm* $\frac{3}{4}$, are represented by two small Mole-like species, externally resembling one another closely, from Japan and North America respectively. Of *Uropsilus*, *U. soricipes*, from the borders of Tibet, is a very interesting species, having the external form of a Shrew but the skull of a Mole.

Subfamily II. **Talpinæ** (True Moles).—Clavicles and humeri very short and broad; manus with a large os falciforme.

A. Front upper incisors much larger than the second pair (New-World Moles).
- *a.* *i* $\frac{3}{2}$, *c* $\frac{1}{0}$, *pm* $\frac{3}{3}$, *m* $\frac{3}{3}$; extremity of nose simple. *Scalops.*
- *b.* *i* $\frac{3}{2}$, *c* $\frac{1}{1}$, *pm* $\frac{4}{4}$, *m* $\frac{3}{3}$; extremity of nose simple. *Scapanus.*
- *c.* *i* $\frac{3}{3}$, *c* $\frac{1}{1}$, *pm* $\frac{4}{4}$, *m* $\frac{3}{3}$; extremity of nose with appendages. *Condylura.*

B. Front upper incisors scarcely larger than the second pair (Old-World Moles).
- *d.* *i* $\frac{3}{2}$, *c* $\frac{1}{1}$, *pm* $\frac{4}{4}$, *m* $\frac{3}{3}$; manus as in *Urotrichus*. *Scaptonyx.*
- *e.* *i* $\frac{3}{3}$ or $\frac{3}{2}$, *c* $\frac{1}{1}$, *pm* $\frac{4}{4}$, *m* $\frac{3}{3}$; manus very broad. *Talpa.*

Scaptonyx, with a single species *S. fusicaudatus*, from west China, connects *Urotrichus* with the true Moles. *Talpa* includes seven species, of which the Common Mole is a familiar example. See MOLE.

Family POTAMOGALIDÆ.

Insectivora with a small brain case, without post orbital processes or zygomatic arches, and with annular tympanics not forming bullæ. There are no clavicles; the pubic bones are connected by a ligament, and there is no true symphysis; the intestine has no cæcum; the tibia and fibula are united low down; and the upper true molars have broadly V-shaped cusps presenting characters intermediate between those of the preceding and succeeding families.

FIG. 60.—*Potamogale velox.* × ¼. Allman, *Trans. Zool. Soc.*, vi., pl. i.

Potamogale, *i* $\frac{3}{3}$, *c* $\frac{1}{1}$, *pm* $\frac{3}{3}$, *m* $\frac{3}{3}$, with *P. velox*. This most interesting species inhabits the banks of streams in west equatorial Africa, and its whole structure indicates an aquatic life. It is nearly 2 feet in length, the tail measuring about half. The long cylindrical body is continued uninterruptedly into the thick laterally compressed tail, the legs are very short, and the toes are not webbed, progression through the water evidently depending wholly on the action of the powerful tail, while the limbs are folded inwards and backwards. The muzzle is broad and flat, and the nostrils are protected by valves. The fur is dark brown above, the extremities of the hairs on the back being of a metallic violet hue by reflected light, beneath whitish.

Geogale, *i* $\frac{2}{2}$, *c* $\frac{1}{1}$, *pm* $\frac{3}{2}$, *m* $\frac{3}{3}$, with *G. aurita*, a small Mouse-like species from Madagascar, agrees closely with *Potamogale* in the general form of the skull and teeth; the tibia and fibula are distinct, but it is not known whether a clavicle exists or not, and the material at present available is insufficient to definitely fix the natural position of the species.

Family SOLENODONTIDÆ.

Insectivora with a small brain case constricted between the orbits, and without post-orbital processes or zygomatic arches. The penis is carried forwards and suspended from the abdomen; the testes are received into perineal pouches; the mammary glands are post-inguinal; the uterine cornua end in cæcal sacs; the intestine has no cæcum; the tympanics are annular; the upper true molars have V-shaped crowns; the symphysis pubis is short; and the tibia and fibula are distinct.

Solenodon, *i* $\frac{3}{3}$, *c* $\frac{1}{1}$, *pm* $\frac{3}{3}$, *m* $\frac{3}{3}$, with *S. paradoxus* and *S. cubanus*, from Hayti and Cuba respectively, alone represents the family. These species, which differ chiefly in the colour and quality of the fur, have each a remarkably long cylindrical snout, a long naked tail, feet formed for running, and the body clothed with long, coarse fur.

The position of the mammæ quite behind on the buttocks is unique among *Insectivora*. The upper front incisors are much enlarged, and with the other incisors, canines, and premolars closely resemble those of *Myogale*; the second lower incisors are, as in

FIG. 61.—*Solenodon cubanus.* × ¼. Peters, *Abh. Akad. Berl.*

Potamogale, much larger than the anterior pair, and are deeply hollowed out internally. While thus apparently showing relationship with the *Talpidæ*, the form of the crowns of the molar teeth connects them with the next family.

Family CENTETIDÆ.

Insectivora with a small cylindrical brain case not constricted between the orbits, and without post-orbital processes or zygomatic arches. The penis is pendent and retractible within the fold of the integument surrounding the anus; the testes are abdominal; the mammary glands are thoracic and ventral; the uterine cornua are terminated by the Fallopian tubes; the intestine has no cæcum; the tympanics are annular; the molars have V-shaped crowns; the pubic symphysis is short, and the tibia and fibula separate or united. All the known species are limited to Madagascar.

Subfamily I. **Centetinæ**.—Tibia and fibula distinct; testes near kidneys; fur with spines.

FIG. 62.—Skull of *Centetes ecaudatus* (reduced).

Centetes, *i* $\frac{3}{3}$ or $\frac{2}{3}$, *c* $\frac{1}{1}$, *pm* $\frac{3}{3}$, *m* $\frac{3}{3}$ or $\frac{4}{3}$. The single species, *C. ecaudatus*, the well-known tailless Ground-Hog of Madagascar, attains a total length of from 12 to 16 inches, and is the largest known Insectivore. The adult males have exceedingly long canines, the extremities of the lower pair being received into pits in front of the upper canines. It is probably the most prolific of all mammals; as many as twenty-one young are said to have been brought forth at a birth. The young have strong white spines arranged in longitudinal lines along the back, but these are lost in the adult animal, which is provided only with a nuchal crest of long rigid hairs. *Hemicentetes*, *i* $\frac{3}{3}$, with *H. semispinosus* and *H. nigriceps*, is distinguished by the persistence of the third upper incisor, and by the form of the skull. The two species are very much smaller than *C. ecaudatus*, and the dorsal spines are retained in the adult state. *Ericulus*, *i* $\frac{2}{2}$, has *E. setosus*, a remarkable Hedgehog-like species having the whole upper surface and even the short tail densely covered with close-set spines. The facial bones are much shorter than in any of the preceding genera, and the upper front incisors are elongated as in *Erinaceus*. Judging from the slight development of the cutaneous muscles compared with those of the true

Hedgehogs, it is probable that complete involution, as in the latter animals, does not take place.

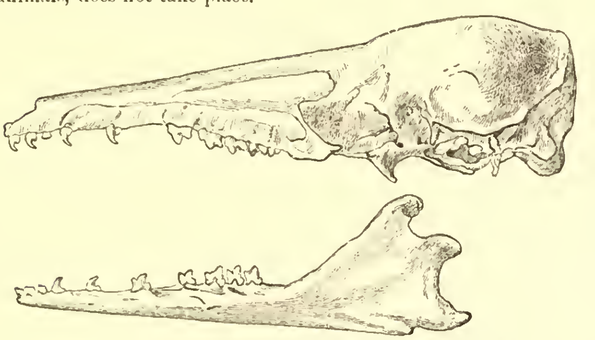

Fig. 63.—Skull of *Hemicentetes semispinosus*. × 2. Mivart, *Proc. Zool. Soc.*, 1871.

Subfamily II. **Oryzorictinæ.**—Tibia and fibula united; testes near urethra; fur without spines.

Microgale, $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $pm\ \frac{3}{3}$, $m\ \frac{3}{3}$, includes *M. longicaudata* and *M. cowani*, small Mouse-like species, the former with a tail double the length of the head and body; teeth like those of *C. ecaudatus*, but, owing to the comparatively much shorter muzzle, not separated by wide spaces, and the last premolar and molars with internal basal processes. *Oryzorictes* contains *O. hova* and *O. tetradactylus*, the latter distinguished by the presence of four digits only in the manus, the three inner having long laterally compressed fossorial claws. The general form of the head and body of the two species known is that of a Mole. They burrow in the rice-fields, and do much damage to the crops.

Family CHRYSOCHLORIDÆ.

Fossorial *Insectivora*, with conical skulls not constricted between the orbits, with well-developed zygomatic arches and tympanic bullæ, but without post-orbital processes. The eyes are covered by the hairy integument, the ears short and concealed by the fur; the internal generative organs and the crowns of the upper molar teeth are as in *Centetinæ*; the mammary teats are thoracic and inguinal, and placed in cup-shaped depressions; there is no pubic symphysis; and the tibia and fibula are united.

This family is evidently closely allied to *Centetidæ*, occupying the same relative position with respect to that family that *Talpidæ* does to *Soricidæ*. All the species are fossorial, and restricted to south Africa. In all the forearm and manus are similarly modified for digging, but in a manner very different from that observable in *Talpidæ* (see MOLE).

Fig. 64.—*Chrysochloris obtusirostris* (reduced).

Chrysochloris, $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $pm\ \frac{3}{3}$, $m\ \frac{3}{3}$ or $\frac{2}{2}$, embraces seven or eight species. Those with $m\ \frac{2}{2}$, with a basal talon to the lower grinders, and without a prominence in the temporal fossa, have been placed in a separate genus *Calcochloris* by Professor Mivart. Nearly all the species have the fur of the upper surface of a brilliant metallic lustre, varying from golden bronze to green and violet of different shades.

FOSSIL INSECTIVORA.

Of fossil *Insectivora* no undoubted traces have been found in deposits earlier than the Eocene. *Amphidozotherium*, allied to *Urotrichus*, and *Neogymnurus* and *Protalpa*, with relationships to *Gymnura* and *Talpa* respectively, have been described from the lacustrine Eocene beds of Quercy. Several genera with insectivorous affinities have been characterized by Cope and Marsh from remains found in the Eocene of Wyoming, but these have been relegated to distinct suborders of a new order *Bunodonta*, of which *Insectivora* is considered a suborder only. The Miocene deposits of the south of France and Germany have yielded fossil forms of *Erinaceidæ* (*Amphechinus*, *Galerix*, *Tetracus*), of *Soricidæ* (*Sorex*, *Mysarachne*, *Plesiosorex*), and of *Talpidæ* (*Dimylus*, *Galeospalax*, *Geotrypus*, *Hyporissus*, *Myogale*). Of the latter family *Galeospalax* has been characterized from the Pliocene of Norfolk; and remains of the common Hedgehog, and of some of the existing species of *Sorex*, have been found in various post-Tertiary deposits.

Bibliography of Insectivora.—Peters, *Reise nach Mossambique—Säugeth.*, 1852; Id., "Ueber die Classification der Insectivora," *Monatsb. Akad. Wissensch. Berlin*, 1865, and other papers; Mivart, "On the Osteology of the Insectivora," *Jour. Anat. and Phys.*, 1867, 1868, and *Proc. Zool. Soc.*, 1871; Gill, "Synopsis of Insectivorous Mammals," *Bull. Geol. and Geog. Survey, U.S.A.*, Washington, 1875 (includes a general bibliography of the order *Insectivora*); Dobson, *Monograph of the Insectivora, Systematic and Anatomical*, London, 1882.

ORDER CHIROPTERA.

Volant mammals, having their fore limbs specially modified for flight. The forearm consists of a rudimentary ulna, a long curved radius, and a carpus of six bones supporting a thumb and four greatly elongated fingers, between which, the sides of the body, and the hinder extremities a thin expansion of the integument (the wing-membrane) is spread out. The knee is directed backwards, owing to the rotation of the hind limb outwards by the wing-membrane; a peculiar elongated cartilaginous process (the calcaneum or calcar), rarely rudimentary or absent, arising from the inner side of the ankle-joint, is directed inwards, and supports part of the posterior margin of an accessory membrane of flight, extending from the tail or posterior extremity of the body to the hinder limbs (the inter-femoral membrane). The penis is pendent; the testes abdominal or inguinal; the mammary glands thoracic and generally post-axillary; the uterus simple or with more or less long cornua; the placenta discoidal and deciduate; and the smooth cerebral hemispheres do not extend backwards over the cerebellum. The dental series consists of four kinds of teeth—incisors, canines, premolars, and molars; and the dental formula never exceeds $i\ \frac{2}{3}$, $c\ \frac{1}{1}$, $pm\ \frac{3}{3}$, $m\ \frac{3}{3}$; total 38 teeth.

The animals comprised in this order are at once distinguished by the presence of true wings, and this peculiarity is accompanied by other modifications of bodily structure having special relation to aerial locomotion. Thus, in direct contrast to all other mammals, in which locomotion is chiefly effected by action from behind, and the hind limbs consequently greatly preponderate in size over the fore, in the *Chiroptera* the fore limbs, being the only agents in propelling the body forward during flight, immensely exceed the short and weak hinder extremities; the thorax, giving origin to the great muscles which sustain flight, and containing the proportionately (compared with other mammals) very large lungs and heart, is remarkably capacious, and the ribs are flattened and close together; the shoulder-girdle is also greatly developed in comparison with the weak pelvic bones.

Linnæus included the Bats among the *Primates*, mainly on account of the number of their upper incisors, supposed to be always four, the thoracic position of the mammæ, and the pendent condition of the penis. Many other zoologists, taking into consideration also the placental characters and the form of the uterus, have followed him; but it is evident that the situation of the mammæ is related to the necessarily central position of the young during flight, the shortness of the uterine cornua, observable in so many species, to the generally uniparous gestation requiring less room, while the discoid deciduate placenta is equally present in and characteristic of the *Insectivora*, many species of which have also the penis pendent. Then, all these reasons for maintaining the Bats in such an exalted position being disposed of, we find in the low organization of their brain another proof of their inferior position in the zoological scale, while furthermore, although they differ widely from all other mammals in external form, it is evident that this is but the result of special adaptation to aerial locomotion; and, taking into account their whole bodily structure, we are forced to admit with Professor Huxley that they may be regarded as exceedingly modified *Insectivora*.

So thoroughly, however, has this adaptation been carried out that of all animals the Bats are the least terrestrial, not one of them being equally well fitted, as most Birds and Insects are, for progression on the earth. This is due to the hind as well as the fore limbs being pressed into the service of aerial locomotion. The hind limb is so rotated outwards by the wing-membrane that, contrary to what obtains in all other vertebrates, the knee is directed backwards, and corresponds in position to its serial homologue the elbow. When placed on the ground, therefore, the animal rests on all fours, having the knees directed upwards like a grasshopper's, while, in order to bring the foot into a position for forward progression, it is rotated forwards and inwards on the ankle. Walking under these circumstances is at best only a species of shuffle, and that this is fully recognized by the animal is evidenced by its great anxiety to take to the wing, or, if this be impracticable, to ascend to some point where it can hitch itself up by the claws of the hind-legs in its usual position when at rest.

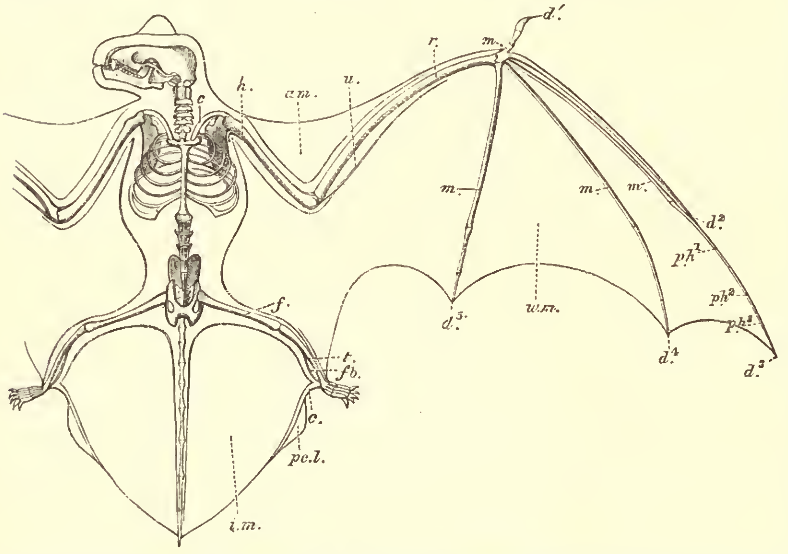

Fig. 65.—Skeleton and Volar Membranes of the Noctule Bat (*Vesperugo noctula*). × ½. *c*, clavicle; *h*, humerus; *r*, radius; *u*, ulna (rudimentary); d^1, first digit or pollex; d^2, d^3, d^4, d^5, other digits of the manus supporting *um*, the wing-membrane; *m*, *m*, metacarpal bones; ph^1, first phalanx; ph^2, second phalanx; ph^3, third phalanx; *am*, antebrachial membrane; *f*, femur; *t*, tibia; *fb*, fibula (rudimentary); *c*, calcaneum or calcar supporting *im*, the interfemoral membrane; *pcl*, post-calcaneal lobe.

The bones entering into the formation of the skeleton in *Chiroptera* are characterized by their slenderness, and by the great size of the medullary canals in those of the extremities. The vertebral column is short, and the vertebræ differ very slightly in number and form throughout the species. The general number of the dorso-lumbar vertebræ is 17, whereof 12 are dorsal; the cervical vertebræ are very broad, but short from before backwards (their breadth is due to the great transverse diameter of the spinal canal rendered necessary by the comparatively very large size of the spinal cord in this position, which, after giving off the nervous supply to the fore limbs and thorax, rapidly diminishes in size, and in the lumbo-sacral region is reduced to a fine thread). Except in the great frugivorous Bats (*Pteropodidæ*), the vertebræ, from the third cervical backwards, are devoid of spinous processes, a characteristic feature in the general osteology of the order. From the first thoracic to the last lumbar vertebra the spinal column forms a single curve backwards, which is most pronounced in the lumbar region. The bodies of the vertebræ are very slightly movable upon each other, and in old individuals appear to become partially ankylosed together. The caudal vertebræ are simple cylindrical bones without processes; their number and length is extremely variable even in closely allied species; and the anterior vertebræ are generally united to the ischial tuberosities. The development of these vertebræ, in fact, is intimately correlated to the habits of the animals, the long tail in the insectivorous species supporting and controlling the position of the large interfemoral membrane which appears not only to aid their rapid doubling motions when in pursuit of their insect prey by acting as a rudder on the air, but also to assist them in the capture and retention of the larger insects; in the frugivorous species, on the other hand, this is not required, and the tail is accordingly rudimentary or absent. In all Bats the presternum has a prominent keel for the attachment of the great pectoral muscles. In most species the ribs are much flattened, and in some partially ankylosed by their contiguous margins.

Great as is the variability of the shape of the skull in *Insectivora*, it is still greater in *Chiroptera*, and evidently depends upon the much wider differences in the nature of the food of different species requiring corresponding modifications of the manducatory apparatus, so that extreme modifications may be found in species of the same family, as in the case of the *Phyllostomidæ*. In some genera, however, as in *Miniopterus*, *Furia*, *Mormops* (*vide infra*), the peculiar shape of the skull cannot thus be accounted for. As in the *Insectivora*, post-orbital processes are developed in some species only, as in the *Pteropodidæ* and in a few *Nycteridæ* and *Emballonuridæ*; in *Pteropus leucopterus* alone does a process from the zygomatic arch meet the post-orbital so as to complete the orbital ring. Zygomatic arches, though slender, are present in all except in some of the species of *Phyllostomidæ*.

The milk teeth differ from those of all other mammals in that they in no respect resemble in form those of the permanent series. They are very slender, with acutely pointed recurved cusps, and are soon shed, but often coexist for a short time with the permanent teeth when the latter are considerably elevated above the gum. In the family *Rhinolophidæ* the milk teeth are absorbed before birth. The permanent teeth exhibit great variety in form, sometimes even in the same family, as in *Phyllostomidæ*, whilst in other families, as in *Rhinolophidæ*, the resemblance between the dentition of species otherwise differing in many important respects is most remarkable. In all, however, they are provided with well-developed roots, and their crowns are acutely tuberculate, with more or less well-defined W-shaped cusps, in the insectivorous species, as in *Insectivora*, or variously hollowed out or longitudinally grooved in the frugivorous, as in some species of *Phyllostomidæ* and in the *Pteropodidæ*.

As might be expected, the shoulder-girdle varies very slightly, having the same office to fulfil in all species. The clavicle is very long, strong, and curved; the scapulæ large, oval, triangular, with a long curved coracoid process. The humerus, though long, is scarcely two-thirds the length of the radius; the ulna is rudimentary; its proximal extremity, which articulates with but a small part of the humerus, is ankylosed with the radius; immediately beyond the joint it is reduced to a very slender splint-like bone, which extends about as far as the middle of the radius. In all species a detached sesamoid bone exists in the tendon of the triceps muscle, and is generally found in skeletons. The radius is very long, in some species as long as the head and body. The proximal row of the carpus consists of a single bone (the united scaphoid, lunar, and cuneiform bones), which, with the extremity of the radius, forms the radio-carpal joint; in the distal row the trapezium, trapezoid, and os magnum vary much in size in the different families; the unciform appears to be the most constant, and the pisiform is generally very small. It will be necessary to again refer to this subject when dealing with the diagnostic characters of the suborders.

The manus is, in all the species, composed of five digits. The first, fourth, and fifth consist each of a metacarpal bone and two osseous phalanges; in the second and third the number of phalanges is different in certain families. The first digit—the pollex—always terminates in a claw, which, with the proximal phalanx, is most developed in the frugivorous species. In most of the species of the frugivorous *Pteropodidæ* the second digit is also provided with a claw, but in all other Bats this and the remaining digits are unarmed. In the genus *Triænops* alone a very peculiar short bony process projects from the outer side of the proximal extremity of the terminal phalanx of the fourth digit. The relative development of the digits and their phalanges will be specially treated of under each family.

As might be expected from the small size of the posterior limbs, the pelvic girdle is very weak. The iliac bones are long and narrow. In most species the pubic bones of opposite sides are very loosely united in front in males; in females they are widely separated; in the family *Rhinolophidæ* alone do these bones form a symphysis. The eminentia ileo-pectinea develops in all species a long pectineal process, which in the subfamily *Phyllorhininæ* alone is continued forwards to the anterior extremity of the ilium (*vide infra*, p. 412), forming a preacetabular foramen which is unique among mammals. The acetabulum is small and directed outwards, and slightly upwards, and with this is related the peculiar position of the hind limb described above as one of the chief characteristics of the order. The femur is slender and cylindrical, with a small head and very short neck, and scarcely differs in form throughout the species. The bones of the leg and foot are more variable; in the subfamily *Molossinæ* alone is there a well-developed fibula; in all other species this bone is either very slender or cartilaginous and ligamentous in its upper third, or reduced to a small bony process above the heel, as in *Megaderma*, or altogether absent, as in *Nycteris*.

The foot consists of a very short tarsus, and of slender, laterally compressed toes, with much curved claws. The first digit is composed of a metacarpal bone, a proximal and an ungual phalanx, and is slightly shorter than the other four toes, which have each an additional phalanx, except in the subfamily *Phyllorhininæ* and in the anomalous genera *Thyroptera* and *Myxopoda*, where all the toes have the same number of phalanges as the first digit, and are equal to it in length. In the very remarkable genus *Cheiromeles* the first digit is thumb-like and separated from the others; and in the *Molossi* the first and fifth digits are much thicker than the intermediate toes.

The *muscular system*, as might be expected, exhibits few striking differences throughout the species. The most noticeable peculiarities in the myology of the order consist in the separated bands or slips into which the platysma is divided, and in the remarkable muscle termed occipito-pollicalis, which extends from the occipital bone to the base of the terminal phalanx of the pollex (see Macalister, "Myology of the *Chiroptera*," *Phil. Trans. Roy. Soc.*, 1872).

Although, as above mentioned, the brain presents a low type of organization, yet probably no animals possess so delicate sense of touch as the *Chiroptera*. It is undoubtedly this perceptive power which enabled the individuals deprived of sight, hearing, and smell, in Spallanzani's well-known experiments, to avoid the numerous threads hung across the rooms in which they were permitted to fly about. In the common Bats the tactile organs evidently exist, not only in the delicate vibrissæ which spring from the sides of the muzzle, but also in the highly sensitive and widely extended integumentary structures entering into the formation of the wing-membranes and ear-conchs, while in many other species, notably in the tropical Rhinolophine and Phyllostomine Bats, peculiar foliaceous cutaneous expansions surrounding the nasal apertures or extending backwards behind them are superadded (*vide infra*). These structures, collectively known as the "nose-leaf" (whence the term "leaf-nosed Bats"), have been shown by the present writer (who has traced their gradual development in different species) to be made up partly of the extended and thickened marginal integument of the nostrils, and partly of the highly differentiated glandular eminences occupying the sides of the muzzle, in which, in all the common Bats, the vibrissæ are implanted.

In all species of leaf-nosed Bats, and especially in the *Rhinolophidæ*, in which the nasal appendages reach their highest development, the superior maxillary division of the fifth nerve is of remarkably large calibre. The nasal branch of this nerve, which is given off immediately beyond the infra-orbital foramen, is by far the largest portion, the palpebral and labial branches consisting of a few slender nerve fibres only. This branch passes forwards and upwards on the sides of the superior maxillary bone, but soon spreads out into numerous filaments which pass into the muscles and integument above, and into the base of the nose-leaf. The nerve supply of the nose-leaf is further considerably augmented by the large nasal branch of the ophthalmic division of the fifth nerve.

While the many foliations, elevations, and depressions which vary the form of the nose-leaf also greatly increase the sensory surface so abundantly supplied by the fifth nerve, and in rapid flight intensify the vibrations conveyed to it, the great number of sweat and oil glands which enter into its structure perform an important function, analogous to that of the glands of the auditory canal in relation to the membrana tympani, in maintaining its surface in a highly sensitive condition.

The nasal appendages of *Chiroptera*, then, may be regarded as performing the office of an organ of a very exalted sense of touch standing in the same relation to the nasal branches of the sensory divisions of the fifth nerve as the aural apparatus to the auditory nerve; for, as the latter organ collects and transmits the waves of sound, so the former receives impressions arising from vibrations communicated to the air by approaching objects.

In no order of mammals is the ear-conch so greatly developed or so variable in form; in most of the insectivorous species the ears are longer than the head, while in some, as in the common Long-eared Bat (*Plecotus auritus*), their length nearly equals that of the head and body. The form of the conch is very characteristic in each of the families; in most the tragus is remarkably large, in some extending nearly to the outer margin of the conch; its office appears to be to cause undulations in the waves of sound, and so intensify and prolong them. It is worthy of notice that in the only family of insectivorous Bats wanting the tragus, the *Rhinolophidæ*, the auditory bullæ osseæ reach their greatest size, and the highly sensitive nasal appendages their highest development; also in the group *Molossi* the ear-conch is divided by a prominent keel; and the antitragus is remarkably large in those species in which the tragus is minute (see fig. 66, *a*). In the frugivorous Bats, as might be expected, the form of the ear-conch is very simple, and but slightly variable throughout the species.

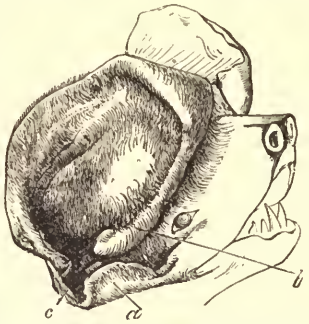

Fig. 66.—Head of *Molossus glaucinus*. Dobson, *Proc. Zool. Soc.*, 1876. *a*, antitragus; *b*, keel of the ear-conch; *c*, notch behind antitragus.

In all Bats the ears are extremely mobile, each moving independently at the will of the animal. This has been observed by the writer even in the frugivorous *Pteropodidæ*, in which the peculiar vibratory movements noticed by Mr Osburn in *Artibeus perspicillatus* may also be seen when the animals are alarmed.

The opening of the mouth is anterior in most species, but in many it is inferior, the extremity of the nose being more or less produced beyond the lower lip, so much so indeed in the small South-American species *Rynchonycteris naso* as to resemble that of the Shrews. The lips exhibit the greatest variety in form, which will be specially referred to under each family. The absence of a fringe of hairs is very characteristic of all fruit-eating Bats, and probably always distinguishes them from the insectivorous species, which they may resemble in the form of their teeth and in other respects.

The œsophagus is narrow in all species, and especially so in the sanguivorous *Desmodontes*. The stomach presents two principal types of structure, which correspond respectively to the two great divisions of the order, the *Megachiroptera* and the *Microchiroptera*; in the former (with the exception of *Harpyia*) the pyloric extremity is more or less elongated and folded upon itself, in the latter it is simple, as in *Insectivora vera*; a third exceptional type is met with in the sanguivorous *Desmodontes*, where the left or cardiac extremity is greatly elongated, forming a long narrow cæcum-like appendage. The intestine is comparatively short, varying from one and a half to four times the length of the head and body, being longest in the frugivorous, shortest in the insectivorous species. In *Rhinopoma microphyllum* and *Megaderma spasma* only has a very small cæcum been found.

The liver is characterized by the great size of the left lateral lobe, which occasionally equals half the size of the whole organ; the right and left lateral fissures are usually very deep; in *Megachiroptera* (*Harpyia* excepted) the Spigelian lobe is ill-defined or absent, and the caudate is generally very large, but in *Microchiroptera*, on the other hand, the Spigelian lobe is very large, while the caudate is small, in most species forming a ridge only. The gall-bladder is generally well developed and attached to the right central lobe, except in *Rhinolophidæ*, where it is connected with the left central.

In most species the hyoid bones are simple, consisting of a chain of slender, elongated, cylindrical bones connecting the small basi-hyoid with the cranium, while the pharynx is short, the larynx shallow with feebly developed vocal cords, and guarded by a short acutely-pointed epiglottis, which in some genera (*Harpyia*, *Vampyrus*, *e.g.*) is almost obsolete. In the *Epomophori*, however, we find a remarkable departure from the general type: the pharynx is long and very capacious, the aperture of the larynx far removed from the fauces, and, opposite to it, a canal, leading from the narial chambers, and extending along the back of the pharynx, opens; the laryngeal cavity is spacious and its walls are ossified; the hyoid bone is

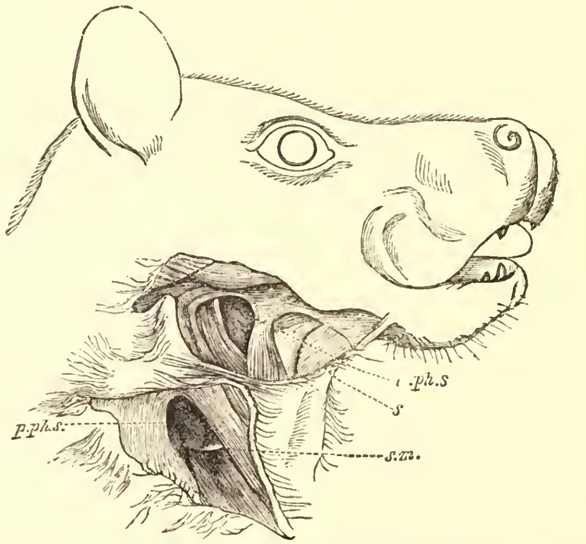

Fig. 67.—Head and Neck of *Epomophorus franqueti* (adult male, natural size). Dobson, *Proc. Zool. Soc.*, 1881. The anterior (*a.ph.s*) and posterior (*p.ph.s*) pharyngeal sacs are opened from without, the dotted lines indicating the points where they communicate with the pharynx; *s*, thin membranous septum in middle line between the anterior pharyngeal sacs of opposite sides; *s.m*, sterno-mastoid muscle separating the anterior from the posterior sac.

quite unconnected, except by muscle, with the cranium; the cerato-hyals and epi-hyals are cartilaginous and greatly expanded, entering into the formation of the walls of the pharynx, and, in the males of three species at least, supporting the orifices of a large pair of air-sacs communicating with the pharynx (see fig. 67).

In extent, peculiar modifications, and sensitiveness, the cutaneous system reaches its highest development in this order. As a sensory organ its chief modifications in connexion with the external ear, and with the nasal and labial appendages, have been described when referring to the nervous system. It remains therefore to consider its relative development as part of the organs of flight.

The extent and shape of the volar membranes depend mainly on the form of the bones of the anterior extremities, and on the presence or absence of the tail. Certain modifications of these membranes, however, are met with, which evidently do not depend on the skeleton, but are related to the habits of the animals, and to the manner in which the wing is folded in repose.

The volar membranes consist of—(1) the "antebrachial membrane," which extends from the point of the shoulder along the humerus and more or less of the forearm to the base of the thumb, the metacarpal bone of which is partially or wholly included in it; (2) the "wing-membrane," which is spread out between the greatly elongated fingers, and extends along the sides of the body to the posterior extremities, generally reaching to the feet; and (3) the "interfemoral membrane," the most variable of all, which is supported between the extremity of the body, the legs, and the calcanea (see fig. 65).

The antebrachial and wing membranes are most developed in those species which are fitted only for aerial locomotion, and which when at rest hang with the body enveloped in the wings; but in the family *Emballonuridæ*, especially in the subfamily *Molossinæ* (the species of which are, of all Bats, the best fitted for terrestrial progression), the antebrachial membrane is reduced to the smallest size, and is not developed along the forearm, leaving also the thumb quite free, and the wing-membrane is very narrow and folded in repose completely under the forearm. The relative development of the interfemoral membrane has been referred to above in describing the caudal vertebræ. Its small size in the frugivorous and sanguivorous species, which do not require it, to which, indeed, its presence would be actually injurious as impeding their motions when searching for food as they hang suspended by their feet, is easily understood. Odoriferous glands and pouches opening on the surface of the outer skin are developed in many species, but in most cases more so in males than in females, and so constitute very remarkable secondary sexual characters. They will be referred to when treating of the peculiarities of certain species. (See also the writer's paper "On Secondary Sexual Characters in *Chiroptera*," *Proc. Zool. Soc. Lond.*, 1873, pp. 241–252.)

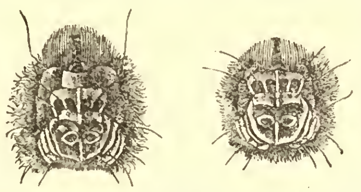

FIG. 68.—Frontal Sac and Nose-Leaf in Male and Female of *Phyllorhina larvata*. Dobson, *Proc. Zool. Soc.*, 1873.

Space does not admit of entering here upon a special description of the respiratory, circulatory, digestive, urinary, and generative organs, which will be found fully treated of in the works noted in the bibliography of the order below, and therefore with the above short account of the general structure of the species we proceed to consider their classification and geographical distribution.

The *Chiroptera* fall naturally into two subdivisions, which may be called suborders.

SUBORDER I. *MEGACHIROPTERA.*

Frugivorous Bats, generally of large size, having the crowns of the molar teeth smooth, marked with a longitudinal groove; with the bony palate continued behind the last molar narrowing slowly backwards; with three phalanges in the index finger, the third phalanx terminated generally by a claw; with the sides of the ear-conch forming a complete ring at the base; with the tail, when present, inferior to (not contained in) the interfemoral membrane; with the pyloric extremity of the stomach generally much elongated; and with the Spigelian lobe of the liver ill-defined or absent, while the caudate is well developed.

Frugivorous; limited to the tropical and subtropical parts of the Eastern Hemisphere.

Family PTEROPODIDÆ.

The characters of the single family are those of the suborder.

Epomophorus, $i\ \frac{2}{2}$ (or $\frac{1}{2}$), $c\ \frac{1}{1}$, $pm\ \frac{2}{3}$, $m\ \frac{1}{2}$; tail very short or none, when present quite free from the interfemoral membrane; second finger with a claw; premaxillary bones united in front. The six species include some of the most remarkable forms of fruit-eating Bats. They are strictly limited to the African continent south of the Sahara, and are readily distinguished by their remarkably large and long head and very expansible, often peculiarly folded, lips, and by the invariable white tuft of hair which adorns the margins of the ears; most of the species also are provided with peculiar glandular pouches, situated in the integument of the side of the neck near the point of the shoulder. These pouches are rudimentary or quite absent in females, thus presenting an interesting secondary sexual character. In the males they are lined with a glandular membrane, from which long coarse yellowish hairs arise, and, projecting from the mouth of the pouches, form conspicuous epaulet-like tufts on the shoulders, hence the generic name. Another and even still more remarkable secondary sexual character has been recently discovered by the writer in the males of *E. franqueti*, *comptus*, *pusillus*, and *monstrosus*. This consists in the presence of a pair of large air-sacs extending outwards on each side from the pharynx beneath the integument of the neck, in the position shown in fig. 67. These sacs are evidently capable of being greatly distended at the will of the animal, and their inflation probably occurs under the same circumstances that the wattles of male gallinaceous birds swell up, namely, when engaged in courting the females. Other remarkable conditions in which these Bats appear to differ from all other species, as in the peculiar structure of the hyoid bones and larynx, may be found described in detail in the writer's paper in the *Proceedings of the Zoological Society* for June 1881. These Bats appear to live principally on figs, the juicy contents of which their voluminous lips and capacious mouths enable them to swallow without loss.

Pteropus, $i\ \frac{2}{2}$, $c\ \frac{1}{1}$, $pm\ \frac{3}{3}$, $m\ \frac{2}{3}$, with forty-one species, includes more than half the *Pteropodidæ*. All are of large size, and the absence of a tail, the long pointed muzzle, and the woolly fur covering the neck render their recognition easy. They are the "Flying Foxes" of Europeans in India, and one of the species, *Pt. edulis*, inhabiting Java, measures 5 feet across the fully extended wings, and is the largest known species of the order. The species resemble one another closely in dentition, and are mainly distinguished by the form of the ears and quality of the fur. *Pt. scapulatus*, from north-east Australia, approaches the species of the second section of the family, the *Macroglossi*, in the remarkable narrowness of its molars and premolars.

FIG. 69.—Head of *Pteropus personatus*. Gray, *Proc. Zool. Soc.*, 1866.

The geographical range of the genus is very peculiar, extending from Madagascar and its islands through the Seychelles to India, Ceylon, Burmah, the Malay Archipelago, southern Japan, New Guinea, Australia, and Polynesia (except the Sandwich Islands, Ellice's Group, Gilbert's Group, Tokelau, and the Low Archipelago). Of the islands inhabited some are very small and remote from any continent, such as Savage Island in the South Pacific, and Rodriguez in the Indian Ocean. Although two species inhabit the Comoro Islands, which are scarcely 200 miles from the African coast, not a single species is found in Africa; yet in India, separated by thousands of miles of almost unbroken ocean, a species exceedingly closely allied to the common Madagascar "Flying Fox" is abundant. The Malay Archipelago and Australia are their headquarters, and in some places they occur in countless multitudes. Mr Macgillivray remarks of *Pt. conspicillatus*:—"On the wooded slope of a hill on Fitzroy Island I one day fell in with this Bat in prodigious numbers, looking while flying in the bright sunshine (so unusual for a nocturnal animal) like a large flock of rooks. On close approach a strong musky odour became apparent, and a loud incessant chattering was heard. Many of the branches were bending under their load of Bats, some in a state of inactivity, suspended by their hind claws, others scrambling along among the boughs, and taking to wing when disturbed." *Cynonycteris*, dentition as in *Pteropus*, but with a short tail, and the fur of the back of the neck not differing from that of the back, with nine species, extends into Africa, but has not been recorded from Australia or Polynesia; otherwise its distribution accords with that of *Pteropus*. *C. ægyptiaca* inhabits the chambers of the Great Pyramid and other deserted buildings in Egypt, and is probably the species so generally figured in Egyptian frescos. *Boneia*, with one species, *B. bidens*, from Borneo, differs from *Cynonycteris* in having two upper incisors only.

Cynopterus, $i\ \frac{2}{2}$ or $\frac{2}{1}$, $c\ \frac{1}{1}$, $pm\ \frac{3}{3}$, $m\ \frac{2}{2}$, muzzle shorter and grooved like *Pteropus* in front, tail and fur as in *Cynonycteris*, with seven species, is almost limited to the Oriental region. *C. marginatus* is very common in India, and extremely destructive to ripe fruit of every description. To a specimen of this Bat obtained by the writer at Calcutta uninjured was given a ripe banana, which, with the skin removed, weighed exactly 2 ounces. The animal immediately, as if famished with hunger, fell upon the fruit, seizing it between the thumbs and the index fingers, and took large mouthfuls out of it, opening the mouth to the fullest extent with extreme voracity. In the space of three hours the whole fruit was consumed. Next morning the Bat was killed, and found to weigh one ounce, half the weight of the food eaten in three hours. Indeed the animal when eating seemed to be a kind of living mill, the food passing from it almost as fast as devoured, and apparently unaltered, eating being, as it were, performed only for the pleasure of eating.

FIG. 70.—Head of *Harpyia major*. Dobson, *Proc. Zool. Soc.*, 1877.

Harpyia, $i\ \frac{1}{0}$, $c\ \frac{1}{1}$, $pm\ \frac{2}{3}$, $m\ \frac{2}{2}$, premaxillary bones well-developed and united in front, facial bones much elevated above the margin of the jaw, nostrils tubular, body and limbs as in *Cynopterus*, includes two species of very remarkable physiognomy (as may be seen from fig. 70), limited to the Austro-Malayan subregion.

Cephalotes, *i* $\frac{1}{1}$, *c* $\frac{1}{1}$, *pm* $\frac{2}{3}$, *m* $\frac{2}{3}$, premaxillary bones not united in front, nostrils simple, muzzle short, index finger without a claw, tail short, includes two species, having the same distribution as those of *Harpyia*; in both the wing-membrane arises from the centre line of the back, to which it is attached by a longitudinal very thin process of the integument; the wings are quite naked, but the back covered by them is well clothed with hair.

Notopteris, *i* $\frac{2}{1}$, *c* $\frac{1}{1}$, *pm* $\frac{2}{3}$, *m* $\frac{2}{2}$, index finger without a claw, wings from the spine, tail long. With this genus we enter the second division of the family, the *Macroglossi*, which have the facial part of the skull much produced, the molar teeth narrow, and scarcely raised above the gum, and the tongue exceedingly long, attenuated in the anterior third, and armed with long recurved papillæ near the tip. The single representative of the genus, *N. macdonaldii*, inhabits the Fiji Islands, Aneiteum Island, and New Guinea. It is at once distinguished from all other Bats of this family by the remarkable length of its tail, which is nearly as long as the forearm.

Eonycteris, *i* $\frac{2}{2}$, *c* $\frac{1}{1}$, *pm* $\frac{3}{3}$, *m* $\frac{2}{3}$, is also represented by a single species, *E. spelæa*, from the Farm Caves, Moulmein, Burmah, which has somewhat the appearance of a *Cynonycteris*, but the absence of a claw in the index finger and the presence of the characteristic tongue and teeth at once distinguish it.

Macroglossus and *Melonycteris*, each with a single species, are closely allied; the index finger in both has a claw, but the number of the teeth is the same as in *Eonycteris*. *Macroglossus minimus* is the smallest known species of the suborder; it is much smaller than the common Serotine Bat of Europe, and its forearm is scarcely longer than that of the Long-eared Bat. It is nearly as common in certain parts of India as *Cynopterus marginatus* (compared with which it is proportionally equally destructive to fruit), and extends eastward through the Malay Archipelago as far as New Ireland, where it is associated with *Melonycteris melanops*, distinguished from it by its larger size and by the total absence of the tail.

Suborder II. *MICROCHIROPTERA.*

Insectivorous (rarely frugivorous or sanguivorous) Bats, of comparatively small size, having the crowns of the molar teeth acutely tuberculated, marked by transverse grooves, with the bony palate narrowing abruptly, not continued backwards laterally behind the last molar; with one rudimentary phalanx (rarely two phalanges or none) in the index finger, which is never terminated by a claw; with the outer and inner sides of the ear-conch commencing inferiorly from separate points of origin; with the tail, when present, contained in the interfemoral membrane, or appearing upon its upper surface; with a simple stomach (except in *Desmodontes*); and with the Spigelian lobe of the liver very large, the caudate lobe generally small. Inhabiting the tropical and temperate regions of both hemispheres.

The Bats included in this suborder are mainly insectivorous, though some are frugivorous, and two species are known to be sanguivorous. They fall into five natural families, which may be arranged in two groups or alliances as follows:—

I. Tail contained within the interfemoral membrane; the middle pair of upper incisors never large, always separated from each other by a more or less wide space. I. *Vespertilionine Alliance.*

- *a.* Middle finger with two osseous phalanges only (except in *Myxopoda aurita*, *Thyroptera tricolor*, and *Mystacina tuberculata*).
  - *a'.* First phalanx of the middle finger extended (in repose) in a line with the metacarpal bone.
    - *a''.* Nostrils opening in a depression on the upper surface of the muzzle, surrounded by foliaceous cutaneous appendages.
      - *a'''.* Tragus none; premaxillary bones rudimentary, represented by thin osseous laminæ suspended from the nasal cartilages in the centre of the space between the canines. *Rhinolophidæ.*
      - *b'''.* Tragus distinct; premaxillary bones cartilaginous or small, separated by a space in front. *Nycteridæ.*
    - *b''.* Nostrils opening by simple crescentic or circular apertures at the extremity of the muzzle, not surrounded by distinct foliaceous cutaneous appendages; premaxillary bones small, lateral, separated by a wide space in front; tragus distinct. *Vespertilionidæ.*

II. Tail perforating the interfemoral membrane, and appearing on its upper surface, or produced considerably beyond the truncated membrane; the middle pair of upper incisors generally large and close together. II. *Emballonurine Alliance.*

  - *b'.* First phalanx of the middle finger folded (in repose) on the dorsal surface of the metacarpal bone (except in *Noctilio* and *Mystacina*).
    - *c''.* Nostrils opening by simple circular or valvular apertures at the extremity of the muzzle, not surrounded or margined by foliaceous cutaneous appendages; tragus distinct. *Emballonuridæ.*
- *b.* Middle finger with three well developed osseous phalanges; first phalanx of the middle finger short; nostrils in the front part of the cutaneous nasal appendages, or opening by simple apertures at the extremity of the muzzle; chin with warts or erect cutaneous ridges; premaxillary bones well-developed, united in front. *Phyllostomidæ.*

I. Vespertilionine Alliance.

Family Vespertilionidæ.

In the above synopsis of the families of *Microchiroptera* the *Vespertilionidæ* take the central position; and this is, indeed, the place really occupied by them in the suborder. This family includes the common simple-faced Bats of all countries, of which the well-known Pipistrelle and the Whiskered Bat (*Vespertilio mystacinus*) may be taken as familiar types, and its species number about 150, considerably more than one-third the total number of the known species of *Chiroptera*, estimated at slightly over 400 (see Introd. to Dobson's *Catal. Chiropt. Brit. Mus.*, 1878). Besides the characters of the family given in the synopsis, it may be added that the skull is of moderate size, the nasal and frontal bones not much extended laterally or vertically, nor furrowed by deep depressions; the number of incisors varies from $\frac{2}{3}$ to $\frac{1}{3}$, rarely (in *Antrozous* only) $\frac{1}{2}$, premolars $\frac{3}{3}$ or $\frac{2}{2}$ or $\frac{1}{2}$, rarely (in *Vesperugo noctivagans* of North America) $\frac{2}{3}$; the upper incisors are small, separated by a wide space in the centre, and placed in pairs or singly near the canines; the molars are well-developed, with acute W-shaped cusps. The family is distributed over the temperate and tropical regions of both hemispheres. The genera may be conveniently divided into four groups:—*Plecoti*, *Vespertiliones*, *Miniopteri*, and *Thyropteri*.

In the *Plecoti*, of which the common Long-eared Bat (*Plecotus auritus*) is the type, the crown of the head is but slightly raised above the face-line, the upper incisors are close to the canines, and the nostrils are margined behind by grooves on the upper surface of the muzzle, or by rudimentary nose-leaves; the ears also are generally very large and united. Of the five genera, *Plecotus*, *i* $\frac{2}{3}$, *pm* $\frac{2}{3}$, has two species:—one the common Long-eared European Bat referred to above; the other, *P. macrotis*, restricted to North America, is distinguished by the great size of the glandular prominences of the sides of the muzzle, which meet in the centre above and behind the nostrils. *Synotus*, *i* $\frac{2}{3}$, *pm* $\frac{2}{2}$, distinguished by dentition and by the outer margin of the ear being carried forwards above the mouth and in front of the eye, includes the European Barbastelle Bat, *S. barbastellus*, and *S. darjelingensis* from the Himalaya. *Otonycteris*, *i* $\frac{1}{3}$, *pm* $\frac{1}{2}$, connecting this group with the *Vespertiliones* through the tropical *Scotophili*, is represented by a single species, *O. hemprichii*, from North Africa and the Himalaya. The next two genera are distinguished by the presence of a rudimentary nose-leaf:—*Nyctophilus*, *i* $\frac{1}{3}$, *pm* $\frac{1}{2}$, with one species, *N. timoriensis*, from the Australian region; and *Antrozous*, *i* $\frac{1}{2}$, *pm* $\frac{1}{2}$, distinguished from all the family besides by having but two lower incisors, and from other *Plecoti* by the separate ears; the single species, *A. pallidus*, inhabits California.

The group *Vespertiliones*, with eight genera, includes nine-tenths of the species. Of these one-third are contained in the genus *Vesperugo*, which is divisible into six subgenera according to the number of premolars and incisors; the latter vary from $\frac{2}{3}$ to $\frac{1}{3}$ in the subgenera *Scotozous* and *Rhogeëssa*, and the premolars from $\frac{2}{2}$ to $\frac{1}{2}$ (in the subgenus *Lasionycteris* $\frac{2}{3}$). The Bats of this genus are generally easily distinguished by their comparatively thickly formed bodies, by their flat broad heads and obtuse muzzles, by their short, broad, and triangular, obtusely-pointed ears, by their obtuse and usually slightly incurved tragus, by their short legs, and by the presence in most species of a well-developed post-calcaneal lobule. This lobule (which is supported by a cartilaginous process derived from the calcaneum) may act as a kind of adhesive disk in securing the animal's grasp when climbing over smooth surfaces. *Vesperugo* probably contains the greatest number of individuals among the genera of *Chiroptera*, and, with the exception of *Vespertilio*, its species have also the widest geographical range, being in fact cosmopolitan; and one of the species, the well-known Serotine, *V.* (*Vesperus*) *serotinus*, is remarkable as the only species of Bat known to inhabit both the Old and the New World; one, *V. borealis*, has been found close to the limits of the Arctic Circle, and another, *V. magellanicus*, inhabits the cold and desolate shores of the Straits of Magellan, doubtless the Bat referred to by Mr Darwin in the *Naturalist's Voyage*. *Chalinolobus* agrees with *Vesperugo* in the dental formula, but is readily distinguished by the presence of a well-defined lobe projecting near the angle of the mouth from the lower lip, and by the unicuspidate upper inner incisors. The species fall into two subgenera:—*Chalinolobus*, *pm* $\frac{2}{2}$, with *C. tuberculatus* from New Zealand, Tasmania, and Australia, and three other species from Australia; and *Glauconycteris*, *pm* $\frac{1}{2}$, limited to southern and equatorial Africa, with *G. argentatus* and two other species, the Bats of this subgenus being especially remarkable for their peculiarly thin membranes traversed by very distinct reticulations and parallel lines. *Scotophilus*, *i* $\frac{1}{3}$, *pm* $\frac{1}{2}$, includes eight species, restricted to the tropical and subtropical regions of the eastern hemisphere, though widely distributed within these limits. The Bats of this genus, though difficult to define, and approaching certain of those of *Vesperugo* in many points, are distinguished especially by the single pair of unicuspidate upper incisors separated by a wide space and placed close to the canines, by the small transverse first lower premolar crushed in between the canine and second premolar, and, generally, by their conical nearly naked muzzles and remarkably thick leathery membranes. *Sc. temminckii* is probably the commonest species of Bat in India, and appears often on the wing even before the sun has touched the horizon, especially when the white ants are swarming, feeding eagerly upon them as they rise in the air. *Sc. gigas*, from equatorial Africa, with the forearm 3·4 inches, is by far the largest species. *Nycticejus*, with the same dental formula as *Scotophilus*, is distinguished by the first lower premolar not being crushed in between the adjoining teeth, and by the comparatively much greater size of the last upper molar. It includes only the common North American species *N. crepuscularis*, a small Bat scarcely larger than the Pipistrelle. *Atalapha*, *i* $\frac{1}{3}$, *pm* $\frac{2}{2}$ or $\frac{1}{2}$, with five species, is also limited to the New World. The Bats of this genus are generally characterized by the interfemoral membrane being more or less covered with hair (in the two commonest species, *A. noveboracensis* and *A. cinerea*, wholly thickly covered), and by the peculiar form of the tragus, which is expanded above and abruptly curved inwards. In these species, which have two upper premolars, the first is extremely small and quite internal to the tooth-row. The genus *Harpyiocephalus*, *i* $\frac{2}{3}$, *pm* $\frac{2}{2}$, includes eight very remarkable small species, distinguished at once by their prominent tube-like nostrils and hairy interfemoral membrane. *H. suillus* from Java and neighbouring islands is the best-known species, and another closely allied, *H. hilgendorfi*, has been described by Professor Peters from Japan. The remaining six species are known only from the Himalaya and Tibet. All appear to be restricted to the hill tracts of the countries in which they are found. Next to *Vesperugo*, the genus *Vespertilio*, *i* $\frac{2}{3}$, *pm* $\frac{3}{3}$, includes by far the largest number of species, amounting to forty-three; it has, however, rather a wider geographical distribution in both hemispheres, one species at least being recorded from the Navigators' Islands. The species are easily recognized by the peculiar character of the pairs of upper incisors on each side, the cusps of which diverge from each other, by the large number of premolars, of which the second upper is always very small, and by the oval elongated ear and narrow attenuated tragus. *Kerivoula*, with the same dental formula as *Vespertilio*, is easily distinguished by the parallel upper incisors, and by the comparatively large size of the second upper premolar. Ten species have been described from the Ethiopian and Oriental regions, of which *K. picta*, from India and the Indo-Malayan subregion, is the best-known, being well characterized by its brilliantly coloured orange fur and conspicuously marked membrane, which are variegated with orange and black. The genus includes the most delicately formed and most truly insectivorous, tropical, forest-haunting Bats, which appear to stand as regards the species of *Vespertilio* in a position similar to that occupied by *Chalinolobus* with respect to *Vesperugo*.

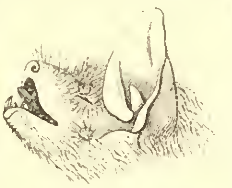

Fig. 71.—Head of *Scotophilus emarginatus*. Dobson, *Monogr. Asiat. Chiropt.*

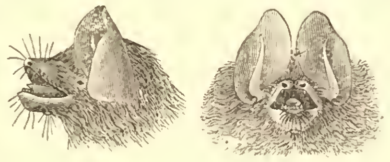

Fig. 72.—Side and Front View of the Head of *Kerivoula hardwickii*. Dobson, *Monogr. Asiat. Chiropt.*

The next group, *Miniopteri*, includes two genera, *Natalus* and *Miniopterus*, characterized by the great elevation of the crown of the head above the face-line, and by the upper incisors being separated from the canines and also in front. *Natalus*, with the same dental formula and general external form as *Kerivoula*, is distinguished by the short triangular tragus, and by the characters of the group enumerated above. It includes three species, all restricted to South and Central America and the West Indies; the head of one, *N. micropus*, lately described by the present writer, is shown in fig. 73. *Miniopterus*, *i* $\frac{2}{3}$, *pm* $\frac{2}{3}$, at once distinguished by the shortness of the first phalanx of the middle finger, and by the great length of the tail, which is wholly contained within the interfemoral membrane, includes four species, restricted to the eastern hemisphere. Of these the best-known, *M. schreibersii*, is very widely distributed, being found almost everywhere throughout the tropical and warmer temperate regions of the eastern hemisphere, specimens from Germany, Madagascar, Japan, and Australia differing in no appreciable respect.

Fig. 73.—Head of *Natalus micropus*. × 2. Dobson, *Proc. Zool. Soc.*, 1880.

The last group, *Thyropteri*, includes also two genera, distinguished not only by the presence of an additional osseous phalanx in the middle finger and an equal number of phalanges in the toes, but also by peculiar accessory clinging organs attached to the extremities. In *Thyroptera tricolor*, *i* $\frac{2}{3}$, *pm* $\frac{3}{3}$, from Brazil, these organs have the appearance of small, circular, pedunculated, hollow disks (fig. 74), resembling in miniature the sucking cups of cuttle-fishes, and attached to the inferior surfaces of the thumbs and soles of the feet, with which the animal is enabled to maintain its hold when creeping over smooth vertical surfaces (for an account of the minute anatomy of these clinging organs see the writer's paper in the *Proc. Zool. Soc.*, 1876, pp. 531–34). In *Myxopoda aurita* from Madagascar (type of the second genus), with the same dental formula, but differing much in the characters of the teeth and in the form of the ears, the whole inferior surface of the thumb supports a large sessile horse-shoe-shaped adhesive pad, with the circular margin directed forwards and notched along its edge, and a smaller pad occupies part of the sole of the foot.

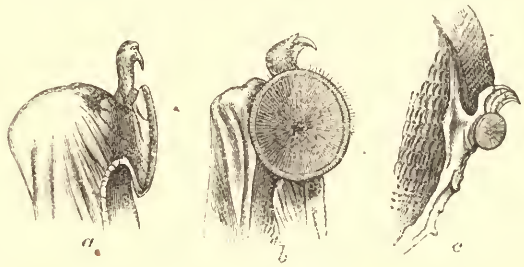

Fig. 74.—Suctorial Disks in *Thyroptera tricolor*. *a*, side, and *b*, concave surface, of thumb disk; *c*, foot with disk, and calcar with projections (all much enlarged). Dobson, *Proc. Zool. Soc.*, 1876.

Family Nycteridæ.

This small family, defined in the synopsis above, includes only two genera of Bats of very peculiar aspect, limited to the tropical and subtropical parts of the eastern hemisphere.

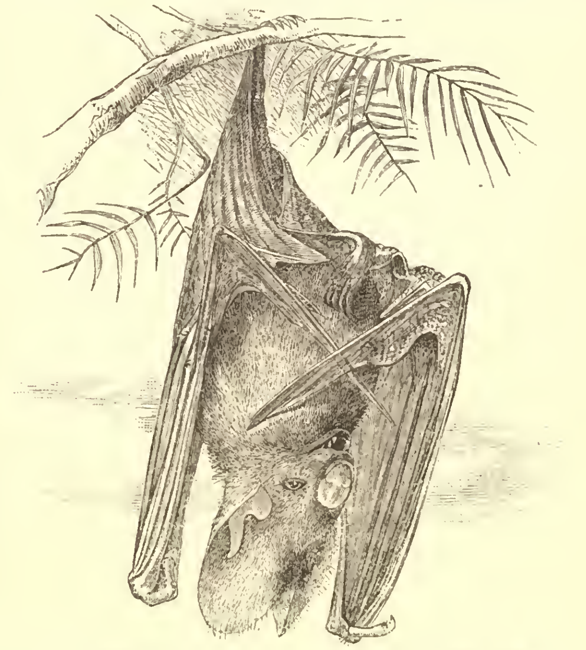

Fig. 75.—*Megaderma gigas*. × ½. Dobson, *Proc. Zool. Soc.*, 1880.

Megaderma, $i\ \frac{0}{2}$, $pm\ \frac{2}{2}$ or $\frac{1}{2}$, with five species, is distinguished by the absence of upper incisors, by the cylindrical narrow muzzle surmounted by an erect naked cutaneous process (the nose-leaf), the base of which conceals the nasal orifices, by the immense connate ears with large bifid tragi, and by the great extent of the interfemoral membrane, in the base of which the very short tail is concealed. *M. gigas*, from central Queensland (forearm 4·2 inches), is not only the largest species of the genus but also of the suborder. *M. lyra*, common in India (forearm 2·7 inches), has been caught in the act of sucking the blood, while flying, from a small species of *Vesperugo*, which it afterwards devoured (see Dobson's *Monograph of the Asiatic Chiroptera*, p 77), so that it is probable that the Bats of this genus do not confine themselves to insect prey alone, but also feed, when they can, upon the smaller species of Bats and other small mammals.

Nycteris, $i\ \frac{2}{3}$, $pm\ \frac{1}{2}$, with seven species, differs so much from *Megaderma* that it may be considered the type of a separate subfamily. As in that genus, the frontal bones are deeply hollowed out and expanded laterally, the muzzle presents a similar cylindrical form, and the lower jaw also projects, but the single elevated nose-leaf is absent, and instead of it the face is marked by a deep longitudinal sharp-edged groove extending from the nostrils (which are on the upper surface of the muzzle near its extremity) to the low band connecting the bases of the large ears; the sides of this depression are margined as far back as the eyes by small horizontal cutaneous appendages. All the species resemble one another closely, and are mainly distinguished by the form of the tragus, and the size and relative position of the second lower premolar. With the exception of *N. javanica*, all the species are limited to the Ethiopian region.

Family Rhinolophidæ.

In all the species of this family the nasal appendages are highly developed, and surround on all sides the nasal apertures, which are situated in a depression on the upper surface of the muzzle; the ears are large and generally separate, without trace of a tragus; the premaxillary bones are rudimentary, are suspended from the nasal cartilages, and support a pair of very small incisors; the molars have acute W-shaped cusps; the skull is large, and the nasal bones which support the large nasal cutaneous appendages are much expanded vertically and laterally; in females a pair of teat-like appendages are found in front of the pubis; and the tail is long and produced to the posterior margin of the interfemoral membrane. The family is found in the temperate and tropical parts of the eastern hemisphere.

From whatever point of view the *Rhinolophidæ* may be considered, they are evidently the most highly organized of insectivorous Bats. In them the osseous and cutaneous systems reach the most perfect development. Compared with theirs the bones of the extremities and the volar membranes of other Bats appear coarsely formed, and even their teeth seem less perfectly fitted to crush the hard bodies of insects. The very complicated nasal appendages, which evidently act as delicate organs of special perception (*vide supra*), here reach their highest development, and the differences in their form afford valuable characters in the discrimination of the species, which resemble one another very closely in dentition and in the colour of the fur.

Subfamily I. **Rhinolophinæ.**—First toe with two, other toes with three phalanges each; ilio-pectineal spine not connected by bone with the antero-inferior surface of the ilium.

Rhinolophus, $i\ \frac{1}{2}$, $c\ \frac{1}{1}$, $pm\ \frac{2}{3}$, $m\ \frac{3}{3}$, nose-leaf with a central process behind and between the nasal orifices, posterior extremity lanceolate, antitragus large, includes twenty-four species. *R. luctus*, forearm 3 inches, is the largest species, inhabiting elevated hill tracts in India and Malayana; *R. hipposideros* of Europe, extending into south England and Ireland, forearm 1·5 inches, is one of the smallest; and *R. ferrum-equinum*, forearm 2·3 inches, represents the average size of the species, which are mainly distinguished from one another by the form of the nose-leaf. The last-named species extends from England to Japan, and southward to the Cape of Good Hope.

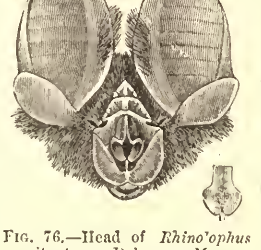

Fig. 76.—Head of *Rhinolophus mitratus*. Dobson, *Monogr. Asiat. Chiropt.*

Subfamily II. **Phyllorhininæ.**—Toes equal, of two phalanges each; ilio-pectineal spine united by a bony isthmus with a process derived from the antero-inferior surface of the ilium.

Phyllorhina, with twenty-two species, and *Rhinonycteris*, *Triænops*, and *Cœlops*, with one each, represent this subfamily. *Phyllorhina*, $i\ \frac{1}{2}$, $c\ \frac{1}{1}$, $pm\ \frac{2}{2}$ or $\frac{1}{2}$, $m\ \frac{3}{3}$, differs from *Rhinolophus* in the form of the nose-leaf, which is not lanceolate behind (see fig. 76), and is unprovided with a central process covering the nostrils; the largest species, *Ph. armigera*, appears to be the most northerly, having been taken at Amoy in China, and in the Himalaya at an elevation of 5500 feet. Many are provided with a peculiar frontal sac behind the nose-leaf, rudimentary in females (see fig. 67), which the animal can evert at pleasure; the sides of this sac secrete a waxy substance, and its extremity supports a pencil of straight hairs. *Rhinonycteris*, represented by *R. aurantia* from Australia, and *Triænops*, by *T. persicus*, from Persia and eastern Africa, are closely allied genera; the latter species is characterized by the very remarkable form of its nasal appendages and ears, and by the presence of a peculiar osseous projection from the proximal extremity of the second phalanx of the fourth finger. *Cœlops* (*C. frithii*), from the Bengal Sunderbunds, Java, and Siam (in the roof of the great pagoda at Laos), is distinguished, not only by the very peculiar form of its nose-leaf, but also by the great length of the metacarpal bone of the index finger, as well as by the shortness of the calcanea and interfemoral membrane.

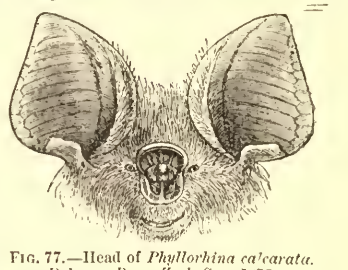

Fig. 77.—Head of *Phyllorhina calcarata*. Dobson, *Proc. Zool. Soc.*, 1877.

II. Emballonurine Alliance.

Family Emballonuridæ.

The second group of families (as defined above) into which the *Microchiroptera* may be divided includes the *Emballonuridæ* and *Phyllostomidæ*. The former is represented by thirteen genera, including sixty-five species. The *Emballonuridæ* are generally easily distinguished by the peculiar form of the muzzle, which is obliquely truncated, the nostrils projecting more or less in front beyond the lower lip, by the first phalanx of the middle finger being folded in repose forwards on the upper surface of the metacarpal bone, by the tail, which either perforates the interfemoral membrane or is produced far beyond it, and by the upper incisors, which are generally a single pair separated from the canines and also in front. They are cosmopolitan like the *Vespertilionidæ*, but rarely extend north or south of the thirtieth parallel of latitude.

Subfamily I. **Emballonurinæ.**—Tail slender, perforating the interfemoral membrane, and appearing upon its upper surface, or terminating in it; legs long, fibulæ very slender; upper incisors weak.

Group I. *Furiæ.*—Tail terminating in the interfemoral membrane; crown of the head greatly elevated above the face-line; thumb and first phalanx of the middle finger very short; $i\ \frac{2}{3}$, $c\ \frac{1}{1}$, $pm\ \frac{2}{2}$, $m\ \frac{3}{3}$.

Two genera, *Furia* and *Amorphochilus*, each including one species of very peculiar aspect, the latter distinguished from the former by the widely separated nostrils and great extension backwards of the bony palate. Habitat South America.

Group II. *Emballonuræ.*—Part of the tail included in the basal half of the interfemoral membrane, the remaining part passing through and appearing upon its upper surface; crown of the head slightly elevated; thumb and first phalanx of the middle finger moderately long; $pm\ \frac{2}{2}$. With five genera.

Emballonura, $i\ \frac{2}{3}$, extremity of the muzzle more or less produced beyond the lower lip, forehead flat, contains five species, inhabiting islands from Madagascar through the Malay Archipelago to the Navigators' Islands. *Coleüra*, $i\ \frac{1}{3}$, extremity of the muzzle broad, forehead concave, has two species from east Africa and the Seychelles Islands. *Rhynchonycteris* is distinguished from *Coleüra* by the much produced extremity of the muzzle; the single species, *R. naso*, from Central and South America, is very common in the vicinity of streams throughout the tropical parts of these countries. It is usually found during the day resting on the vertical

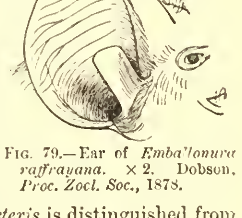

Fig. 79.—Ear of *Emballonura raffrayana*. × 2. Dobson, *Proc. Zool. Soc.*, 1878.

faces of rocks, or on the trunks of trees growing out over the water, and, owing to the peculiar greyish colour of the fur covering the body and growing in small tufts from the antebrachial membrane, counterfeiting the weathered surfaces of the rocks and the bark of the trees, easily escapes notice. As the shades of evening approach it appears early on the wing, flying close to the surface of the water, and seizing the minute insects that hover over it. *Saccopteryx*, *i* $\frac{1}{3}$, antebrachial membrane with a pouch opening on its upper surface, contains six species from Central and South America; the wing-sac varies in position in different species. It is developed only in the male; in the female it is quite rudimentary. In the adult males of the different species a valvular longitudinal opening is found on the upper surface of the membrane. This opening leads into a small pouch (in some species large enough to hold a pea), the interior of which is lined with a glandular membrane secreting an unctuous substance of a reddish colour with a strong ammoniacal odour. The presence of this sac in males only indicates that it is a secondary sexual character analogous to the shoulder pouches of *Epomophorus*, the frontal sacs of *Phyllorhina*, &c.

The next genus *Taphozous*, including ten species, inhabiting the tropical and subtropical parts of all the eastern hemisphere except Polynesia, forms the second section of this group, distinguished by its cartilaginous premaxillaries, deciduous pair of upper incisors, and by the presence of four lower incisors only. Most of the species have a peculiar glandular sac (see fig. 80) placed between the

♂ ♀

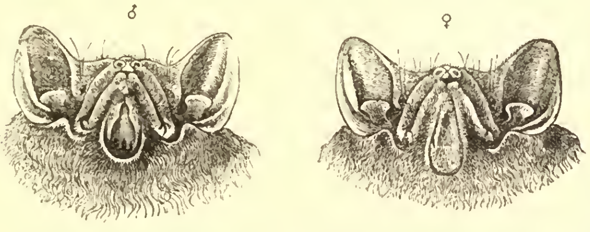

FIG. 80.—Heads of *Taphozous longimanus*, showing relative development of gular sacs in male and female. Dobson, *Proc. Zool. Soc.*, 1873.

angles of the lower jaw, a sexual character; for, while always more developed in males than in females, in some species, although distinct in the male, it is quite absent in the female. An open gular sac is wanting in both sexes in *T. melanopogon*, but about its usual position the openings of small pores may be seen, the secretion exuding from which probably causes the hairs to grow very long, forming the black beard found in many male specimens of this species.

Group III. *Dicliduri.*—This is represented by a single genus, *Diclidurus*, including two species. *D. albus*, from Central and South America, *i* $\frac{1}{3}$, *c* $\frac{1}{1}$, *pm* $\frac{2}{2}$, *m* $\frac{3}{3}$, resembles the species of *Taphozous* in the form of the head and ears, but, besides other characters, differs from all other Bats in possessing a peculiar pouch, opening on the centre of the inferior surface of the interfemoral membrane; the extremity of the tail enters this, and perforates its fundus.

Group IV. *Noctiliones.*—This also is represented by a single genus and two species, *Noctilio leporinus* and *N. dorsatus*, *i* $\frac{2}{1}$, *pm* $\frac{1}{2}$, from Central and South America. The group connects the family *Emballonuridæ* with the *Phyllostomidæ*, possessing characters common to both, but also so many remarkable special peculiarities as almost to warrant the formation of a separate family for its reception. The type, *N. leporinus* of Linnæus, is a Bat of very curious aspect, with strangely folded lips, erect cutaneous processes on the chin, and enormous feet and claws. The two middle incisors are close together, and so large as to conceal the small outer ones, while in the lower jaw there are but two small incisors. This apparent resemblance to a Rodent actually led the great naturalist to remove this species from the Bats and place it in his order *Glires* or Rodents. Similarly the next group *Rhinopomata*, represented by a single species, *R. microphyllum*, might also be elevated into the rank of a family, for it is very difficult to determine its exact affinities, a kind of cross relationship attaching it to the *Nycteridæ* on the one hand and to this family, in which it is here placed provisionally, on the other. This curious species, distinguished from all other *Microchiroptera* as well by the presence of two phalanges in the index finger as by its remarkably long and slender tail projecting far beyond the narrow interfemoral membrane, inhabits the subterranean tombs in Egypt and deserted buildings generally from north-east Africa to Burmah.

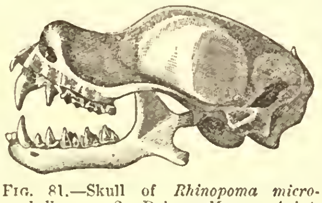

FIG. 81.—Skull of *Rhinopoma microphyllum.* × 2. Dobson, *Monogr. Asiat. Chiropt.*

Subfamily II. **Molossinæ.**—Tail thick, produced far beyond the posterior margin of the interfemoral membrane (except in *Mystacina*); legs short and strong, with well-developed fibulæ; upper incisors strong. This subfamily includes all the species of *Emballonuridæ* with short and strong legs and broad feet—whereof the first toe (and in most species the fifth also) is much thicker than the others, and furnished with long curved hairs,—with well-developed callosities at the base of the thumbs, and with a single pair of large upper incisors occupying the centre of the space between the canines. In all the species the feet are free from the wing-membrane, which folds up very perfectly under the forearm and legs; the interfemoral membrane is retractile, being movable backwards and forwards along the tail, and this power of varying its superficial extent must confer upon these Bats great dexterity in quickly changing the direction of their flight, as when obliged to double in pursuing their swiftly-flying insect prey, which their extremely expansible lips evidently enable them to secure with ease.

Group I. *Molossi.*—Tail produced beyond the posterior margin of the interfemoral membrane.

Cheiromeles, *i* $\frac{1}{1}$, *c* $\frac{1}{1}$, *pm* $\frac{1}{2}$, *m* $\frac{3}{3}$, hallux much larger than the other toes and separable from them, ears separate, is represented by a single species, *C. torquatus*, of large size (forearm 3·1 inches) and very peculiar aspect, inhabiting the Indo-Malayan subregion. This species is nearly naked, a collar only of thinly spread hairs half surrounding the neck, and is further remarkable for its enormous throat sac and curious nursing pouches. The former consists of a great semicircular fold of skin forming a deep pouch round the neck beneath, concealing the orifices of large subcutaneous pectoral glands which discharge an oily fluid of insufferably offensive smell. The nursing pouch is formed on each side by an extension of a fold of skin from the side of the body to the inferior surfaces of the humerus and femur. In the anterior part of this pouch the mamma is placed. For figures of these throat sacs and notes on the use of the nursing pouches see *Catal. Chiroptera*, p. 406, pl. xxi.

Molossus, *i* $\frac{1}{1}$ or $\frac{1}{2}$, *pm* $\frac{1}{2}$ or $\frac{2}{2}$, upper incisors close together in front, with ten species, is restricted to the tropical and subtropical regions of the New World. The woodcut of *M. glaucinus* (fig. 82) exhibits the general physiognomy of the Bats of this genus. *M. obscurus*, a small species, is very common in tropical America. It inhabits the hollow trunks of palms and other trees, and also the roofs of houses. The males and females live apart (as, indeed, appears to be the case in most if not in all species of Bats). In the hollow trunk of a palm two colonies were discovered, one consisting of from 150 to 200 individuals, exclusively males, while the other was composed of females with a male here and there among them.

FIG. 82.—Head of *Molossus glaucinus*. Dobson, *Proc. Zool. Soc.*, 1876.

Nyctinomus, *i* $\frac{1}{3}$ or $\frac{1}{2}$, *pm* $\frac{2}{2}$ or $\frac{1}{2}$, upper incisors separate in front, includes twenty-one species, inhabiting the tropical and subtropical parts of both hemispheres. The lips of the Bats of this genus are even more expansible than in *Molossus*, in many of the species (as in the woodcut of the head of *N. macrotis*, fig. 83) showing vertical wrinkles. *N. cestonii*, one of the largest species, alone extends into Europe, and has been taken as far north as Switzerland. *N. johorensis*, from the Malay Peninsula, is remarkable from the extraordinary form of its ears. *N. brasiliensis* is nearly as common as *M. obscurus* in tropical America, and extends farther north (California) and south than that species.

FIG. 83.—Head of *Nyctinomus macrotis*. Dobson, *Proc. Zool. Soc.*, 1876.

Group II. *Mystacinæ.*—Tail perforating the interfemoral membrane, and appearing upon its upper surface.

This includes a single genus and species, *Mystacina tuberculata*, a very peculiar form restricted to New Zealand, where, with *Chalinolobus tuberculatus*, it represents the whole indigenous mammalian fauna of the islands. There are three distinct phalanges in the middle finger; the greater part of the wing-membrane is exceedingly thin, but a narrow portion along the forearm, the sides of the body, and the legs is remarkably thick and leathery; beneath this thickened portion the wings are folded, and it is evidently analogous to the thickened part of the anterior wings in hemipterous insects and to the elytra of the *Coleoptera*. With the wings thus encased, this species is the most quadrupedal of Bats. Other peculiarities of structure are found in the remarkable form of the claws of the thumbs and toes, which have each a small talon projecting from its concave surface near the base, also in the sole of the foot and inferior surface of the leg, as shown in fig. 84. The plantar surface, including the toes, is covered with soft and very lax integument deeply wrinkled, and each toe is marked by a central longitudinal groove with short grooves at right angles to it,

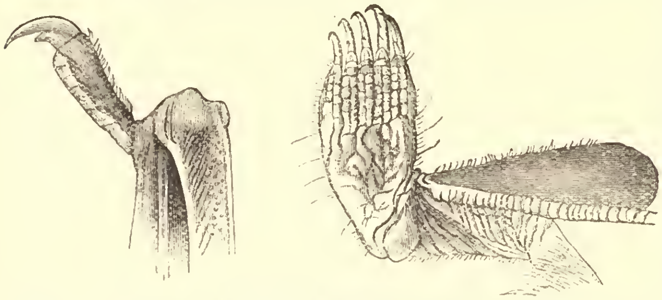

FIG. 84.—Thumb and Leg and Foot of *Mystacina tuberculata* (enlarged). Dobson, *Proc. Zool. Soc.*, 1876.

as in the genus *Hemidactylus* (*Geckotidæ*). The lax wrinkled integument is continued along the inferior flattened surface of the ankle and leg. These peculiarities appear to be related to climbing habits in the species. See the writer's remarks in *Proc. Zool. Soc.*, 1876, p. 488.

Family PHYLLOSTOMIDÆ.

The Bats included in this family are readily distinguished by the presence of a well-developed third phalanx in the middle finger, associated either with distinct cutaneous nasal appendages, or with well-developed central upper incisors, or with both. Unlike the *Rhinolophidæ*, their eyes are generally large, and the tragus well developed, maintaining almost the same form throughout the species, however much the outer parts of the body may vary. Their fur is of a dull colour, and the face and back (in the *Stenodermata* especially) are often marked with white streaks, as in the *Pteropodidæ*, of which they take the place in the western hemisphere. A few species, probably all those with the tail and interfemoral membrane well-developed, feed principally on insects, while the greater number of the species of the groups *Vampyri* and *Glossophagæ* appear to live on a mixed diet of insects and fruits, and the *Desmodontes*, of which two species only are known, are true blood-suckers, and have their teeth and intestinal tract specially modified in accordance with their habits. Limited to the tropical and sub-tropical parts of Central and South America.

Subfamily 1. **Lobostominæ.**—Nostrils opening by simple apertures at the extremity of the muzzle in front, not margined by a distinct nose-leaf; chin with expanded leaf-like appendages.

It includes two genera. In *Chilonycteris* (six species) the crown of the head is moderately elevated above the face-line, and the basi-cranial axis is almost in the same plane as the facial, while in *Mormops* the crown of the head is greatly elevated above the face-line, and the basi-cranial axis is almost at right angles to the facial; *i* $\frac{2}{2}$, *pm* $\frac{2}{3}$ in both genera. The latter genus contains two species, which, in their very peculiar physiognomy, are probably the most remarkable among the many strange forms exhibited by the different species of this order.

FIG. 85.—Head of *Mormops blainvillii*. Dobson, *Catal. Chiropt. Brit. Mus.*

Subfamily 2. **Phyllostominæ.**—Nostrils opening on the upper surface of the muzzle, the nasal apertures more or less surrounded or margined by well-developed cutaneous appendages, forming a distinct nose-leaf; chin with warts.

Group 1. *Vampyri.*—Muzzle long and narrow in front, the distance between the eyes generally less than, rarely equal to, the distance from the eye to the extremity of the muzzle; nose-leaf well-developed, horse-shoe-shaped in front, lanceolate behind; interfemoral membrane well-developed; tail generally distinct, rarely absent; inner margin of the lips not fringed; *i* $\frac{2}{2}$ or $\frac{2}{1}$, *pm* $\frac{2}{2}$ or $\frac{2}{3}$; molars with W-shaped cusps, usually well-developed.

Nearly all the species of *Vampyri* appear to be insectivorous, so that the term applied to this group cannot be considered indicative of their habits. A few, if not all, probably supplement their insect diet with fruit. *Vampyrus spectrum* (the largest Bat in the New World, forearm 4·2 inches) is said to be wholly frugivorous, and *Macrotus waterhousii* appears to prey occasionally on small species of Bats, like *Megaderma lyra* of the eastern hemisphere, which it resembles in many respects.

The species may be divided into two sections, according as the tail is produced to the hinder margin of the interfemoral membrane or perforates it and appears upon its upper surface. Those included in the first section fall into three genera, *Lonchorhina*, *Macrotus*, and *Macrophyllum*, the first-named including a very remarkable species, *L. aurita*, with an extraordinary long nose-leaf and peculiarly large ears and tragi. In the second section are included the genera *Vampyrus*, *Lophostoma*, *Schizostoma*, *Trachyops*, *Phylloderma*, *Phyllostoma*, *Tylostoma*, *Mimon*, *Carollia*, and *Rhinophylla*, all, with the exception of the last, distinguished from one another chiefly by the form of the skull and the presence or absence of the second lower premolar; *Trachyops*, *Phylloderma*, and the three last-named genera are each represented by a single species. *Phyllostoma hastatum*, forearm 3·2 inches, next in point of size to *Vampyrus spectrum*, is a well-known species in South America; *Ph. elongatum* (see fig. 86) differs in its smaller size and much larger nose-leaf. *Carollia brevicauda*, a small species, is generally found represented in collections, and externally so closely resembles *Glossophaga soricina* (of the next group) that it has often been confounded with that species. It forms a connecting link between this group and the next. *Rhinophylla pumilio*, forearm 1·25 inches, tail none, is the smallest known species of the family; it is further distinguished by the narrowness of its molars, which do not form W-shaped cusps, and by the very small size of the last upper molar, characters connecting it, and consequently the group, with the *Stenodermata*.

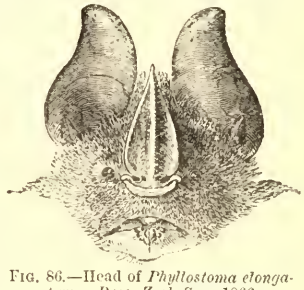

FIG. 86.—Head of *Phyllostoma elongatum*. *Proc. Zool. Soc.*, 1866.

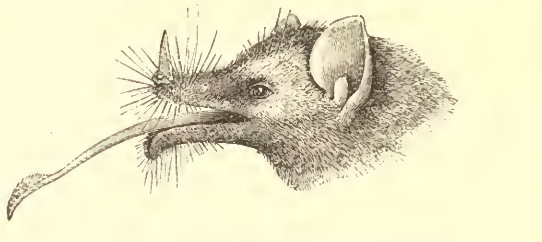

FIG. 87.—Head of *Chœronycteris mexicana*, showing fibrillated tongue. Dobson, *Cat. Chiropt. Brit. Mus.*

Group II. *Glossophagæ.*—Muzzle long and narrow; tongue remarkably long and extensible, much attenuated towards the tip, and beset with very long filiform recurved papillæ; lower lip with a wide groove above, and in front margined by small warts; nose-leaf small; tail short or none; *i* $\frac{2}{2}$, *pm* $\frac{2}{3}$ or $\frac{3}{3}$ or $\frac{2}{2}$, *m* $\frac{3}{3}$ or $\frac{2}{3}$ or $\frac{2}{2}$; teeth very narrow; molars with narrow W-shaped cusps, sometimes indistinct or absent; lower incisors very small or deciduous.

The ten species included in this group represent seven genera, which are distinguished principally by differences in the form and number of the teeth, and by the presence or absence of the zygomatic arches. The form and position of the upper incisors are extremely variable. In *Glossophaga* and *Phyllonycteris* the upper incisors form, as in the *Vampyri*, a continuous row between the canines; in *Monophylla* and *Ischnoglossa* they are separated into pairs by a narrow interval in front; while in *Lonchoglossa*, *Glossonycteris*, and *Chœronycteris* they are widely separated and placed in pairs near the canines; in the first four genera the lower incisors are present (at least up to a certain age), in the last three they are deciduous even in youth. The zygomatic arch is wanting in *Phyllonycteris*, *Glossonycteris*, and *Chœronycteris*.

The typical species is *Glossophaga soricina*, which so closely resembles *Carollia brevicauda*, both in external form and dentition, that it has frequently been confounded with it. Its long fibrillated tongue (which it possesses in common with other species of the group) led Spix to describe it as a very cruel blood-sucker (*sanguisuga crudelissima*), believing that it was used to increase the flow of blood. This view is, however, altogether without foundation, and from the observations of Osburn and others it is evident that the peculiarly shaped tongue is used by the animal, as in the case of the *Macroglossi* among the frugivorous *Pteropodidæ*, to lick out the pulpy contents of fruits having hard rinds. The food of the species of this group appears to consist of both fruit and insects, and the long tongue may also be used for extracting the latter from the deep corollæ of certain flowers.

Group III. *Stenodermata.*—Muzzle very short and generally broad in front, the distance between the eyes nearly always exceeding (rarely equal to) the distance from the eye to the extremity of the muzzle; nose-leaf short, horse-shoe-shaped in front, lanceolate behind (except in *Brachyphylla* and *Centurio*); interfemoral membrane always concave behind; tail none; inner margin of the lips fringed with conical papillæ; *i* $\frac{2}{2}$ or $\frac{2}{1}$, *pm* $\frac{2}{2}$, *m* $\frac{3}{3}$ or $\frac{2}{3}$ or $\frac{2}{2}$; premolars and molars very broad (except in *Sturnira*), the latter with concave or flat crowns margined externally by raised cutting edges.

Although the *Stenodermata* are generally easily distinguished from the *Vampyri* by the peculiar shortness and breadth of the muzzle, and by the form of the molar teeth, certain species of the latter group closely resemble those of the former in external appearance, agreeing almost absolutely in the form of the nose-leaf, of the ears and tragus, and of the warts on the chin. These resemblances show that, while the form of the teeth and jaws has become modified to suit the food of the animals, the external characters, being but slightly affected by this cause, have remained much the same, and now indicate their common origin. The food of these Bats appears to be wholly or in great part tree fruit. The twenty species have been divided into nine genera, distinguished by the form of the skull and teeth. *Artibeus*, with five, includes among them the well-known frugivorous Bat, *A. perspicillatus* of Linnæus, so common in collections. *Stenoderma achradophilum*, found in Jamaica and Cuba, associated with the above, and scarcely distinguishable externally except by its very much smaller size, differs altogether in the absence of the horizontal plate of the palate bones. *Sturnira lilium*, while agreeing with the above in the form of the nose-leaf and ears, differs from all the species of the family in its longitudinally-grooved molars, which resemble those of the frugivorous *Pteropodidæ* more closely than those of any other Bats; and the presence of tufts of long differently-coloured hairs over glands in the sides of the neck shows yet another character in common still more remarkable, which can scarcely be considered, like the teeth, the result of adaptive change. *Centurio senex* is the type of a genus distinguished from *Stenoderma* and other genera of this group by the absence of a distinct nose-leaf. This most remarkable form stands alone among the species of *Chiroptera*, and, indeed, in its peculiar and grotesque physiognomy is unrivalled among known mammals.

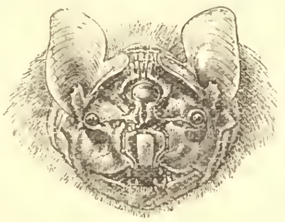

FIG. 88.—Head of *Centurio senex*. Dobson, *Cat. Chiropt. Brit. Mus.*

Group IV. *Desmodontes.*—Muzzle short and conical; nose-leaf distinct; interfemoral membrane very short; tail none; *i* $\frac{1}{2}$, *pm* $\frac{2}{3}$, *m* $\frac{1}{1}$ or $\frac{0}{0}$; upper incisors very large, trenchant, occupying the whole space between the canines; premolars very narrow, with sharp-edged longitudinal crowns; molars rudimentary or none; stomach greatly elongated, intestiniform.

There are two genera, *Desmodus*, without calcaneum or true molars, and *Diphylla*, with a short calcaneum and with a single rudimentary molar on each side,—restricted to Central and South America. *Desmodus rufus*, the commoner species, is a little larger than the Noctule Bat of Europe, and abundant in certain parts of South America, where it is very troublesome owing to its attacks upon domestic animals, sucking their blood and often leaving them much weakened from repeated bleedings. See VAMPIRE.

FOSSIL CHIROPTERA.

Fossil remains of *Chiroptera* extend as far back as the Upper Eocene of Europe and America, if, indeed, the beds in which they have been found are rightly considered as belonging to that age. Of these *Vesperugo* (*Nyctitherium*) *parisiensis*, described by Cuvier from the gypsum of Montmartre, is very like a small specimen of the widely distributed *V. serotinus*; *V. velox* and *priscus* of the same subsection, and *Nyctilestes serotinus*, have been characterized by Marsh from the Eocene of the United States, and *Vespertilio morloti*, Pictet, from that of Switzerland. From the Quercy lacustrine deposits comes *Rhinolophus antiquus*, Filhol, but these are very doubtfully of Eocene age. *Palæonycteris* (allied to *Rhinolophus*), with *P. robustus*, *Vesperugo*, with *V. noctuloides* and *murinoides*, and *Vespertilio*, with *V. aquensis*, *præcox*, and *insignis*, have been found in Miocene beds of France and Germany. Pliocene bone caves have also yielded remains, in all cases closely allied to species now inhabiting the same countries. All these forms, however, exhibit as much specialization in their general structure as any existing species of the same families, indicating (if the age assigned to the deposits can be trusted) that the first appearance of *Chiroptera* must be referred to a very remote period.

Bibliography of Chiroptera.—G. E. Dobson. *Catalogue of the Chiroptera in the Collection of the British Museum*, 1878, including descriptions of all the species of Bats then known; subsequent papers by the same author in *Rep. Brit. Assoc. Adv. Science, Proc. Zool. Soc.*, *Ann. Mag. Nat. Hist.*, and *Bullet. Soc. Zool. de France*, by Peters in *Monatsb. Akad. Wissensch. Berlin*, and by Oldfield Thomas and J. Scully in *Ann. Mag. Nat. Hist.*; H. A. Robin, *Recherches Anatomiques sur les Mammifères de l'Ordre des Chiroptères*, Paris, 1881.

ORDER RODENTIA.

Terrestrial, rarely arboreal or natatorial, diphyodont placental mammals of small size; with plantigrade or semiplantigrade, generally pentadactyle, unguiculate, rarely subungulate, feet; with clavicles (sometimes imperfect or rudimentary); with never more than two incisors in the mandible, and without canines.

The upper incisors resemble the lower in growing uninterruptedly from persistent pulps, and (except in *Lagomorpha*) agree with them in number; the premolars and molars are rooted or rootless, with tuberculated or laminated crowns, and arranged in an unbroken series; the orbits are not circumscribed by bone; the mandibular condyle is antero-posteriorly elongated; the intestine (except in *Myoxidæ*) has a large cæcum; the testes are inguinal or abdominal; the uterus is two-horned, the cornua opening separately into the vagina or uniting to form a corpus uteri; the placenta is discoidal and deciduate; and the smooth cerebral hemispheres do not extend backwards so as to cover any part of the cerebellum.

The Rodents form a very compact order, readily distinguished by their large chisel-shaped incisors, and by the absence of canines. They include by far the greatest number of species (over 900), and have the widest distribution, of any of the orders of terrestrial mammals, being in fact cosmopolitan, although more abundant in some parts, as in South America, which may be considered their headquarters, than in others, as in Australasia and Madagascar, where representatives of a few genera of one family (*Muridæ*) only are found, thus contrasting remarkably with the *Insectivora*, which constitute at least half the mammalian fauna of Madagascar, but are without living representatives in South America.

If, as we have seen, the term entomophagous is applicable to most *Insectivora*, much more so, on the other hand, may the species of this great order be defined as phytophagous, and this uniformity in their food and in the mode of obtaining it, namely, by gnawing, has evidently led to such corresponding general uniformity in structure, which is observable throughout the species, that with difficulty we obtain characters sufficiently salient for dividing them into genera and families. Although, like the *Insectivora*, they present much diversity of habit,—some being arboreal, as the Squirrels, many species of which are provided with cutaneous parachutes on which they glide from tree to tree; some cursorial, as the Hares; some agile jumpers, as the Jerboas; some fossorial, as the great Mole-Rats; and some natatorial, as the Beavers and Water-Rats,—yet we do not find corresponding structural modifications comparable with those noticed in that order.

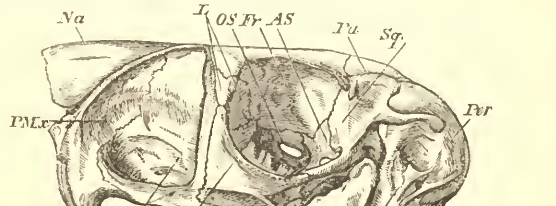

FIG. 89.—Side View of Skull of Cape Jumping Hare (*Pedetes caffer*). $\times \frac{2}{3}$. *PMx*, premaxilla; *Mx*, maxilla; *Ma*, malar; *Fr*, frontal; *L*, lachrymal; *Pa*, parietal; *Na*, nasal; *Sq*, squamosal; *Ty*, tympanic; *ExO*, exoccipital; *AS*, alisphenoid; *OS*, orbito-sphenoid; *Per*, mastoid bulla. Flower, *Osteol. Mammal.*

The Rodent skull is characterized by the great size of the premaxillary bones, which completely separate the nasals from the maxillaries, by the invariable presence of zygomatic arches, and by the wide unoccupied space existing between the alveoli of the incisors and the molar teeth, and (except in *Lagomorpha*) by the antero-posteriorly elongated glenoid cavity. Post-orbital processes of the frontals exist only in the Squirrels, Marmots, and Hares; in all other genera they are rudimentary or altogether absent; the zygoma never sends upwards a corresponding process, and the orbit in all is freely continuous with the temporal fossa; the lachrymal foramen is always within the orbital margin; in many species the infra-orbital foramen is very large (in some as large as the orbit), and

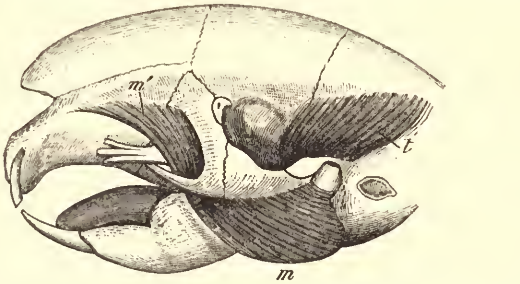

FIG. 90.—Skull of *Hystrix cristata* (juv.). *t*, temp ral muscle; *m*, masseter, *m′*, portion of masseter transmitted through the infra-orbital foramen, the superior maxillary nerve passing outwards between it and the maxillary bone.

transmits part of the masseter muscle; the zygomatic arch is variously developed, and the position of the malar in it is used as a distinguishing character for grouping the families; the nasals are, with few exceptions, large, and extend far forwards; the parietals are moderate, and there is generally a distinct interparietal; the palate is narrow from before backwards,—this is especially pronounced in the Hares, where it is reduced to a mere bridge between the premolars,—in others, as in the great Rodent Moles (*Bathyerginæ*), it is extremely narrow transversely, its width being less than that of one of the molar teeth; tympanic bullæ osseæ are always present and generally large; in some genera, as in the Gerbilles (*Gerbillinæ*) and Jerboas (*Dipodinæ*), there are supplemental mastoid bullæ which form great hemispherical bony swellings at the back of the skull (see fig. 89, *Per*); in these genera, and in the true Hares, the meatus auditorius is tubular and directed upwards and backwards. The mandible is characterized by its abruptly narrowed and rounded symphysial part supporting the pair of large incisors, as well as by the small size of the coronoid process and great development of the angular portion.

The dental formula varies from $i\,\frac{2}{1}$, $c\,\frac{0}{0}$, $pm\,\frac{3}{2}$, $m\,\frac{3}{3}$ (total 28) in the Hares and Rabbits to $i\,\frac{1}{1}$, $c\,\frac{0}{0}$, $pm\,\frac{0}{0}$, $m\,\frac{2}{2}$ (total 12) in the Australian Water-Rats; but in the vast majority of the species it presents striking uniformity, and may be set down typically as $i\,\frac{1}{1}$, $c\,\frac{0}{0}$, $pm\,\frac{1}{1}$ or $\frac{0}{0}$, $m\,\frac{3}{3}$. In *Lagomorpha* only are there more than a single pair of incisors, and in them the additional pair are small and placed quite behind the middle pair,[1] and in this group alone does the enamel extend even partially to the back of the tooth; in all others it is restricted to its front surface, and so, by the faster wearing away of the softer structures behind, a chisel-shaped edge is always maintained. Both the upper and lower incisors are regularly curved, the upper slightly more so than the lower, and, their growth being continuous, should anything prevent the normal attrition by which their length is regulated, as by the loss of one of them, or by displacement owing to a broken jaw or other cause, the unopposed unused incisor may gradually curve upon itself until a complete circle or more has been formed, the tooth, perhaps, passing during its growth through some part of the animal's head. The molar teeth may be rooted or

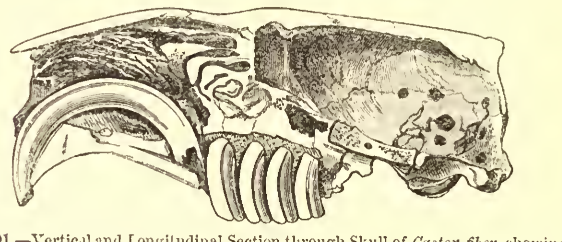

FIG. 91.—Vertical and Longitudinal Section through Skull of *Castor fiber*, showing the cerebral cavity, the greatly-developed turbinal lamellæ, the mode of implantation of the large ever-growing chisel-edged incisor, and the curved rootless molars.

rootless, tuberculated or laminated; and this diversity of structure may be noticed even in the same family. When there are more than three back teeth those which precede the last three have succeeded milk teeth, and must therefore be considered premolars. In some species, as in the Agoutis (*Dasyproctidæ*), the milk teeth are long retained, while in the allied Cavies (*Caviidæ*) they are shed before birth.

There are generally nineteen dorso-lumbar vertebræ (13 thoracic and 6 lumbar), and their forms vary in the different genera; in the cursorial and leaping species the lumbar transverse processes are generally very long, and in the Hares there are large compressed hypapophyses. The caudal vertebræ exhibit as much variety as in *Insectivora*, from their rudimentary condition in the Guinea-Pig to their great size in the Jumping Hares and prehensile-tailed Porcupines. The scapula is usually narrow, with a long acromion; the clavicles may be altogether absent or imperfect, as in the Porcupines, Cavies, and Hares, but in most species they are well developed; the humerus has no supra-condylar foramen, and the forearm bones are distinct; in most species the manus has five digits with phalanges normally developed, the pollex rarely rudimentary or absent. In contrast to the normal condition of the pelvis in *Insectivora*, we find here largely developed ischiatic and pubic bones, with a long usually osseous symphysis; the femur varies considerably in form, and there is generally a well-defined third trochanter; in the Sciurine and Hystricine Rodents the tibia and fibula are distinct, but in the Rats and other Murines, and in the Hares, these bones are united, often high up; the pes is much more variable than the manus, the digits varying in number from five, as in the Squirrels and Rats, to four, as in the Hares, or even three, as in the Capybara, Viscacha, and Agouti; in the *Dipodidæ* the metatarsals are greatly elongated, and in some of the species, as in the Jerboas, they are ankylosed together.

The mouth is divided into two cavities communicating by a constricted orifice, an anterior containing the large incisors and a posterior in which the molars are placed, the hairy integument of the face being continued inwards behind the incisors. This evidently prevents substances not intended for food getting into the mouth, as when the animal is engaged in gnawing through an obstacle. In the Hares and Pacas the inside of the cheeks is hairy, and in some species, as in the Pouched Rats and Hamsters, there are large internal cheek pouches lined with the hairy integument, which open near the angles of the mouth and extend backwards behind the ears; in the New-World Pouched Rats (*Geomyidæ*) the pouches open externally on the cheeks.

[1] Professor Huxley remarks (*Proc. Zool. Soc.*, 1880, p. 655):—"The deciduous molars and the posterior deciduous upper incisors of the Rabbit have long been known. But I have recently found that unborn Rabbits possess, in addition, two anterior upper and two lower deciduous incisors. Both are simple conical teeth, the sacs of which are merely embedded in the gum. The upper is not more than one-hundredth of an inch long, the lower rather larger."

The tongue presents little of that variability in length observable in the preceding orders; it is characteristically short and compressed, with an obtuse apex never protruded beyond the incisors; in most species there are, as in *Insectivora*, three papillæ circumvallatæ at the base; and the apical portion is generally covered with small filiform papillæ, some of which in the Porcupines (*Hystrix*) become greatly enlarged, forming toothed spines. The stomach varies in form from the simple oval sac of the Squirrel to the complex ruminant-like organ of the Lemming. In the Water-Vole (*Arvicola amphibius*) and in the Agouti (*Dasyprocta agouti*) it is strongly constricted between the œsophagus and pylorus; in the common Dormouse the œsophagus immediately before entering the stomach is much dilated, forming a large egg-shaped sac with thickened glandular walls, and in some other species, as in *Lophiomys imhausi* and in the Beaver, glandular masses are attached to and open into the cardiac or pyloric pouches. All Rodents, with the exception only of the species of Dormice (*Myoxidæ*), have a cæcum, often of great length and sacculated, as in the Hares, Water-Voles, and Porcupines, and the long colon is in some, as in the Hamster and Water-Vole, spirally twisted upon itself near its commencement. The liver is typically divided in all, but the lobes are variously subdivided in the different species (in *Capromys* they are divided into minute lobules); and the gall-bladder, though present in most, is absent in a few. In most species, as in many *Insectivora*, the penis (which is generally provided with a bone) may be more or less completely retracted within the fold of integument surrounding the anus, and lie curved backwards upon itself under cover of the integument, or it may be carried forward some distance in front of the anal orifice, from which in the breeding season, as in the Voles and Marmots, the prominent testicular mass separates it. The testes in the rut form projections in the groins, but (except in *Lagomorpha*) do not completely leave the cavity of the abdomen. Prostatic glands and, except in *Lagomorpha*, vesiculæ seminales are present in all. The uterus may be double, each division opening by a separate os uteri into a common vagina, as in *Leporidæ*, *Sciuridæ*, and *Hydrochœrus*, or two-horned, as in most species. The mammary teats vary in number from the single abdominal pair of the Guinea-Pig to the six thoracico-abdominal pairs in the Rats. In the *Octodontidæ* the teats are placed high up on the sides of the body.

The peculiar odour evolved by many Rodents is due, as in the *Insectivora*, to the secretions of special glands, which may open into the prepuce, as in *Mus*, *Arvicola*, *Cricetus*, &c., or into the rectum, as in *Arctomys* and *Aulacodus*, or into the passage common to both, as in the Beaver, or into pouches opening near the anus, as in the Hare, Agouti, and Jerboa.

The integument is generally thin, and the panniculus carnosus rarely much developed. The fur varies exceedingly in character,—in some very fine and soft, as in the Chinchillas and Hares, in others more or less replaced by spines on the upper surface, as in the Spiny Rats and Porcupines; in several genera, as in *Xerus*, *Acomys*, *Platacanthomys*, *Echiothrix*, *Loncheres*, and *Echinomys*, the spines are flattened. In the muscular structures the chief peculiarities are noticeable in the comparatively small size of the temporal muscles, generally so largely developed in *Insectivora*, and in the great double masseters, which are the principal agents in gnawing; the digastrics also are remarkable for their well-defined central tendon, and in many species their anterior bellies are united between the mandibular rami; the cleidomastoid generally arises from the basi-occipital, and the pectoralis major is connected with the latissimus dorsi; in the Porcupines and Hares the tendons of the flexor digitorum longus and flexor hallucis longus are connected in the foot, while in the Rats and Squirrels they are separate, and the flexor digitorum longus is generally inserted into the halluceal metatarsal. (See Dobson, *Journ. Anat. Phys.*, vol. xvii.)

Suborder I. *RODENTIA SIMPLICIDENTATA.*

Rodents with two incisors only in the upper jaw, having their enamel confined to their front surfaces. The incisive foramina are moderate and distinct; the fibula does not articulate with the os calcis; and the testes are abdominal, and descend periodically only into the inguinal canal.

Section I. Sciuromorpha.

Zygomatic arch slender, chiefly formed by the malar, which is not supported by a long maxillary process extending backwards beneath it; post-orbital processes present or absent; infra-orbital

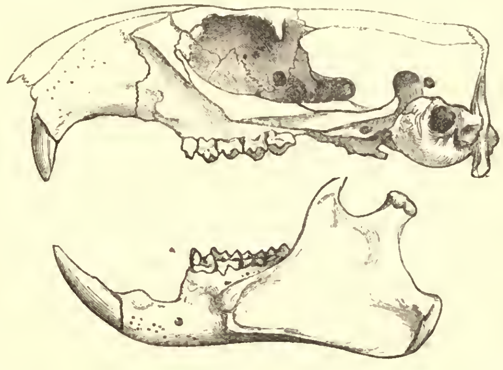

Fig. 92.—Skull of *Arctomys monax*.

opening small (except in *Anomalurus*); mandible with the angular part arising from the inferior surface of the bony socket of the lower incisor; clavicles well-developed; fibula distinct.

Family 1. Anomaluridæ.

Arboreal Rodents, having their limbs connected by a cutaneous expansion supported by a cartilaginous process arising from the olecranon; with a long hairy tail having large scales on its inferior surface near its root; with sixteen pairs of ribs, and without post-orbital processes of the frontals; *pm* $\frac{1}{1}$; molars not tuberculate, with transverse enamel folds. Ethiopian.

Fig. 93.—*Anomalurus fulgens* (reduced). Alston, *Proc. Zool. Soc.*, 1875.

Anomalurus, with (?) five species from West Africa, alone represents the family. The peculiar caudal scales, which evidently assist the animal in climbing, and the position of the cartilaginous support of the parachute, are well shown in the above woodcut (fig. 93).

Family 2. SCIURIDÆ.

Arboreal or terrestrial Rodents, with cylindrical hairy tails, without scales, and with twelve or thirteen pairs of ribs. Skull with distinct post-orbital processes; infra-orbital opening small; palate broad; $pm\ \frac{2}{1}$; first upper premolar very small or deciduous; molars rooted, tubercular.

Subfamily 1. **Sciurinæ.**—Incisors compressed, form slender, tail long and hairy (True Squirrels). Cosmopolitan (excluding Australian region).

There are four genera. *Pteromys*,—limbs united by a cutaneous expansion forming a parachute, the supporting cartilage of which springs from the carpus,—includes the Flying Squirrels of both hemispheres. *Sciurus*, with more than eighty species, comprises the true Tree Squirrels. To this group also belong the Short-eared Squirrels of the genera *Xerus* and *Tamias*; the first-named, distinguished from *Sciurus* by possessing only two pairs of mammary teats, by the comparatively short tail, and by the fur being mixed with flattened spines, includes a few African species which live in burrows; *Tamias*, separated by the presence of large internal cheek-pouches, includes the well-known Ground Squirrels of North America, of which one species (*T. asiaticus*) extends into North Europe and Asia. See SQUIRREL.

Subfamily 2. **Arctomyinæ.**—Incisors not compressed; form stout; tail short (Marmots). Palæarctic and Nearctic.

Spermophilus, distinguished by its large cheek-pouches and by the absence or rudimentary condition of the pollex claw, resembles *Tamias* in the slender form of the body, and connects the Marmots with the true Squirrels. The distribution and habits of the species are similar to those of *Tamias*. *Cynomys*, with shallow cheek-pouches, long pollex claw and stout form, includes the well-known Prairie Dogs peculiar to North America, which live together in large communities, inhabiting burrows which they excavate at short distances apart; they feed on the buffalo-grass which covers the plains. The small burrowing owl (*Athene cunicularia*) and the rattlesnake are often found inhabiting their burrows, the former probably availing itself of the convenience of a ready-made habitation, the latter coming there to feed on the young Marmots. *Arctomys*, distinguished by its rudimentary pollex, includes the true Marmots. See MARMOT.

Family 3. HAPLODONTIDÆ.

Terrestrial Rodents, distinguished from *Sciuridæ* by the absence of post-orbital processes, the depressed form of the skull, and the rootless molars. Premolars $\frac{2}{1}$, the first upper one small.

Haplodon, with *H. rufus*, from North America west of the Rocky Mountains, alone represents the family. The habits of the single species are similar to those of the Prairie Dog.

Family 4. CASTORIDÆ.

Natatorial Rodents, with massive skulls, without post-orbital processes, with mandibular angle rounded, and with semi-rooted or rootless molars with re-entering enamel folds; $pm\ \frac{1}{1}$.

Castor, with one species only, *C. fiber*, the Beaver of the northern parts of Asia, Europe, and America. The upper molars are subequal, each with one internal and two external enamel folds; the stomach has a large glandular mass situated to the right of the œsophageal orifice; the anal and urethro-genital orifices open within a common cloaca; the tail is broad, horizontally flattened, and naked; and the hind feet are webbed. See BEAVER.

Section II. MYOMORPHA.

Zygomatic arch slender, the malar rarely extending far forwards, and usually supported below by the long zygomatic process of the

FIG. 94.—Skull of *Fiber zibethicus*. Natural size.

maxillary; no post-orbital processes; infra-orbital opening variable; mandible with the angular part arising from the inferior surface of the bony socket of the lower incisor (except in *Bathyerginæ*); clavicles well-developed (except in *Lophiomys*); tibia and fibula united.

Family 1. MYOXIDÆ.

Arboreal Rodents, with long hairy tails, large eyes and ears, and short fore limbs. The intestine is without a cæcum; the skull has contracted frontals; the infra-orbital foramen is moderate, high, and narrow; and the mandible has a long and slender coronoid process. $Pm\ \frac{1}{1}$; molars rooted, with transverse enamel plates. Palæarctic and Ethiopian.

There are four genera:—*Myoxus*, with *M. glis* of Europe, with bushy, distichous tail, simple stomach, and large molars with well-marked enamel folds; *Muscardinus*, with *M. avellanarius*, the common Dormouse, distinguished by the cylindrical bushy tail and thickened glandular walls of the cardiac extremity of the œsophagus; *Eliomys*, with about six species, with tufted and distichous tail, simple stomach and smaller molar teeth with concave crowns and faintly marked enamel folds; and *Graphiurus*, with two species, with short cylindrical tail ending in a pencil of hairs, and very small molars almost without trace of enamel folds. The Dormice form a very natural family, distinguished from all other Rodents by the absence of a cæcum. In their habits and form they evidently closely approach the Squirrels.

Family 2. LOPHIOMYIDÆ.

Arboreal Rodents, with rudimentary clavicles and rooted tuberculate molars. Premolars none. Skull murine in form, but the temporal fossæ are completely arched over by thin plates arising from the temporal ridge and malar bone. Intestine with a small cæcum.

FIG. 95.—*Lophiomys imhausi* (reduced). A. Milne-Edwards.

Lophiomys, with *L. imhausi* (fig. 95), alone represents the family. This very extraordinary species from north-east Africa differs from all other Rodents in the peculiar granulated plates which cover the temporal fossæ, and from all the species of the section in the rudimentary condition of the clavicles as well as in the possession of an opposable hallux. The hair is very peculiar in structure, and forms a crest along the back and tail. For full description see A. Milne-Edwards, *L'Institut*, xxxv. p. 46.

Family 3. MURIDÆ.

Rodents of various habit, but generally terrestrial; with contracted frontals, with the lower root of the maxillary zygomatic process more or less flattened into a perpendicular plate; with a short and slender malar, generally reduced to a splint between the maxillary and squamosal processes; with (in typical forms) a high, perpendicular infra-orbital foramen, wide above and narrow below; with compressed lower incisors and rooted or rootless molars, tuberculate or with angular enamel folds. Premolars none (except in *Sminthinæ*); pollex rudimentary; tail generally sub-naked and scaly.

This large family includes more than one-third of all the species of Rodents, and is represented by thirty-five genera of cosmopolitan distribution. These fall into two sections corresponding to the rooted or rootless condition of the molars.

I. *Molars rooted.*

Subfamily 1. **Sminthinæ.**—$Pm\ \frac{1}{0}$, $m\ \frac{3}{3}$; infra-orbital opening subtriangular, widest below; incisive foramina long.

Sminthus, with one species, *S. vagus*, a Rat-like Rodent inhabiting northern Asia and Europe.

Subfamily 2. **Hydromyinæ.** $M\ \frac{2}{2}$, divided into transverse lobes; infra-orbital opening crescentic, scarcely narrowed above; incisive foramina very small.

Hydromys, with two species from Australia, Tasmania, and New Guinea, includes the Water-Rats of the Australian region, with partially webbed toes. They are distinguished from all other Rodents by the small number of their molars.

Subfamily 3. **Platacanthomyinæ.**—*M* $\frac{3}{3}$, with transverse laminæ; fur mixed with flattened spines; tail densely hairy.

Platacanthomys, with *P. lasiurus*, a small Dormouse-like species from western India, inhabiting the rocky mountains of Travancore.

Subfamily 4. **Gerbillinæ.**—Incisors narrow, molars with transverse laminæ; auditory bullæ osseæ usually large; hind limbs elongated; tail generally long and hairy. Palæarctic, Indian, and Ethiopian.

Gerbillus, with nearly fifty species, has a range coextensive with that of the subfamily. *Pachyuromys* is distinguished by the enormous size of the auditory bullæ, as well as by the short fleshy club-shaped tail. *Mystromys*, *Otomys*, and *Dasymys* differ in the form of the molars, and are represented by a few species, all from South Africa.

Subfamily 5. **Phlæomyinæ.**—Incisors broad, molars with transverse laminæ; claws large. Indian.

Phlæomys, with *P. cumingii* from the Philippines, and *Nesokia*, with eight species widely distributed throughout the Indian Region. The latter (distinguished from the former genus by the short, subnaked, scaly tail) includes the Great Bandicoot Rat of India (*N. bandicota*).

Subfamily 6. **Dendromyinæ.**—Incisors convex in front, molars tuberculate; ears hairy; claws long. Ethiopian.

Three genera, *Dendromys*, *Steatomys*, and *Lophuromys*, include several species of small Mouse-like Rodents with the habits of Dormice generally, though some burrow in corn-fields.

Subfamily 7. **Cricetinæ.**—Molars tuberculate. Large internal cheek-pouches. Palæarctic and Ethiopian.

Of the three genera, *Cricetus*, *Saccostomus*, and *Cricetomys*, the last is distinguished from the others by the grooved upper incisors, while *Saccostomus* is separated from *Cricetus* by the tubercles of the molar teeth being arranged in threes. The cheek pouches in *Cricetus* are very large, and their walls are connected with muscles arising from the lumbar vertebræ. The best-known species is *C. frumentarius*. See HAMSTER.

Subfamily 8. **Murinæ.**—Molars tuberculate, at least in youth. Cheek-pouches absent. Tail scaly, more or less naked. Cosmopolitan.

This includes the typical murine forms, divided into fifteen genera with over three hundred species, of which nearly half, however, are contained in the genus *Mus*. *M. decumanus*, the common Grey Rat, and *M. musculus* (see MOUSE) are familiar examples which have been introduced in ships into almost every part of the habitable world. In *Acomys* the skull and teeth are as in *Mus*, but the fur is mixed with sharp flattened spines. *A. dimidiatus* presents the appearance of a little Hedgehog when its spines are erected; it inhabits the stony deserts of Arabia Petræa and Palestine, and feeds on bulbs. *Echiothrix*, *Uromys*, and *Hapalotis*, the latter with about a dozen species, are limited to the Australian region. *Brachytarsomys*, *Nesomys*, *Hallomys*, and *Hypogeomys*, each with one or two species, are peculiar to Madagascar, where they alone represent the order. *Drymomys*, *Holochcilus*, *Ochetodon*, and *Hesperomys* are New-World genera, the last-named including many species representing the Old-World Mice, but distinguished by the indenting enamel folds of the molars. Of the remaining genera, *Reithrodon*, with grooved incisors, includes two very remarkable Rabbit-like species, one inhabiting Patagonia, the other Tierra del Fuego.

II. *Molars Semi-Rooted or Rootless.*

Subfamily 9. **Arvicolinæ.**—Molars composed of triangular prisms placed alternately; limbs moderate; tail moderate or short, hairy. Palæarctic and Nearctic.

Arvicola, with over thirty species, includes the Voles, of which the Field-Vole (*A. agrestis*) and the Water-Vole (*A. amphibius*) are well-known examples (see VOLE). *Myodes*, distinguished by the hairy foot-sole, includes two species, of which *M. lemmus*, of the Scandinavian Peninsula, is remarkable for its extraordinary migrations (see LEMMING). *Fiber* is represented by a single large species, *F. zibethicus* (see fig. 94), the Musk-Rat, or Musquash, a Beaver-like Water-Rat with webbed toes, but a laterally flattened tail, inhabiting the banks of rivers and lakes in North America, and constructing dome-roofed dwellings like those of the Beaver; it is much hunted for its fur.

Subfamily 10. **Siphneinæ.**—Molars as in *Arvicolinæ*; form cylindrical; ear-conch rudimentary; limbs and tail very short. Palæarctic.

Ellobius, with short claws, connects the species of this subfamily of fossorial Mole-like Rodents with the *Arvicolinæ*. *Siphneus*, on the other hand, leads to the next family, which includes the true Mole-Rats; the species, which chiefly inhabit northern Asia, closely resemble the Golden Moles (*Chrysochloris*) in general form and in the great development of the claws of the fore feet (compare fig. 96 with fig. 64, p. 405).

Family 4. SPALACIDÆ.

Rodent Moles, with very small or rudimentary eyes and ear-conchs, large claws, and short or rudimentary tail. Form cylindrical. Incisors large; molars rooted, with re-entering enamel folds; palate narrow.

Subfamily 1. **Spalacinæ.**—Angular part of the mandible arising from the lower edge of the socket of the lower incisor. Palæarctic, Indian, and Ethiopian.

Spalax, with *S. typhlus* of south-east Europe, agrees with the insectivorous Golden Moles in the complete external absence of the eye, which is covered by the hairy skin, showing similar adaptive modification in widely removed species. In *Rhizomys*, including several species from China, Tibet, Malay Peninsula, and eastern Africa, the eye is very small.

FIG. 96.—*Siphneus armandii* (reduced). A. Milne-Edwards, *Mammif. Tibet.*

Subfamily 2. **Bathyerginæ.**—Angular part of the mandible arising from the side of the socket of the lower incisor. Ethiopian.

Bathyergus, with *B. maritimus*, the Great Rodent-Mole, inhabiting the sand-dunes along the coast in the vicinity of the Cape of Good Hope, is distinguished chiefly by its grooved incisors from the other species included in the genera *Georychus* and *Heliophobius*, the former with several, the latter with one species, and differing from both in the presence of two or three premolars.

Family 5. GEOMYIDÆ.

Terrestrial or fossorial Rodents, with large cheek-pouches opening on the cheeks outside the mouth. The squamosal bones are much expanded, and the malars extend forwards to the lachrymals. *Pm* $\frac{1}{1}$; molars rooted or rootless. Nearctic and Neotropical.

Subfamily 1. **Geomyinæ.**—Incisors broad; mastoid not appearing on the top of the skull; eyes small; ear-conch rudimentary; limbs short, subequal. Fossorial.

Geomys bursarius, the common Pouched Rat of North America, with deeply-grooved incisors, inhabits the plains of the Mississippi, living in burrows like the Mole. Four other species from the Southern States, Mexico, and Central America are recognized. *Thomomys talpoides*, with plain incisors, extends all over Canada and North America west of the Rocky Mountains.

Subfamily 2. **Heteromyinæ.**—Incisors narrow; mastoid appearing largely on the top of the skull; eyes and ears moderate or large; hind limbs and tail elongated. Terrestrial.

Dipodomys has the molars rootless; *D. phillipsi* is the Kangaroo-Rat of the desert regions east of the Rocky Mountains. *Perognathus* and *Heteromys* have rooted molars; the latter genus is distinguished by the presence of flattened spines among the fur, with species extending into South America.

Family 6. DIPODIDÆ.

Terrestrial leaping Rodents, of slender form, with elongated hind limbs. The incisors are compressed, the molars have transverse enamel folds, the infra-orbital opening is rounded and very large, the malar ascends in front to the lachrymal in a flattened perpendicular plate (see fig. 89, p. 415), and the mastoid part of the auditory bulla is usually greatly developed.

Subfamily 1. **Zapodinæ.**—Molars rooted; cervical vertebræ free; metatarsals separate; hind feet with five digits. Nearctic.

Zapus hudsonius, the American Jumping-Mouse, extends over almost the whole North-American continent from Labrador to Mexico.

Subfamily 2. **Dipodinæ.**—Molars rooted; cervical vertebræ more or less ankylosed; metatarsals united; hind feet with three functional digits only. Palæarctic and Ethiopian.

This includes the true Jerboas. It contains three genera: *Dipus* with three toes, and *Alactaga* and *Platycercomys* with five, the last-named distinguished by the total absence of premolars, comprising many species extending from Siberia to Nubia.

Subfamily 3. **Pedetinæ.**—Molars rootless; cervical vertebræ free; metatarsals separate; hind feet with four digits. Ethiopian.

Pedetes caffer, the Cape Jumping Hare, by far the largest species of the family, extends from Mozambique and Angola to the Cape of Good Hope. See JERBOA.

Section III. HYSTRICOMORPHA.

Zygomatic arch stout; malar not supported below by a continuation of the maxillary zygomatic process; infra-orbital opening large;

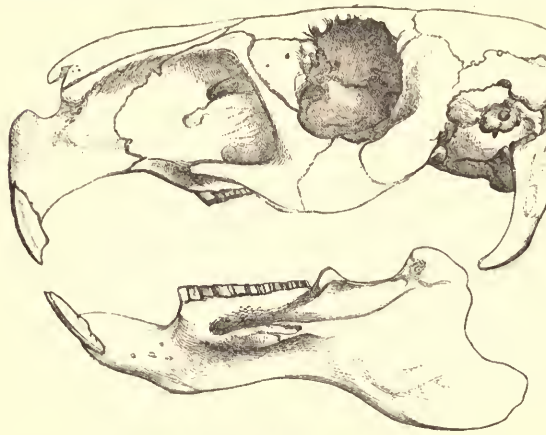

FIG. 97.—Skull of *Hydrochœrus capybara* (reduced).

mandible with the angular part arising from the outer side of the bony socket of the lower incisor; clavicles perfect or imperfect; fibula distinct.

Family 1. OCTODONTIDÆ.

Terrestrial, rarely fossorial or natatorial Rodents, with perfect clavicles and long incisive foramina extending into the maxillaries. Malar with an inferior angle; molars with external and internal enamel folds; mammary teats placed high on the sides of the body.

Subfamily 1. **Ctenodactylinæ.**—Molars semi-rooted; malar as in *Dipodidæ*; the two inner toes of the hind feet with a horny comb and rigid bristles. Ethiopian.

Ctenodactylus gundi and *Pectinator spekei*, both from North Africa, alone represent the subfamily; the peculiar comb-like inner toes are used in dressing the soft fur.

Subfamily 2. **Octodontinæ.**—Molars semi-rooted or rootless, with simple enamel folds; fur soft. Ethiopian and Neotropical.

There are six genera, including several species of Rat-like Rodents. *Octodon cumingii*, common in Chili and Peru, about the size of a Rat, lives like Rabbits in large communities. *Petromys typicus* is the only African representative.

Subfamily 3. **Echiomyinæ.** Molars semi-rooted or rooted, with deep, curved enamel folds; fur more or less harsh, often mixed with spines. Neotropical and Ethiopian.

Aulacodus, with *A. swinderianus*, the Ground-Rat of western Africa; the remaining nine genera are all Neotropical. Of these *Myopotamus* includes *M. coypu*, about 2 feet in length, the largest species of the family, common in South America, living in burrows near water, and feeding on aquatic plants. *Capromys pilorides*, nearly as large, is arboreal in habits, and inhabits Cuba and Hayti, where it is the largest indigenous mammal; the species of this genus are remarkable for the manner in which the liver is divided into minute lobules. *Plagiodontia ædium* is peculiar to Hayti and Jamaica, and in the latter island (besides Bats and Mice, the latter probably introduced) appears to be the only indigenous mammal. In *Loncheres* and *Echinomys* most of the species have the fur mixed with flattened lanceolate spines.

Family 2. HYSTRICIDÆ.

Terrestrial or arboreal Rodents, of stout form, with subequal limbs and more or less spiny integument. Malar without an inferior angle; the facial part of the skull short and broad; molars with external and internal enamel folds.

Subfamily 1. **Spingurinæ.**—Molars rooted; clavicles perfect; soles of feet tuberculated; teats four; tail generally prehensile. Arboreal. Nearctic and Neotropical.

There are three genera, including several species. Of these *Erethizon dorsatus*, the Urson, is distributed all over the forest regions of North America; *Synetheres* (=*Cercolabes*) *prehensilis*, the well-known prehensile-tailed Porcupine of South America (fig. 98), has the whole upper surface of the body protected by long white-tipped spines; *Chætomys subspinosus* is clothed with strong wavy bristles; in the last two genera the feet have four digits only.

Subfamily 2. **Hystricinæ.**—Molars semi-rooted; clavicles imperfect; soles of feet smooth; teats six; tail not prehensile. Terrestrial. Palæarctic, Indian, and Ethiopian.

Hystrix cristata, the Common Porcupine of southern Europe and northern Africa, is typical of this genus, which includes several other

FIG. 98.—*Synetheres prehensilis.*

species from the Indian region. The spines are cylindrical, the tail short and covered with spines and slender stalked open quills. In *Atherura fasciculata* of the Malay Peninsula the spines are flattened, and the tail is long and scaly, with a tuft of compressed bristles. A closely allied species, *A. africana*, inhabits western Africa. See PORCUPINE.

Family 3. CHINCHILLIDÆ.

Terrestrial Rodents, with elongated hind limbs, bushy tails, very soft fur, and perfect clavicles. The malar is without an inferior angle, and extends forwards to the lacrymal; the palate is contracted in front and deeply emarginate behind; the incisors are short, and the molars divided by continuous folds into transverse laminæ. Neotropical.

This small family includes only three species, divided into as many genera. *Chinchilla lanigera* and *Lagidium peruanum* are restricted to the alpine zones of the Andes from the northern boundary of Peru to the southern parts of Chili, and *Lagostomus trichodactylus*, the Viscacha, to the pampas from the Uruguay river to the Rio Negro. In *Chinchilla* the fore feet have five and the hind four digits, the tail is long and bushy, and the auditory bullæ are enormous, appearing on the top of the skull; *Lagidium* has four digits in both fore and hind feet, and *Lagostomus* three only in the hind feet, while the auditory bullæ are much smaller. See CHINCHILLA.

Family 4. DASYPROCTIDÆ.

Terrestrial Rodents, with subequal limbs, hoof-like claws, short or obsolete tail, and rudimentary clavicles. Mandibular masseteric ridge obsolete; palate broad; incisors long; molars semi-rooted, with external and internal enamel folds. Neotropical.

With two genera:—*Dasyprocta*, including several species of slender-limbed, subungulate Rodents with three hind toes, inhabiting Central and South America, one (*D. cristata*) extending into the West-Indian Islands; and *Cœlogenys*, with five hind toes, remarkable for the extraordinary development of its zygomatic arches, which are enormously expanded vertically, forming great convex bony capsules on the sides of the face, enclosing on each side a large cavity lined with mucous membrane internally, and communicating by a small opening with the mouth; *C. paca* is about 2 feet long, and, like the species of *Dasyprocta*, lives generally in the forests or along the banks of rivers.

Family 5. DINOMYIDÆ.

Terrestrial Rodents, distinguished from *Dasyproctidæ* by the cleft upper lip and rather long and bushy tail, and by the presence of four digits in the fore and hind feet. The manubrium is broad; the optic foramina are confluent, the incisors broad and the molars rootless, with folds dividing them into transverse lobes.

This family includes but a single species, *Dinomys branickii*, known only from a single specimen obtained in Peru, which resembles *Cœlogenys paca* in the general form of its body and in size. It is regarded by its describer, Professor Peters, as a connecting link between the families *Octodontidæ*, *Chinchillidæ*, *Dasyproctidæ*, and *Caviidæ*.

Family 6. CAVIIDÆ.

Terrestrial or natatorial Rodents, with short incisors, strong mandibular masseteric ridges, long and curved paroccipitals, and palate contracted in front. Fore feet with four digits, hind feet with three; clavicles imperfect; molars divided by enamel folds into transverse lobes; milk teeth shed before birth. Other characters as in *Dasyproctidæ*. Neotropical.

Cavia, limbs and ears short, subequal, tail none, includes several species widely distributed throughout South America, extending even to the Straits of Magellan, from one of which (*C. aperea*, probably) the common Guinea-Pig is derived. *Dolichotis* has the limbs and ears long, tail very short, with *D. patagonica*, a large species, nearly 3 feet long, inhabiting the gravelly plains of Patagonia. The palate is so much contracted in front that the premolars of opposite sides touch by their antero-internal edges. *Hydrochœrus*, with all the feet fully webbed, also includes a single species, which is the largest of living Rodents. The skull (fig. 97) is distinguished, not only by its great size, but also by the enormous development of the paroccipital processes. See CAVY and CAPYBARA.

SUBORDER II. *RODENTIA DUPLICIDENTATA.*

Rodents with four incisors in the upper jaw (two of them very small, and placed directly behind the large middle pair), the enamel of which extends round to their posterior surfaces. At birth there are six of these incisors, but the outer one on each side is soon lost. The incisive foramina are large and usually confluent; the bony palate is very narrow from before backwards; there is no true alisphenoid canal; the fibula is ankylosed to the tibia, and articulates with the os calcis; and the testes are permanently external.

Section IV. LAGOMORPHA.

Characters those of the suborder.

Family 1. LAGOMYIDÆ.

Terrestrial Rodents, with complete clavicles, subequal limbs, no external tail, and short ears. Skull depressed, frontals contracted and without post-orbital processes; *pm* $\frac{1}{1}$ or $\frac{2}{2}$; molars rootless, with transverse enamel folds. Palæarctic and Nearctic.

Lagomys, with about a dozen species of small Guinea-Pig-like animals, inhabiting chiefly the mountainous parts of northern Asia (from 11,000 to 14,000 feet), one species only being known from south-east Europe and one from the Rocky Mountains.

Family 2. LEPORIDÆ.

Terrestrial Rodents, with imperfect clavicles, elongated hind limbs, short recurved tail, and long ears. Skull compressed,

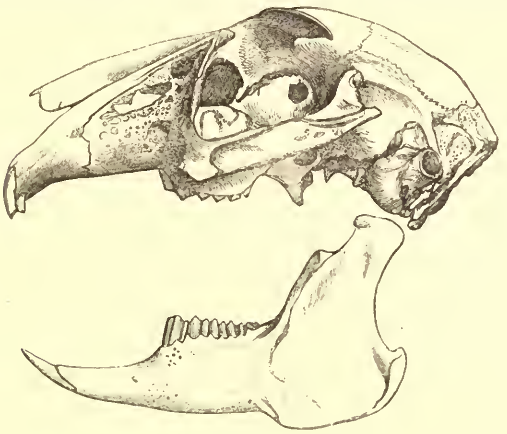

FIG. 99.—Skull of *Lepus timidus*.

frontals with large wing-shaped post-orbital processes (fig. 99); *pm* $\frac{3}{2}$; molars as in *Lagomyidæ*. Cosmopolitan (except Australasia).

Lepus includes about twenty species, which all resemble one another in general external characters. In all the fore limbs have five and the hind only four digits, and the soles of the feet are densely clothed with hairs similar to those covering the legs; the inner surface of the cheeks also is hairy. Although the family has such a wide distribution, the greater number of the species are restricted to the Palæarctic and Nearctic regions, and a single species only (*L. brasiliensis*) extends into South America. See HARE and RABBIT.

FOSSIL RODENTIA.

Fossil representatives of all the above-defined families, with the exception only of the small groups included under *Anomaluridæ*, *Haplodontidæ*, *Lophiomyidæ*, *Spalacidæ*, and *Dinomyidæ*, have been described from various deposits. Of these the earliest have been found in the Upper Eocene of Europe and America, and belong to the family *Sciuridæ*, of which the genera *Colonomys*, *Taxymys*, *Tillomys*, *Paramys*, *Heliscomys*, and *Mysyops* have been characterized from the Eocene of North America, and *Plesiarctomys* from that of both America and France, while examples of even the recent genus *Sciurus* have been found in beds of the same age in the latter country. Other recent families have representatives in later deposits, as *Castoridæ* with *Steneofiber* and *Palæomys* from the Miocene of Europe and North America, *Trogonotherium* from that of India, *Chalicomys* from that of Germany, and *Eucastor* from North America, *Myoxidæ* with *Myoxus* and *Muridæ* with *Elomys*, *Decticus*, *Oreomys*, and *Cricetodon* from the European Miocene, *Hystricidæ* with *Erethizon* extending back to the Miocene of India, *Geomyidæ* with *Entoptychus* and *Pleurolicus* and *Dasyproctidæ* with *Paciculus* from the Miocene of North America, *Lagomyidæ* with *Titanomys* and *Myolagus* from the European Miocene, and *Leporidæ* with *Palæolagus* from corresponding North American beds. Later Tertiary strata have yielded Rodent remains more abundantly; many of them referable to recent genera, or even closely allied to or undistinguishable from existing species, have been described from Brazilian bone-caves.

Besides those referable to existing families, several fossil remains have been discovered which cannot be so classed. These have been included in three families:—*Ischromyidæ* with *Pseudotomus* from the Eocene, and *Ischromys* and *Gymnoptychus* from the Miocene of North America; *Theridomyidæ* with *Theridomys* extending from the Eocene to the Pliocene of France, and *Archæomys*, *Issidioromys*, and *Dipoides* from the Miocene; and *Castoroididæ* with *Castoroides* from post-Pliocene deposits of North America, and *Amblyrhiza* and *Loxomylus* from the bone-breccias of the island of Anguilla. The first-named family appears to be intermediate between the *Sciuridæ* and *Castoridæ*; the second is allied to *Geomyidæ* and *Dipodidæ*; and the last, connected with *Chinchillidæ*, includes *Castoroides ohioensis*, a species vastly exceeding in size the largest of existing Rodents. A fourth family, *Mesotheriidæ*, including a single fossil form, *Mesotherium cristatum*, also of large size, from the Pliocene of South America, has been referred to this order, but it is evident that an animal which, besides presenting many other structural differences, possesses four lower incisors completely surrounded by enamel, and in which the mandibular condyle is transversely extended and the maxillaries articulate freely with the nasals, cannot be considered as coming under the definition of a Rodent.

Thus, like the *Insectivora* and *Chiroptera*, fossil remains of *Rodentia* are found as far back as the Eocene period, and of these some are even referable to one or more recent genera, and differ but slightly from existing species, while all others are either capable of being classed in recent families or are more or less closely related to them. It follows therefore (if the age of the beds in which these remains were found has been correctly determined) that, as in the case of these orders also, the first appearance of true Rodents must be sought for much farther back in time, and the question of their descent must be deferred till the discovery of sufficient material admits of reliable generalizations.

[For the above sections on the *Insectivora*, *Chiroptera*, and *Rodentia* we are indebted to Dr G. E. Dobson.]

ORDER UNGULATA.

Under this term may be included provisionally a large and rather heterogeneous group of mammals, the existing members of which form the *Pecora* and *Belluæ* of Linnæus, the *Ruminantia* and *Pachydermata* of Cuvier. A few years ago it was found convenient to restrict the order to a well-marked and distinctly circumscribed group, comprising the two sections known as *Perissodactyla* and *Artiodactyla*, and to leave out such isolated forms as the Elephant and Hyrax; but the discovery of a vast number of extinct species, which could not be brought under the definition of either Perissodactyle or Artiodactyle Ungulates, and yet are evidently allied to both, and which to a certain extent bridge over the interval between these and the isolated groups just mentioned, makes it necessary either to introduce a number of new and ill-defined ordinal divisions, or to widen the scope of the original order so as to embrace them all.

They are all animals eminently adapted for a terrestrial life, and in the main for a vegetable diet. Though a few are more or less omnivorous, and may under some circumstances kill living creatures smaller and weaker than themselves for food, none are distinctly and habitually predaceous. Their teeth are markedly heterodont and diphyodont,—the milk set being well developed and not completely changed until the animal attains its full stature. The molars have broad crowns with tuberculated or ridged surfaces. They have no clavicles. Their toes are provided with blunt, broad nails, or in the majority of cases with hoofs, more or less enclosing the ungual phalanges. The scaphoid and lunar bones of the carpus are always distinct.

The whole group may be divided into the *Ungulata Vera*, containing the suborders *Perissodactyla* and *Artiodactyla*, and a less well-known assemblage of animals which may be called *Subungulata* or *Ungulata Polydactyla*. Cope has pointed out a character in the structure of the carpus by which the latter are differentiated from the former. In all the *Subungulata* the bones of the proximal and distal row retain the primitive or more typical relation to each other (see fig. 100). The os magnum of the second row articulates mainly with the lunar of the first, or with the cuneiform, but not with the scaphoid, while in the group to which the vast majority of modern Ungulates belong the second or distal row has been shifted altogether towards the inner side of the limb (see figs. 107 and 109), so that the magnum is brought considerably in relation with the scaphoid, and is entirely removed from the cuneiform, as in the great majority of existing mammals.

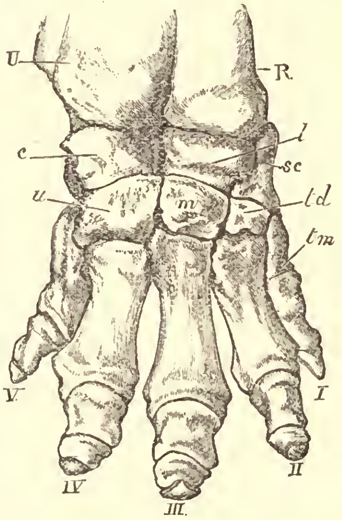

Fig. 100.—Right Fore Foot of Indian Elephant. × ⅙. U, ulna; R, radius; c, cuneiform; l, lunar; sc, scaphoid; u, unciform; m, magnum; td, trapezoid; tm, trapezium; I to V, first to fifth digit.

SUBUNGULATA.

By far the greater number of the *Subungulata* are extinct, and of many of those whose former existence has been revealed, chiefly by the labours of the American palæontologists, our knowledge is at present necessarily imperfect, though daily extending. It will only be possible here to give any details of some of the more interesting or best-known forms.

Suborder *HYRACOIDEA*.

This division is constituted to receive a single family of mammals, the affinities of which have long constituted a puzzle to zoologists. They were first placed among the Rodents, to which animals their small size and general appearance and habits give them much superficial resemblance. Cuvier's investigations into their anatomical structure, and especially their dental characters, led him to place them among the Ungulates, near the genus *Rhinoceros*, a position still accepted by many zoologists. Further knowledge of their organization and mode of development has caused Milne-Edwards, Huxley, and others to disassociate them from this connexion, and, failing to find any agreement with any other known forms, to place them in a group entirely apart. Palæontology has thrown no light upon the affinities of this anomalous and isolated group, as no extinct animals possessing their distinctive characters have as yet been discovered.

The dentition consists only of incisors and molars, the formula in all known species being $i\ \frac{1}{2}$, $c\ \frac{0}{0}$, $p\ \frac{4}{4}$, $m\ \frac{3}{3}$. The upper incisors have persistent pulps, and are curved longitudinally, forming a semicircle as in Rodents. They are, however, not flattened from before backwards as in that order, but prismatic, with an antero-external, an antero-internal, and a posterior surface, the first two only being covered with enamel; their apices are consequently not chisel-shaped, but sharp pointed. They are preceded by functional, rooted milk teeth. The lower incisors have

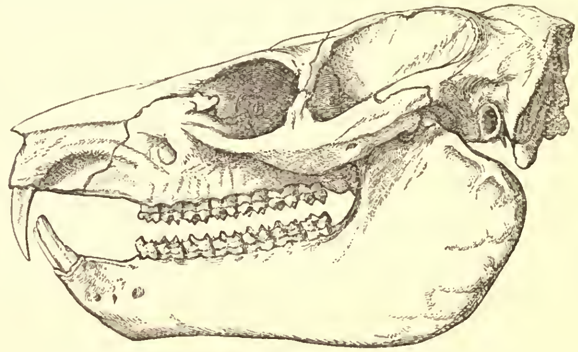

Fig. 101.—Skull and Dentition of *Dendrohyrax dorsalis*. × ⅔.

long tapering roots, but not of persistent growth. They are straight, procumbent, with awl-shaped, trilobed crowns. Behind the incisors is a considerable diastema or interval. The molars and premolars are all contiguous, and formed almost exactly on the pattern of some of the Perissodactyle Ungulates. The hyoid arch is unlike that of any known mammal. The dorsal and lumbar vertebræ are very numerous, 28 to 30, of which 21 or 22 bear ribs. The tail is extremely short. There are no clavicles. In the fore foot, the three middle toes are subequally developed, the fifth is present, but smaller, and the hallux is rudimentary, although, in one species at least, all its normal bones are present. The ungual phalanges of the four outer digits are small, somewhat conical, and flattened in form. The carpus has a distinct os centrale. There is a slight ridge on the femur in the place of a third trochanter. The fibula is complete, thickest at its upper end, where it generally ankyloses with the tibia. The articulation between the tibia and astragalus is more complex than in other mammals, the end of the malleolus entering into it. The hind foot is very like that of Rhinoceros, having three well-developed toes. There is no trace of a hallux, and the fifth metatarsal is represented by a small nodule only. The ungual phalanx of the inner (or second) digit is deeply cleft, and has a peculiar long curved claw, the others having short broad nails. The stomach is formed upon much the same principle as that of the Horse or Rhinoceros, but is more elongated transversely and divided by a constriction into two cavities—a large left *cul de sac*, lined by a very dense white epithelium, and a right pyloric cavity, with a very thick, soft, vascular lining. The intestinal canal is long, and has an arrangement perfectly unique among mammals, indeed among vertebrated animals, for, in addition to the ordinary short, but capacious and sacculated cæcum at the commencement of the colon, there is, lower down, an additional pair of large, conical, pointed cæca. The liver is much subdivided, and there is no gall-bladder. The brain resembles that of the typical Ungulates far more than the Rodents. The testes are permanently abdominal. The ureters open into the fundus of the bladder as in some Rodents. The female has six teats, of which four are inguinal and two axillary, and the placenta is zonary, as in the Elephant and *Carnivora*.

There are two distinct forms of Hyrax, differing both in structure and habits, and which may well be accorded generic rank.

1. *Hyrax*.—Molar teeth having the same pattern as those of *Rhinoceros*. Interval between upper incisors less than the width of the teeth. Lower incisors slightly notched at the cutting edge. Vertebræ: C 7, D 22, L 8, S 6, C 6. Of this form the earliest known species, *H. capensis*, is the type. There are several other species, as *H. syriacus* and *habessinicus*, from eastern Africa and Syria. They inhabit mountainous and rocky regions, and live on the ground.

2. *Dendrohyrax*.—Molar teeth having the same pattern as *Palæotherium* (except that the third lower molar has but two lobes). Interval between upper incisors exceeding the width of the teeth. Lower incisors with very distinctly trilobed crowns. Vertebræ: C 7, D 21, L 7, S 5, C 10. The members of this section frequent the trunks and large branches of trees, sleeping in holes. There are several species, not distinctly defined, from western and south Africa, as *D. arboreus* and *D. dorsalis*. The members of both groups appear to have a power like that possessed by the Lizards called Geckos of clinging to vertical surfaces of rocks and trees by the soles of their feet. See HYRAX.

The anatomy of Hyrax was first described by Pallas (*Spicilegia Zoologica*). Besides minor memoirs, two very detailed accounts of its structure have recently appeared—one by Brandt, in *Mém. Acad. Nat. Scien. St Pétersbourg*, series vii. vol. xiv., No. 2, 1869; and another by George, in *Annales des Sciences Naturelles*, series vi. tom. i., 1874, in which references to all the previous literature will be found. The mechanism by which the sole of the foot is enabled to adhere to smooth surfaces is fully described by G. E. Dobson, *Proc. Zool. Soc.*, 1876, p. 526.

SUBORDER *PROBOSCIDEA*.

This name has been appropriated to a well-marked group of animals, presenting some very anomalous characters, allied in many respects to the *Ungulata*, but belonging neither to the Artiodactyle nor Perissodactyle type of that order. It has been thought that they possess some, though certainly not very close, affinities with the *Rodentia*, and also with the *Sirenia*. It is certain, however, that the two species of Elephant which are the sole living representatives of the group, stand quite alone among existing mammals, differing widely from all others in many points of their structure. In some respects, as the skull, proboscis, and dentition, they are highly specialized, but in others, as in the presence of two anterior venæ cavæ, and in the structure of the limbs, they retain a low or generalized condition. A considerable series of extinct forms, extending back through the Pliocene and Miocene epochs, show the same type under different modifications, and in still more generalized outlines; and certain recently discovered forms from the Eocene of North America, if their affinities are rightly interpreted, appear to link the true *Proboscidea* to some unknown primitive type of Perissodactyle *Ungulata*.

The following are the principal characters common to existing, and, by inference, to the extinct, *Proboscidea*. The nose extended into a long, muscular, very flexible and prehensile proboscis, at the end of which the nostrils are situated, and from which the name given to the group is derived. The teeth consisting of ever-growing incisors of very great size, but never exceeding one pair in each jaw, and often present in one jaw only; no canines; large and transversely ridged molars. No clavicles. Limbs strong, the upper segment, especially in the hind limb, the longest. Radius and ulna distinct, the latter articulating extensively with the carpus. Fibula and tibia distinct. Astragalus very flat on both surfaces. Manus and pes short, broad, and massive, each with five toes, though the outer pair may be more or less rudimentary, all encased in a common integument, though with distinct, broad, short, hoofs. Third digit the largest. Two anterior venæ cavæ entering the right auricle. Stomach simple. A capacious cæcum. Testes permanently abdominal. Uterus bicornuate. Placenta non-deciduate and zonary. Mammæ two pectoral.

With regard to the teeth, the incisors,[1] which project largely out of the mouth, and are commonly called "tusks," are of an elongated conical form, and generally curved. They are composed mainly of solid dentine, the fine elastic quality and large mass of which renders it invaluable as "ivory" for commerce and the arts. A peculiarity of the dentine of the *Proboscidea* is that it shows, in transverse fractures or sections, striæ proceeding in the arc of a circle from the centre to the circumference in opposite directions, and forming by their decussations curvilinear lozenges, as in the "engine-turning" of the case of a watch. The enamel covering in existing species is confined to the extreme apex, and very soon wears off, but in some extinct species it forms persistent longitudinal bands of limited breadth. The tusks have small milk predecessors, shed at an early age.

The molar teeth present a remarkable series of modifications from the comparatively simple form in *Dinotherium*, with two or three strongly pronounced transverse ridges and a normal mode of succession, to the extremely complex structure and anomalous mode of replacement found in the true Elephants. The intermediate conditions occur in the various species of *Mastodon*. In this genus the enamel-covered transverse ridges of each tooth are generally more numerous than in *Dinotherium*, and often complicated by notches dividing their edge or by accessory columns attached

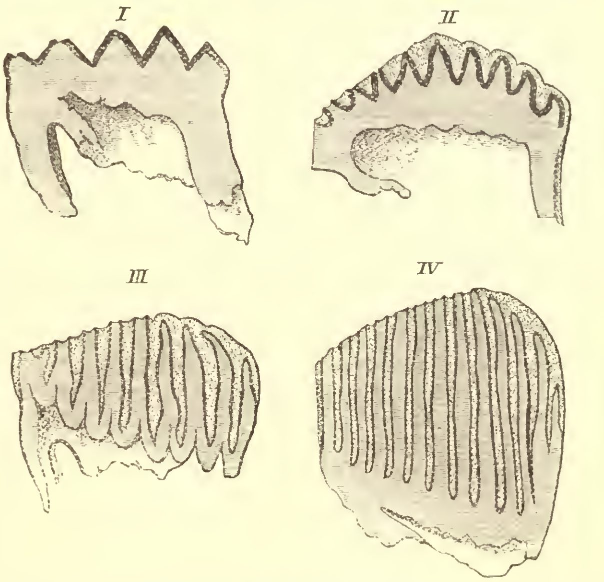

FIG. 102.—Longitudinal Sections of the Crown of a Molar Tooth of various Proboscideans, showing stages in the gradual modification from the simple to the complex form. I, *Mastodon ohioticus*; II, *Stegodon insignis*; III, *Loxodon africanus*; IV, *Elephas primigenius*. The dentine is indicated by transverse lines, the cementum by a dotted surface, and the enamel is black.

to them, but in the unworn tooth they stand out freely on the surface of the crown, with deep valleys between (fig. 102, I). In the Elephants the ridges are still further increased in number, and consequently narrower from before backwards, and are greatly extended in vertical height, so that, in order to give solidity to what would otherwise be a laminated or pectinated tooth, it becomes necessary to envelop and unite the whole in a large mass of cementum,

[1] These teeth are by some writers classed as canines, as their roots are implanted in the maxillæ; but, as in Rodents, they are originally developed in the gum covering the premaxillæ, in which bones their primitive alveoli are sunk. As growth proceeds, however, firm support for such massive and weighty bodies can only be obtained by their roots gradually sinking through the premaxillæ into the great and specially modified alveolar processes of the maxillæ, but this does not vitiate their homology with the incisors of other mammals.

which completely fills up the valleys, and gives a general smooth appearance to the organ when unworn; but as the wear consequent upon the masticating process proceeds, the alternate layers of tissue of different hardness—cementum, dentine, and enamel—which are disclosed upon the surface form a fine and very efficient triturating instrument. The modification of the tooth of a Mastodon into that of an Elephant is therefore precisely the same in principle as that of the molar of a Palæotherium into that of a Horse (see vol. xiii. p. 174), or of the corresponding tooth of one of the primitive Artiodactyles into that of an Ox. The intermediate stages, moreover, even in the present state of our knowledge, are so numerous that it is not possible to draw a definite line between the two types of tooth structure (see fig. 102, II, III, IV).

As regards the mode of succession, that of modern Elephants is, as before mentioned, very peculiar. During the complete lifetime of the animal there are but six molar teeth on each side of each jaw, with occasionally a rudimentary one in front, completing the typical number of seven. The last three represent the true molars of ordinary mammals; those in front appear to be milk molars, which are never replaced by permanent successors, but the whole series gradually moves forwards in the jaw, and the teeth become worn away and their remnants cast out in front, while development of others proceeds behind. The individual teeth are so large, and the processes of growth and destruction by wear take place so slowly, that not more than one, or portions of two, teeth are ever in place and in use on each side of each jaw at one time, and the whole series of changes coincides with the usual duration of the animal's life. On the other hand, the Dinotherium, the opposite extreme of the Proboscidean series, has the whole of the molar teeth in place and use at one time, and the milk molars are vertically displaced by premolars in the ordinary fashion. Among Mastodons transitional forms occur in the mode of succession as well as in structure, many species showing a vertical displacement of one or more of the milk molars, and the same has been observed in one extinct species of Elephant (*E. planifrons*) as regards the posterior of these teeth.

All known Proboscideans are animals of large dimensions, and some are the most colossal of land mammals. The head is of great proportionate size; and, as the brain case increases but little in bulk during growth, while the

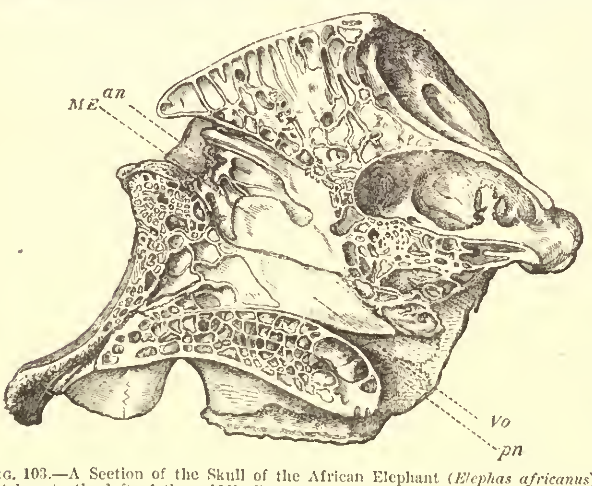

Fig. 103.—A Section of the Skull of the African Elephant (*Elephas africanus*) taken to the left of the middle line, and including the vomer (*Vo*) and the mesethmoid (*ME*). *an*, anterior, and *pn*, posterior narial aperture. 1/12 nat. size. Flower's *Osteology of Mammalia*.

exterior wall of the skull is required to be of great superficial extent to support the trunk and the huge and ponderous tusks, and to afford space for the attachment of muscles of sufficient size and strength to wield the skull thus heavily weighted, an extraordinary development of air-cells takes place in the cancellous tissue of nearly all the bones of the cranium. These cells are not only formed in the walls of the cranium proper, but are also largely developed in the nasal bones and upper part of the premaxillæ and maxillæ, the bones forming the palate and the basi-cranial axis, and even extend into the interior of the ossified mesethmoid and vomer. Where two originally distinct bones come into contact, the cells pass freely from one to the other, and almost all the sutures become obliterated in old animals. The intercellular lamellæ in the great mass which surrounds the brain cavity superiorly and laterally mostly radiate from the inner to the outer table, but in the other bones their direction is more irregular. Like the similar but less developed air-cells in the skulls of many other mammals, they all communicate with the nasal passages, and they are entirely secondary to the original growth of the bones, their development having scarcely commenced in the new-born animal, and they gradually enlarge as the growth of the creature proceeds towards maturity. The nasal bones are very short, and the anterior narial aperture situated high in the face. The zygomatic arch is slender and straight, the malar bones being small, and forming only the middle part of the arch, the anterior part of which (unlike that of all true Ungulates) is formed only by the maxilla. The maxillo-turbinals are but rudimentary, the elongated proboscis supplying their place functionally in warming and clearing from dust the inspired air.

The neck is very short. The limbs are long and stout, and remarkable for the great length of the upper segment (especially the femur) as compared with the distal segment, the manus and pes. It is owing to this and the vertical position of the femur that the knee-joint in the hind leg is placed much lower, and is more conspicuous externally than in most quadrupedal mammals, and, this having been erroneously compared with the hock-joint or ankle of Ungulates, the popular fallacy that the joints of the Elephant's leg bend in a contrary direction to that of other mammals has arisen. There is no round ligament in the hip-joint, or third trochanter to the femur. The radius and ulna are distinct, though fixed in a crossed or prone position. The fibula also is quite distinct from the tibia. The feet are short and broad, the carpal and tarsal bones being very square, with flattened surfaces for articulation; the astragalus especially differs from that of true Ungulates in its flatness, in the absence of a distinct pulley-like articular surface at either extremity, and in having no articular facet for the cuboid. The fibula articulates with the calcaneum, as in Artiodactyles. Of the five toes present on each extremity (see fig. 100), the middle one is somewhat the largest, and the lateral ones smallest, and generally wanting (especially in the hind foot) the complete number of phalanges. The ungual phalanges are all small, irregular in form, and late in ossification. The whole are encased in a common integument, with a flat, subcircular, truncated sole, the only external indication of the toes being the broad oval nails or hoofs arranged in a semicircle around the front edge of the sole. The hind foot is smaller and narrower than the front. The liver is small and simple, and there is no gall-bladder. In form the brain resembles that of the Rodents and other lower orders of mammals, the cerebellum being entirely behind and uncovered by the cerebrum, but the hemispheres of the latter are richly convoluted.

The *Proboscidea* are exclusively vegetable feeders, living chiefly on leaves and young branches of forest trees and various kinds of herbage, which they gather and convey to their mouth by the very mobile proboscis, an organ which combines in a marvellous manner strength with dexterity of application, and is a necessary compensation for the shortness and inflexibility of the neck, as by it many of the functions of the lips of other animals are performed. By its means the Elephant is enabled to drink without bending the head or limbs; the end of the trunk being dipped into the stream or pool, a forcible inspiration fills the two capacious air-passages in its interior with water, which, on the tip of the trunk being turned upwards and inserted into the mouth, is ejected by a blowing action, and swallowed; or if the animal wishes to refresh and cool its skin, it can throw the water in a copious stream over any part of its surface. Elephants can also throw dust and sand over their bodies by the same means and for the same purpose, and wild animals have been frequently observed fanning themselves with leafy boughs held in the trunk. The species are at present limited in their geographical distribution to the Ethiopian and Oriental regions, but they formerly had a far more extensive range.

Elephas.—Dentition: $i\,\frac{1}{0}$, $c\,\frac{0}{0}$, $m\,\frac{6}{6}=26$. The incisors variable, but usually of very large size, especially in the male sex, directed somewhat outwards, and curved upwards, without enamel except on the apex before it is worn; preceded by small milk incisors. The molars succeed each other by horizontal replacement from before backwards, never more than one or part of two being in use on each side of each jaw at the same time; each composed of numerous flattened enamel-covered plates or ridges of dentine, projecting from a common many-rooted base, surrounded and united together by cementum. The number of plates increases from the anterior to the posterior molar in regular succession, varying in the different species, but the third and fourth (or the last milk molar and the first true molar), and these only, have the same number of ridges, which always exceeds five. Skull of adult very high and globular. Mandible ending in front in a prolonged deflected and spout-like symphysis. Vertebræ: C 7, D 19–21, L 3–4, S 4, C 26–33.

The existing species of the genus differ so much that they must be placed in two distinct sections, considered by some zoologists as distinct genera.

1. *Elephas* proper. *Elasmodon*, F. Cuv.; *Euelephas*, Falc.—Average number of plates of the six successive molar teeth expressed by the "ridge formula" 4, 8, 12, 12, 16, 24. The plates compressed from before backwards, the anterior and posterior surfaces (as seen in the worn grinding face of the tooth) being nearly parallel. Ears of moderate size. Upper margin of the end of the proboscis developed into a distinct finger-like process, much longer than the lower margin. Five nails on the fore feet, and four (occasionally five) on the hind feet.

The well-known Asiatic Elephant, *E. indicus*, inhabits in a wild state the forest lands of India, Burmah, the Malay Peninsula, Cochin China, Ceylon, and Sumatra. Those from the last-named islands, presenting some variations from those of the mainland, have been separated under the name of *E. sumatranus*, but the distinction has not been satisfactorily established. The appearance of the Asiatic Elephant is familiar to all. Though rarely breeding in captivity, it has been domesticated from the most remote antiquity, and is still extensively used in the East as a beast of burden. In the wild state it is gregarious, associating in herds of ten, twenty, or more individuals, and, though it may under certain circumstances become dangerous, it is generally inoffensive and even timid, fond of shade and solitude and the neighbourhood of water. The height of the male at the shoulder when full grown is usually from 8 to 10 feet, occasionally as much as 11. The female is somewhat smaller. See ELEPHANT.

2. *Loxodon.*—Molar teeth of coarse construction, with fewer and larger plates and thicker enamel. Ridge formula: 3, 6, 7, 7, 8, 10. The plates not flattened, but thicker in the middle than at the edges, so that their worn grinding surfaces are lozenge-shaped. Ears very large. The upper and lower margins of the end of the trunk forming two nearly equal prehensile lips. But three hoofs on the hind foot. The one species, *E. africanus*, now inhabits the wooded districts of the whole of Africa south of the Sahara, except where it has been driven away by human settlements. Fossil remains of Pleistocene age, undistinguishable specifically, have been found in Algeria, Spain, and Sicily. It was trained for war and show by the ancient Carthaginians and Romans, and recent experience of the species in captivity in England shows that it is as intelligent as its Asiatic relative, if not more so, while surpassing it in courage, activity, and obstinacy. Nevertheless, in modern times, no people in Africa have been sufficiently civilized or enterprising to care to train it for domestic purposes. It is hunted chiefly for the sake of the ivory of its immense tusks, of which it yields the principal source of supply to the European market, and the desire to obtain which is rapidly leading to the extermination of the species. In size the male African elephant often surpasses that of Asia, but the female is usually smaller. The circumference of the forefoot is half the height at the shoulder, a circumstance which enables the hunters to judge from the footprints the exact size of the animals of which they are in pursuit.

Extinct Species of Elephant.—Abundant remains of Elephants are found embedded in alluvial gravels, or secreted in the recesses of caves, into which they have been washed by streams and floods, or dragged as food by Hyænas and other carnivorous inhabitants of these subterranean dens. Such remains belonging to the Pleistocene and Pliocene periods have been found in many parts of Europe, including the British Isles, in North Africa, throughout the North American continent from Alaska to Mexico, and extensively distributed in Asia, where the deposits of the sub-Himalayan or Sivalik hills, belonging to the earliest Pliocene, are rich in the remains of Elephants of varied form. These species are chiefly known and characterized at present by the teeth, some of which resemble the existing Indian and some the African type, but the majority are between the two, and make the distinction between *Elephas* and *Loxodon* as different genera quite impracticable. Others again approach so closely in the breadth and coarseness of the ridges and paucity of cementum to *Mastodon* as to have been placed by some zoologists in that genus. These form the group or subgenus called *Stegodon* by Falconer.

Among the best known extinct Elephants are *E. primigenius*, the Mammoth, very closely resembling the existing Indian species, and one of the most recently extinct and extensively distributed (see MAMMOTH); *E. antiquus* and *E. meridionalis*, also found in Britain, as well as in Europe generally, of rather earlier date, and inclining more to the *Loxodon* type, as also do two species found in the island of Malta, *E. mnaidiensis* and *E. melitensis*, the latter the smallest known species of the suborder, sometimes not exceeding 3 feet in height when adult. The *Stegodon* forms, *E. clifti*, *bombifrons*, *insignis*, and *ganesa*, are all from India, which locality would appear, from the abundance of remains and variety of forms, as well as the generalized character of some and the geological horizon (Plio-Miocene) in which the remains are found, to be the earliest habitation of the true Elephants yet discovered. Remains of Elephants of the last-named group have also lately been found in China and Japan. A tusk the dentine of which presents the characters hitherto considered peculiar to the *Proboscidea*, from Australia, has been lately described by Professor Owen under the name of *Notelephas*.

Mastodon.—Dentition: $i\,\frac{1}{1\text{ or }0}$, $c\,\frac{0}{0}$, p and $m\,\frac{6}{6}$. Upper incisors very large, as in *Elephas*; sometimes with longitudinal bands of enamel, more or less spirally disposed. Lower incisors variable: when present comparatively small and straight, sometimes persistent, sometimes early deciduous, and in some species never present. Grinding surface of molars with transverse ridges, the summits of which are divided more or less into conical or mammillary cusps, and often with secondary or additional cusps between and clustering against the principal ridges; enamel thick; cementum very scanty, never filling up the interspaces between the ridges. The third, fourth, and fifth molars having the same number of ridges,[1] which never exceeds five. In some species (*M. ohioticus*) no vertical succession has been observed, but in others, as *M. angustidens*, the two posterior premolars, and in the American *M. productus* apparently all three, are preceded by milk molars. There is also a horizontal succession as in Elephants, the anterior teeth being lost before the posterior ones are fully developed, but not so complete as in the former genus, for as many as three teeth may be in place in one jaw at one time. The skull generally is less elevated and less cellular than in *Elephas*; otherwise the remainder of the skeleton is similar.

All known Mastodons are gigantic animals, equalling or exceeding the recent Elephants in size. Their remains have been found in Europe and southern Asia and America, from the Miocene to the Pleistocene epochs.

Dinotherium.—Dentition of adult: $i\,\frac{0?}{1}$, $c\,\frac{0}{0}$, $p\,\frac{2}{2}$, $m\,\frac{3}{3}=22$; all present at the same time, there being no horizontal succession, but the premolars replace milk teeth in the ordinary manner. The presence or absence of upper incisors has not yet been clearly ascertained. Lower incisors, large, conical, descending and slightly curved backwards, implanted in a greatly thickened and deflected beak or prolongation of the symphysis. In section they do not show the decussating striæ characteristic of Mastodons and Elephants. Crowns of molars with strong, transverse, crenulated ridges, with deep valleys between, much resembling those of the Tapirs. Ridge formula of the permanent molar series: 2, 2, 3, 2, 2. The three ridges of the first true molar appear to be constant in both upper and lower jaws, although it is quite an anomalous character among

[1] This, and the larger number of ridges in the latter, are the only absolute distinctions which Falconer could find between *Mastodon* and *Elephas* (*Palæont. Memoirs*, ii. p. 9), and it is clear that they are somewhat arbitrary. The line between the two genera is drawn at this point more as a matter of convenience for descriptive purposes than as indicating any great natural break in the sequence of modifications of the same type.

Proboscideans for this molar to have more ridges than those which come behind it. The last milk molar has also three ridges, the penultimate but two. The cranium is much depressed, with compara-

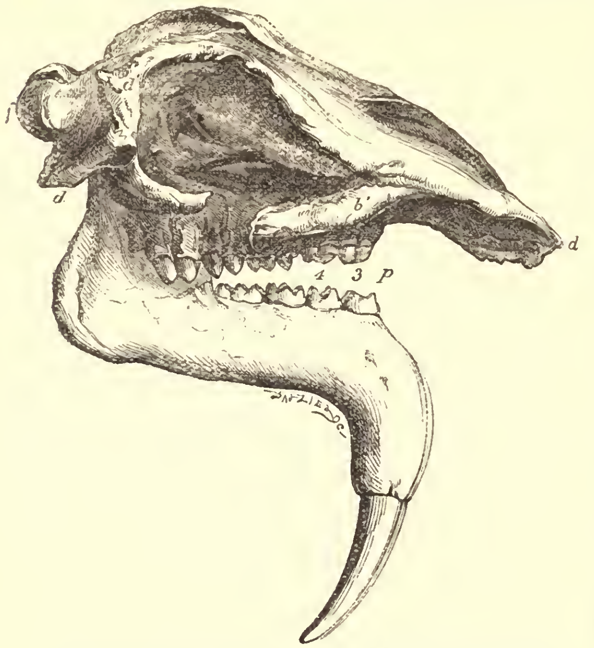

FIG. 104.—Skull of *Dinotherium giganteum* (Miocene, Eppelsheim).

tively little development of air-cells. The remainder of the skeleton is imperfectly known, but apparently agrees in its general characters with that of the other Proboscideans.

Remains of *Dinotherium giganteum*, an animal of elephantine proportions, strikingly characterized by the pair of huge tusks descending nearly vertically from the front of the lower jaw, were first discovered at Eppelsheim, near Darmstadt, and described by Kaup. They have since been met with in various Middle and Upper Miocene formations in the south of Germany, France, Greece, and Asia Minor. Three species, *D. pentapotamiæ*, *D. indicum*, and *D. sindiense*, have been described by Falconer and Lydekker from north-western India. The genus has hitherto not been found in England or in America.

The genus *Phenocodus*, from the Lower Eocene of Wyoming, lately described by Cope (*Am. Naturalist*, December 1881 and June 1882), is placed by that zoologist in a special group called *Condylarthra*, allied to the *Proboscidea*, but distinguished by "a post-glenoid process, and a third trochanter of the femur, and no calcaneal facet for the fibula." This and the *Proboscidea* are united by Cope to form the order *Taxeopoda*, one of his primary divisions of the *Ungulata*.

In all the preceding forms the astragalus articulates only with the navicular bone, in those that follow with both navicular and cuboid.

SUBORDER *AMBLYPODA.*

Among the most remarkable of the recent discoveries in the Eocene formations of the western States of North America has been that of a group of animals of huge size, approaching if not equalling that of the largest existing Elephants, presenting a combination of characters quite unlike those known among either recent or extinct creatures, and of which there were evidently many species living contemporaneously, but all of which became extinct before the close of the Eocene period. To form some idea of their appearance, we must imagine animals very elephantine in general proportions and in the structure of their limbs. The fore foot had five, and the hind foot four toes. The tail, as in the Elephants, was long and slender, but the neck, though still short, was not so much abbreviated as in modern Proboscideans, and there is no evidence that they possessed a trunk. The head differed greatly from that of the Elephants, being long and narrow, more like that of a Rhinoceros, and, as in that animal, was elevated behind into a great occipital crest, and it had developed upon its upper surface three pairs of conspicuous, laterally diverging protuberances, one pair in the parietal region, one on the maxillaries in front of the orbits, and one (much smaller) near the fore part of the elongated nasal bones. Whether these were merely covered by bosses of callous skin, as the rounded form and ruggedness of their extremities would indicate, or whether they formed the bases of attachment for horns of still greater extent, like those of the Rhinoceros or of the Cavicorn Ruminants, can only be a matter of conjecture. There were no upper incisors, but three on each side below, of comparatively small size, as was also the lower canine. A huge, compressed, curved, sharp-pointed canine tusk, very similar in form and position to that of the Musk-Deer, descended from each side of the upper jaw. These were present in both sexes, but very much smaller in the female, as was also the flange-like process of the lower jaw by which they were guarded. Behind these, and at some distance from them, were on each side above and below six molar teeth, of comparatively small size, placed in continuous series, each with a pair of oblique ridges conjoined internally and diverging externally in a V-like manner, and provided with a stout basal cingulum. The dental formula was therefore $i\,\frac{0}{3}$, $c\,\frac{1}{1}$, $p\,\frac{3}{3}$, $m\,\frac{3}{3} = 34$; and the dentition had thus already attained a remarkable degree of specialization, although the brain was smaller and more rudimentary in characters than in almost any other known mammal.

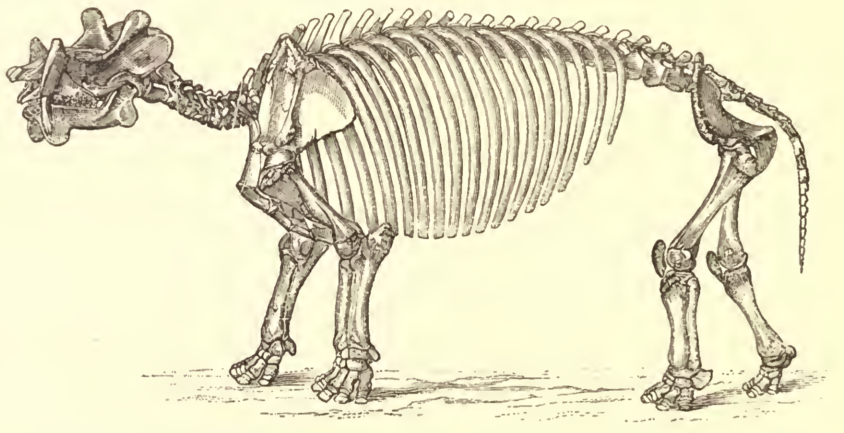

FIG. 105.—Restoration of *Dinoceras mirabile.* $\frac{1}{30}$ nat. size. From Marsh (*Am. Jour. Sci.*, vol. xii. pl. 2).

The first-discovered evidences of the existence of animals of this group were described by Leidy in 1872, under the name of *Uintatherium* (from the Uintah mountains, near which they were found). Other nearly allied forms have been named *Dinoceras* (restoration of which is shown in fig. 105), *Tinoceras*, and *Loxolophodon.* They constitute the order *Dinocerata* of Marsh, but are included by Cope in the *Amblypoda.*

Another interesting form referred to this suborder is *Coryphodon*, which appears to connect the *Proboscidea* with the most primitive *Perissodactyla*, especially *Lophiodon.* It was first described by Owen in 1846 from a fragment of a jaw from the London Clay. More perfect remains were afterwards discovered in France, and lately in great abundance, indicating many species from the size of a Tapir to that of a Rhinoceros, in the lowest Eocenes of New Mexico and Wyoming, in the United States. It had forty-four teeth; the canines of both jaws were large and sharp-pointed, and the molars had strongly pronounced oblique ridges. The general proportions were those of a Bear, but the tail was of moderate length, and the feet short and wide, with five toes on each.

The Tertiaries of South America have yielded some very remarkable forms of mammalian life, the nature and affinities of which have greatly puzzled all zoologists who have attempted to unravel them. *Macrauchenia*, an animal with a Camel-like neck, is now known to be a Perissodactyle, though in some characters somewhat aberrant. The articulation of the fibula with the calcaneum is an Artiodactyle or perhaps generalized character. The teeth ally it to *Palæotherium* and *Rhinoceros*. *Homalodontotherium*, from the banks of the river Gallegos, south-east Patagonia, is known by the teeth alone, which, though very generalized, are on the whole rhinocerotic. *Nesodon*, from the same locality, also only known by the dentition and some parts of the skull, connects the last and *Macrauchenia* with *Toxodon*. These three genera have the typical dental formula of $i\,\frac{3}{3}$, $c\,\frac{1}{1}$, $p\,\frac{4}{4}$, $m\,\frac{3}{3} = 44$. *Toxodon* is an animal about the size of a Hippopotamus; it was first discovered by Darwin, and many specimens have since been found in Pleistocene deposits near Buenos Ayres, and described by Owen, Gervais, and Burmeister. The teeth consist of large incisors, very small lower canines, and strongly curved molars, all with persistent roots, the formula being apparently $i\,\frac{2}{3}$, $c\,\frac{0}{1}$, $p\,\frac{4}{3}$, $m\,\frac{3}{3} = 38$. The cranial characters exhibit a combination of those found in both Perissodactyles and Artiodactyles, but the form of the hinder part of the palate and the absence of an alisphenoid canal belong to the latter; and the tympanic, firmly fixed in between the squamosal and the exoccipital, ankylosed to both, and forming the floor of a long upward-directed meatus auditorius, is so exactly like that of the *Suina* that it is difficult to believe it does not indicate some real affinity to that group. These characters seem to outweigh in importance those by which some zoologists have linked *Toxodon* to the *Perissodactyla*, and the absence of the third trochanter and the articulation of the fibula with the calcaneum tell in the same direction. The structure of the feet is not completely known, but Cope has shown that the tarsal bones differ altogether from those of either Artiodactyles or Perissodactyles, and more nearly resemble those of the *Proboscidea* than any other known Ungulates.

Mesotherium, also called *Typotherium*, from the same locality, was an animal rather larger than a Capybara, and of much the same general appearance. Its skeleton is completely known, and shows a singular combination of characters, resembling *Toxodon* or a

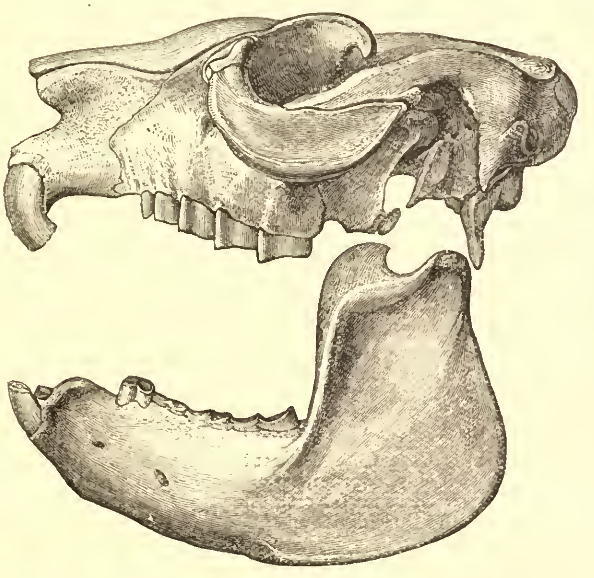

Fig. 106.—Cranium and Lower Jaw of *Mesotherium cristatum*. ½ nat. size. From Gervais.

generalized Ungulate on the one hand, and the Rodents, especially the *Leporidæ*, on the other. In the presence of clavicles it differs from all known Ungulates, and in having four lower incisors from all Rodents. The teeth are $i\,\frac{1}{2}$, $c\,\frac{0}{0}$, $p\,\frac{2}{1}$, $m\,\frac{3}{3} = 24$.

It will thus be seen that, although our knowledge of many of these forms is still very limited, we may trace among them a curious chain of affinities, which would seem to unite the Ungulates on the one hand with the Rodents on the other; but further materials are required before we can establish with certainty so important a relationship, one which, if true, would alter materially some of the prevailing views upon the classification of mammals.

UNGULATA VERA.

In the typical *Ungulata* the feet are never plantigrade, and the functional toes do not exceed four,—the inner digit being suppressed, at all events in all forms which have existed since the Early Eocene period. The os magnum of the carpus articulates freely with the scaphoid. The allantois is largely developed, and the placenta, so far as is known, is non-deciduate, the chorionic villi being either evenly diffused or collected in groups or cotyledons (in *Pecora*). The testes descend into a scrotum. There is never an os penis. The uterus is bicornuate. The mammæ are usually few and inguinal, or may be numerous and abdominal (as in *Suina*), but are never solely pectoral. The cerebral hemispheres in existing Ungulates are well convoluted.

The group is now, and has been throughout the whole of the Tertiary period, composed of two perfectly distinct sections, differing from each other, not only in the obvious characters of the structure of the limbs, but in so many other parts of their organization that they must be considered as of the rank at least of suborders. The characters of these divisions, first indicated by Cuvier, were thoroughly established by Owen, by whom the names whereby they are now generally known were proposed.

Suborder *PERISSODACTYLA*.

This is a perfectly well-defined group of Ungulate mammals, represented in the actual fauna of the world by only three distinct types or families—the Tapirs, the Rhinoceroses, and the Horses—poor in genera and species, and (except in the case of the two domesticated species of *Equus*, which have been largely multiplied and diffused by man's agency) not generally numerous in individuals, though widely scattered over the earth's surface. Palæontological records show very clearly that these are but the surviving fragments of a very extensive and much varied assemblage of animals which flourished upon the earth throughout the whole of the Tertiary geological period, and which, if it could be reconstructed in its entirety, would not only show members filling up structurally the intervals between the existing apparently isolated forms, but would show several marked lines of specialization which have become extinct without leaving any direct successors.

The following are the principal characters distinguishing them from the *Artiodactyla*. Premolar and molar teeth in

A B C

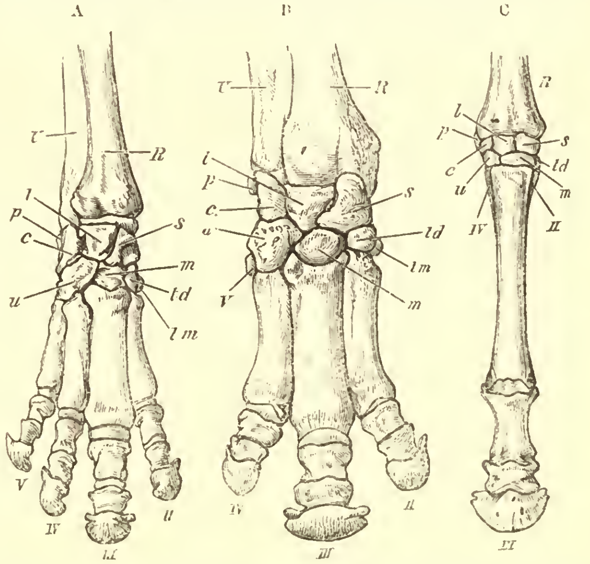

Fig. 107.—Bones of Fore Foot of existing Perissodactyles. A, Tapir (*Tapirus indicus*), × ⅕; B, Rhinoceros (*Rhinoceros sumatrensis*), × ⅕; C, Horse (*Equus caballus*), × ⅙. continuous series, with massive, quadrate, transversely ridged or complex crowns,—the posterior premolars resembling the true molars in size and structure. Crown of the last lower molar commonly bilobed.[1] Dorso-lumbar vertebræ never fewer than twenty-two, usually twenty-three in the existing species. Nasal bones expanded posteriorly. An alisphenoid canal. Femur with a third trochanter. The middle or third digit on both fore and hind feet larger than any of the others, and symmetrical in itself, the free border of the ungual phalanx being evenly rounded (see fig. 107). This may be the only functional toe, or the second and fourth may be subequally developed on each side of it. In the Tapirs and many extinct forms, the fifth toe also remains on the fore limb, but its presence does not interfere with the symmetrical arrangement of the remainder of the foot around the median line of the third or middle digit. Traces of a hallux have only been found in some extremely ancient and primitive forms. The astragalus has a pulley-like surface above for articulation into the tibia, but its distal surface is flattened and unites to a much greater extent with the navicular than with the cuboid, which bone is of comparatively less importance than in the Artiodactyles. The calcaneum does not articulate with the lower end of the fibula. The stomach is simple, the cæcum large and capacious, the placenta diffused, and the mammæ inguinal.

The very distinct minor groups into which the Perissodactyles are divided in the later periods of the earth's history are, even by the knowledge already gained of the ancient members of the sub-order, so closely united by connected forms that it is difficult to make any satisfactory classification of the whole. This is of course what might be expected, and would probably be the case with all other groups if we knew as much of their past history as we do of that of the Perissodactyles. It is necessary, however, for descriptive purposes to have some arrangement; and perhaps, if not the most natural, the most convenient division (especially as it is chiefly or only by these organs that many are known) is one founded upon the structure of the lower molar teeth. By this character we may make three primary divisions, each of which has a representative at the present time:—(*A*) those in which the crowns of the lower molars are disposed in transverse ridges, as in the Tapirs; (*B*) those in which the crowns of the lower molars are formed by a pair of crescents, as in Rhinoceros; (*C*) those in which the crowns of the lower molars are formed of a pair of crescents, with the addition of inner lobes or columns, as in the Horses. As these forms are all modifications of the same essential pattern, transitions in certain or all of the teeth must be expected in many cases, and, as before implied, the grouping of the Perissodactyles into Tapiroid, Rhinocerotic, and Equine sections according to the pattern of their molar teeth may not be a true exposition of the real affinities of the genera, but must be looked upon rather as a convenient provisional arrangement.

A. Tapiroid Section.

Lower molars bilophodont.

Family Lophiodontidæ.

Both upper and lower true molars bilophodont. Premolars smaller and simpler than the true molars. Four toes on the anterior and three on the posterior feet. This family includes a large number of more or less imperfectly known forms, all extinct, ranging from the size of a Rabbit to that of an Ox. They are the earliest in time and most generalized in structure of the known Perissodactyles. It is possible that from some either of the known or the still undiscovered members of this group most of the other types of the order have been derived. Their remains have been found in Europe only in the Lower and Middle Eocene, though in North America they appear to have lingered to a somewhat later date. The genus *Hyracotherium* was established in 1839 by Owen for a small animal, no larger than a Hare, the skull of which was found in the London Clay at Herne Bay. A more perfect specimen apparently of the same species was afterwards (in 1857) described under the name of *Philophus vulpiceps.* Closely allied forms from the European continent have been named *Pachynolophus* and *Lophiotherium.* These have all the complete dentition, viz., $i\,\frac{3}{3}$, $c\,\frac{1}{1}$, $p\,\frac{4}{4}$, $m\,\frac{3}{3} = 44$. The posterior lower molar has three lobes. The genus *Lophiodon* (Cuvier, 1822) contains animals of much larger size and later geological period (Middle or Upper Eocene), in which the dentition was so far specialized as to have lost the anterior premolar of both jaws, the formula being $i\,\frac{3}{3}$, $c\,\frac{1}{1}$, $p\,\frac{3}{3}$, $m\,\frac{3}{3} = 40$. The transverse ridges of the upper molars are placed obliquely, the posterior is smaller than the anterior, and they are united by their external borders; those of the mandible are distinct and only connected by a feeble diagonal crest, the last bearing a talon or rudiment of a third lobe. On the premolars the anterior ridge only is developed. Nearly allied was the American genus *Hyrachyus*, the structure of which is now very completely known from well-preserved remains. The skeleton closely resembles that of the Tapir, though the dentition is more like that of *Lophiodon*, except that the last lower molar has but two lobes. As many as nine species have been already described, all from the Upper Eocene. Another form from the same deposits, *Colonoceras* of Marsh, is said to have had an attachment for a dermal horn on each nasal bone. *Triplopus*, otherwise closely similar to *Hyrachyus*, wants the fifth digit of the manus, and hence is placed by Cope in a distinct family, *Triplopidæ.*

Family Tapiridæ.

Both upper and lower true molars bilophodont. Posterior premolars above and below resembling the true molars. This family is connected with the last by the Middle Miocene genus *Listriodon.* The genus *Tapirus*, in which as many as three premolars resemble the true molars, and in which the last lower molar has no talon, appears first in the Upper Miocene of Europe, and has continued with scarcely any appreciable change until the present time, being represented by several species in Central and South America, and one in the Malay Peninsula and adjacent islands. It is therefore probably the oldest existing genus of mammals. One of the American species differs from all the others in the great anterior prolongation of the ossification of the mesethmoid cartilage, and has been separated generically by Gill under the name of *Elasmognathus.* See Tapir.

B. Rhinocerotic Section.

Lower molar teeth with the ridges, instead of being transverse, curved in a crescentic manner. The outer extremity of each ridge is curved forwards so that the hinder ridge abuts against the external surface of the ridge in front of it. An unworn lower molar of a Rhinoceros has thus externally two convex areas separated by a vertical groove, and internally two principal sinuses, corresponding to the projections externally. The entrances to these sinuses are bordered by three conical pillars—the first of comparatively little importance, representing the anterior talon of the Tapir's tooth, the second, the largest, representing the antero-internal principal cusp, and the third the postero-internal principal cusp. The upper molars of all the animals of this section resemble those of *Lophiodon* in principle, the transverse ridges being joined by an outer wall and placed obliquely, their inner ends inclining backwards and their posterior surfaces being more or less concave. There are two further chief modifications of this type:—(1) that in which the free edge of the outer wall acquires a strongly zigzag or bicrescentic character, being deviated inwards opposite each of the principal outer cusps, and outwards at the anterior and posterior angles of the tooth and in the middle between the cusps, as in *Palæotherium*; and (2) that in which the outer wall is greatly developed, and in the main flat or smoothly convex, though with slight elevations and depressions corresponding with those so regular and well-marked in the last section; this is the character of the teeth of Rhinoceros and its allies.

Family Hyracodontidæ.

Separated by Cope from the next, and containing the genus *Hyracodon* of Leidy, a primitive or simple Rhinoceros-like type, from the Lower Miocene of North America, with the full number of teeth, but only three digits on each foot.

Family Rhinocerontidæ.

A very extensive group, of which many modifications, forming a gradual series, showing increasing specialization from primitive *Lophiodon*-like animals, have been discovered both in North America and in the Old World. One of the most remarkable of these specializations has been the development of dermal horns over the nasal bones, either in laterally placed pairs as in some of the early forms, or in the median line, either single or double. In America they all became extinct before the close of the Pliocene period; but in the Old World, although their geographical distribution has become greatly restricted, at least five well-marked species survive. See Rhinoceros.

Family Macraucheniidæ.

This contains one extinct genus, *Macrauchenia*, with two species *M. patachonica* and *M. boliviensis*, both from South America, and apparently from Pliocene formations. They are very singular and specialized forms, quite out of the line of descent of any of the existing Perissodactyles, and the steps by which they are connected with the rest of the group have not yet been discovered. Of the larger species, *M patachonica*, the skeleton is completely known. It had the full number of forty-four

[1] These dental characters are not strictly applicable to the most ancient forms.

teeth, forming an uninterrupted series. The cervical vertebræ resemble those of the Camels in the position of the vertebrarterial canal, but the ends of the centra are flat, and not opisthocœlous as in the allied forms. In some of the limb characters it resembles

but others have been gradually becoming more specialized and more perfected in structure, and its latest modification, the Cavicorn Ruminants or *Bovidæ* (Antelopes, Sheep, and Oxen), are now the dominating members of the great Ungulate order, widespread in geographical range, rich in generic and specific variation, and numerous in individuals, —forming in all these respects a great contrast to such

are very singular and specialized forms, quite out of the line of descent of any of the existing Perissodactyles, and the steps by which they are connected with the rest of the group have not yet been discovered. Of the larger species, *M patachonica*, the skeleton is completely known. It had the full number of forty-four

[1] These dental characters are not strictly applicable to the most ancient forms.

teeth, forming an uninterrupted series. The cervical vertebræ resemble those of the Camels in the position of the vertebrarterial canal, but the ends of the centra are flat, and not opisthocœlous as in the allied forms. In some of the limb characters it resembles the *Equidæ*, but in the articulation of the fibula with the calcaneum it agrees with the Artiodactyles. The structure of the feet is, however, distinctly Perissodactyle, there being three toes on each.

Families CHALICOTHERIIDÆ *and* MENODONTIDÆ.

These families, with not very distinctly defined boundaries, contain a large number of extinct forms from Eocene and Miocene formations of both the Old and the New World. Among the latter the most remarkable is a group of animals of gigantic size, to the first-known fragment of which the name of *Menodus* was given in 1849 by Pomel, but of which more perfect remains have since been described by Leidy as *Titanotherium* and *Megacerops*, by Marsh as *Brontotherium*, and by Cope as *Symborodon*, some of which appear to represent distinct generic modifications, but the synonymy of the group is at present much confused. The head was large and much elongated, as in the Rhinoceros; but they had a pair of stout diverging osseous protuberances like horn-cores on the maxillaries in front of the orbits. Their molar teeth were of a simple palæotheroid type, and the incisors and canines were very much reduced. Their fore feet had four and their hind feet three short, stout toes. Their remains abound in the Lower Miocene strata of North America.

Family PALÆOTHERIIDÆ.

The structure of the type of this family, *Palæotherium*, was made known by Cuvier, from specimens found in the Paris gypsum beds (Upper Eocene). Fig. 108 gives an idea of its general appearance, not unlike that of a Tapir, which also it resembled in size. It had, however, but three toes on the fore feet. The dentition was $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{3}{3} = 44$. Many species and allied genera (as

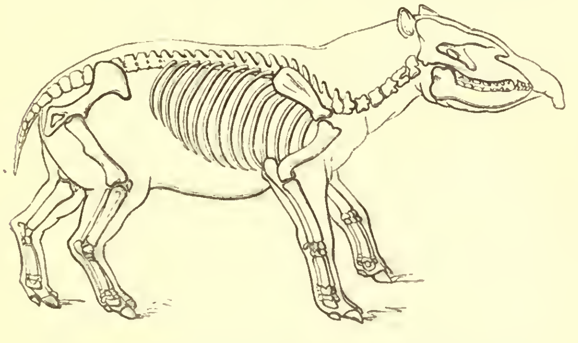

FIG. 108.—Restoration of *Palæotherium* (Upper Eocene). Cuvier.

Palaplotherium, an earlier form from the Middle Eocene, and *Anchitherium*, a later one from the Miocene) have been discovered both in Europe and North America. To some of these the ancestral form of the modern Horses may be traced, the transition from this to the next family being formed by almost imperceptible gradations.

C. EQUINE SECTION.

Lower molars formed of a pair of crescents complicated by the addition of columns or lobes at the inner extremities. Upper molars a modification of the palæotheroid type, but gradually passing as time advanced from the brachyodont to the hypsodont form. Outer digits becoming gradually reduced, until, as in the modern Horses, there is but one (the third) functional digit on each foot. To these alone the family *Equidæ* is restricted by some authors, but in few groups is the artificial nature of the boundaries placed between such divisions so apparent as in the Perissodactyles, for the simple reason that their palæontological history is better known than that of most others, and so many of the intermediate forms have been preserved. For the history, characters, and present distribution of the *Equidæ*, see the article HORSE, vol. xii. p. 172 *sq.*

SUBORDER *ARTIODACTYLA*.

This is an equally well-defined group, traceable from the Early Eocene period, though then apparently by no means so numerous as the Perissodactyles. Some of its types, as that represented in the existing Swine, have retained to the present time much of the primitive character of the group; but others have been gradually becoming more specialized and more perfected in structure, and its latest modification, the Cavicorn Ruminants or *Bovidæ* (Antelopes, Sheep, and Oxen), are now the dominating members of the great Ungulate order, widespread in geographical range, rich in generic and specific variation, and numerous in individuals,—forming in all these respects a great contrast to such decadent types as those represented by the Tapirs and Rhinoceroses.

The principal anatomical characters by which they are distinguished from the Perissodactyles are as follows. The premolar and molar teeth not alike, the former being single and the latter two-lobed. The last lower molar of both first and second dentition almost invariably three-lobed. Nasal bones not expanded posteriorly. No alisphenoid canal. Dorsal and lumbar vertebræ together always nineteen, though the former may vary from twelve to fifteen. Femur without third trochanter. Third and fourth digits of both feet almost equally developed, and their ungual phalanges flattened on their inner or contiguous surfaces, so that each is not symmetrical in itself,

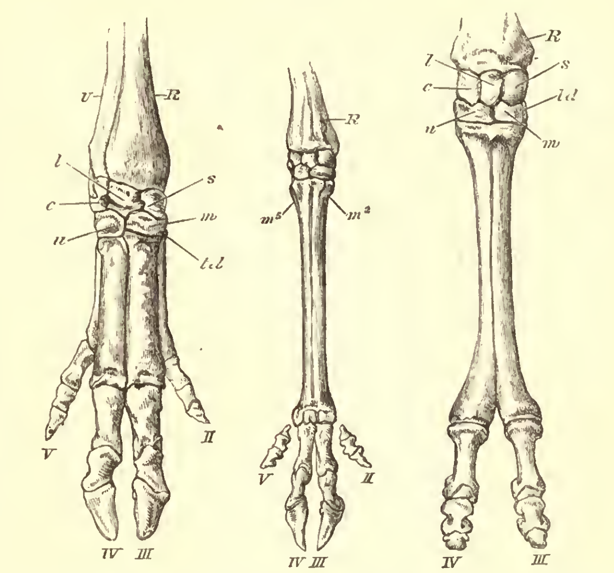

FIG. 109.—Bones of Fore Foot of existing Artiodactyles. A, Pig (*Sus scrofa*). ×⅓; B, Red Deer (*Cervus elaphus*), ×⅓; C, Camel (*Camelus bactrianus*), ×⅕. U, ulna; *R*, radius; *c*, cuneiform; *l*, lunar; *s*, scaphoid; *u*, unciform; *m*, magnum; *td*, trapezoid; *tm*, trapezium. From *Osteology of Mammalia.*

but when the two are placed together they form a figure symmetrically disposed to a line drawn between them. Or, in other words, the axis or median line of the whole foot is a line drawn between the third and fourth digits, while in the Perissodactyles it is a line drawn down the centre of the third digit. Distal articular surface of the astragalus divided into two nearly equal facets, one for the navicular and one for the cuboid bone. The calcaneum with an articular facet for the lower end of the fibula. Stomach almost always more or less complex. Colon convoluted. Cæcum small. Placenta diffused or cotyledonary. Mammæ few and inguinal, or numerous and abdominal.

In treating of many sections of mammals, it is only from the existing species that our characters and classification can be derived, and to these chiefly our observations upon the group must be directed, the extinct forms being so little known that they can only be referred to incidentally. With the *Ungulata*, however, it is quite otherwise. As with the last section, the history of the *Artiodactyla* throughout the Tertiary period is now well known, and throws great light upon the position and relations of the existing groups.

The principal modifications which have taken place in the type from its earliest known and most generalized manifestation have been the following:—

1. As regards the teeth. Assumption of the grinding surfaces of the molar teeth either of a distinctly tubercular (*bunodont*) or of a crescentic ridged (*selenodont*) form. Modification of the latter from

a brachyodont to a hypsodont type. Loss of upper incisors. Development of canines into projecting tusks. Loss of anterior premolars.

2. As regards the limbs. Reduction of the ulna from a complete and distinct bone to a comparatively rudimentary state in which it coalesces more or less firmly with the radius. Reduction of the fibula till nothing but its lower extremity remains. Reduction and final loss of outer pair of digits (second and fifth), with coalescence of the metapodial bones of the two middle digits. Union of the navicular and cuboid, and sometimes the ectocuneiform bone, of the tarsus.

3. Change of form of the odontoid process of the axis from a cone to a hollow half-cylinder.

4. Development of horns or antlers on the frontal bones, and gradual complication of form of antlers.

5. By inference only, increasing complication of stomach with ruminating function superadded. Modification of placenta from simple diffused to cotyledonary form.

The primitive Artiodactyles, with the typical number (44) of incisor, canine, and molar teeth, brachyodont molars, conical odontoid process, four distinct toes on each foot, with metapodium and all carpal bones discrete, no frontal appendages, and (in all probability) simple stomach and diffused placenta, were separated even in the earliest known forms into *Bunodonta* and *Selenodonta.*

A. Bunodonta.

This, the most primitive group, with various offsets which became partially specialized and then extinct, unable apparently to adapt themselves to new conditions, has been continued to the present day with comparatively little change in the section of the suborder called *Suina,* containing the families *Hippopotamidæ* and *Suidæ.* See HIPPOPOTAMUS, PECCARY, and SWINE.

B. Selenodonta.

Members of this group having the complete typical dentition as regards number, but with various modifications in the details of the form of the teeth, and also in the structure of the feet, abounded in the Middle and Upper Eocene and Lower Miocene of Europe and America. One of the earliest known, *Anoplotherium,* was fully described by Cuvier from remains found in the Paris gypsum beds (Upper Eocene). Its teeth formed a series unbroken by a gap or diastema, and were of uniform height (as in Man alone of existing mammals). Its tail was long, with large chevron bones

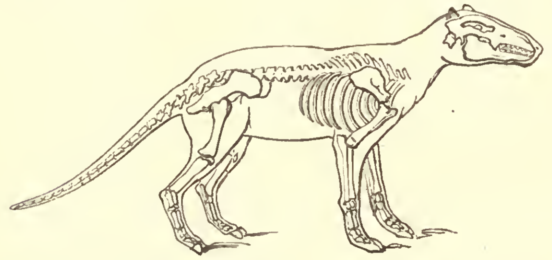

FIG. 110.—Restoration of *Anoplotherium commune* (Upper Eocene). Cuvier.

underneath, not usually found in Ungulates, and there were but two toes on each foot. It was in many respects a much specialized form, apparently not on the line of descent of any of the existing groups. *Chœropotamus, Anthracotherium, Hyopotamus, Xiphodon, Dichodon, Dichobune, Cainotherium,* the American *Oreodon,* and numerous others were forms more or less intermediate in character between the three distinct sections into which, by their extinction, the Selenodont Artiodactyles can now be divided,—the *Tylopoda,* also called *Phalangigrada,* the *Tragulina,* and the *Pecora* or *Cotylophora.*

I. TYLOPODA.

Represented at the present time by the two species of Camels of the Old World and the Llamas of America. For their special distinguishing characters see articles LLAMA and CAMEL.

II. TRAGULINA.

No teeth in premaxillæ. Upper canines well-developed, especially in the males; narrow and pointed. Lower canines incisiform. No caniniform premolars in either jaw. Molariform teeth in a continuous series consisting of $p\ \frac{3}{3}$, $m\ \frac{3}{3}$. Odontoid process of axis conical. Fibula complete. Four complete toes on each foot. The middle metapodials generally confluent, the outer ones (second and fifth) very slender but complete, *i.e.*, extending from the carpus or tarsus to the digits. Navicular, cuboid, and ectocuneiform bones of tarsus united. Tympanic bullæ of skull filled with cancellar tissue. No frontal appendages. Ruminating, but the stomach with only three distinct compartments, the maniplies or third cavity of the stomach of the *Pecora* being rudimentary. Placenta diffused.

This section contains the single family *Tragulidæ,* containing a few animals of small size, commonly known as Chevrotains, intermediate in their structure between the Deer and the Pigs. The large size of the canines of the male and the absence of horns caused them to be associated formerly with *Moschus,* one of the true Deer; hence they are often spoken of as "Pigmy Musk-Deer," although they have no musk-secreting gland, or, except in the above-named trivial external characters, no special affinities with the true Musk. There has scarcely been a more troublesome and obdurate error in zoology than in this association of animals so really distinct. It has been troublesome, not only as preventing a just conception of the relations of existing Artiodactyles, but also in causing great confusion and hindrance in palæontological researches among allied forms; and most obdurate, inasmuch as all that has been recently done in advancing our knowledge of both groups has not succeeded in eradicating it, not only from nearly every one of our zoological text-books, whether British or Continental, but even from works of the highest scientific pretensions.

The family is now generally divided into two genera.

Tragulus, containing the smallest of the existing Ungulates, animals having more of the general aspects and habits of some Rodents, as the Agoutis, than of the rest of their own order. The best-known species are *T. javanicus, T. napu, T. kanchil, T. stanleyanus,* and *T. memmina.* The first four are from the Malay Peninsula, or the islands of the Indo-Malayan Archipelago, the last from Ceylon and Hindustan.

Hyomoschus is distinguished chiefly by the feet being stouter and shorter, the outer toes better developed, and the two middle metacarpals not ankylosed together. Its dental formula (as that of *Tragulus*) is $i\ \frac{0}{3}$, $c\ \frac{1}{1}$, $p\ \frac{3}{3}$, $m\ \frac{3}{3} = 34$. Vertebræ: C 7, D 13, L 6, S 5, C 12–13. The only existing species, *H. aquaticus* (fig. 111), from the west coast of Africa, is rather larger than any of the

FIG. 111.—African Water Chevrotain (*Hyomoschus aquaticus*).

Asiatic Chevrotains, which it otherwise much resembles, but it is said to frequent the banks of streams, and have much the habits of Pigs. It is of a rich brown colour, with back and sides spotted and striped with white. It is evidently the survivor of a very ancient form, as remains of a species only differing in size (*H. crassus*) have been found in Miocene deposits at Sansan, department of Gers, France.

III. PECORA or COTYLOPHORA.

No premaxillary teeth or caniniform premolars. Upper canines generally absent, though sometimes largely developed. Inferior incisors, three on each side with an incisiform canine in contact with them. Molariform teeth consisting of $p\ \frac{3}{3}$, $m\ \frac{3}{3}$, in continuous series. Auditory bullæ simple and hollow within. Odontoid process in the form of a crescent, hollow above. Distal extremity of the fibula represented by a distinct malleolar bone of peculiar shape, articulating with the outer surface of the lower end of the tibia. Third and fourth metacarpals and metatarsals confluent. Outer toes small and rudimentary, or in some cases entirely suppressed; their metapodial bones never complete. Navicular and cuboid bones of tarsus united. Horns or antlers usually present, at least in the male sex. Left brachial artery arising from a common innominate trunk, instead of coming off separately from the aortic arch as in the preceding sections. Stomach with four complete cavities. Placenta cotyledonous.

The Pecora or true Ruminants form at the present time an extremely homogeneous group, one of the best-defined and most closely united of any of the *Mammalia*. But, though the original or common type has never been departed from in essentials, variation has been very active among them within certain limits; and the great difficulty which all zoologists have felt in subdividing them into natural minor groups arises from the fact that the changes in different organs (feet, skull, frontal appendages, teeth, cutaneous glands, &c.) have proceeded with such apparent irregularity and absence of correlation that the different modifications of these parts are most variously combined in different members of the group. It appears, however, extremely probable that they soon branched into two main types, represented in the present day by the *Cervidæ* and the *Bovidæ*,—otherwise the Antlered and Horned Ruminants. Intermediate smaller branches produced the existing Musk-Deer and Giraffe, as well as the extinct *Helladotherium* inclining to the first-named group and the extinct *Sivatherium*, *Brahmatherium*, *Hydaspitherium* and others more allied to the latter, although upon the true relationship of these forms there is a difference of opinion between the two palæontologists who have paid most attention to the group, Rütimeyer and Lydekker, but the materials forthcoming at present are scarcely sufficient for forming a decided opinion.

The earliest forms of true *Pecora*, as *Gelocus* and *Dremotherium* (Miocene), had no frontal appendages, and some few forms (*Moschus* and *Hydropotes*) continue to the present day in a similar case. In the very large majority, however, either in both sexes or in the male only, a pair or occasionally two pairs (*Tetraceros* and the extinct *Sivatherium*) of processes are developed as weapons of offence and defence from the frontal bones, these being almost always formed on one or other of two types.

1. "Antlers" are an outgrowth of true bone, covered during their growth with vascular, sensitive integument coated with short hair. In this state they remain permanently in the Giraffe, but in the true *Cervidæ*, when the growth of the antler is complete, the supply of blood to it ceases, the skin dies and peels off, leaving the bone bare and insensible, and after a time, by a process of absorption near the base it becomes detached from the skull and is "shed." A more or less elongated portion or "pedicle" always remains on the skull, from the summit of which

FIG. 112.—Head of Deer (*Cervus schomburgkii*), showing Antlers. From Sclater, *Proc. Zool. Soc.*, 1877, p. 682.

a new antler is developed. In the greater number of existing species of Deer this process is repeated with great regularity at the same period of each year. The antler may be simple, straight, subcylindrical, tapering and pointed, but more often it sends off one or more branches called "tynes" or "snags." In this case the main stem is termed the "beam." Commonly all the branches of the antler are cylindrical and gradually tapering. Sometimes they are more or less expanded and flattened, the antler being then said to be "palmated." In young animals the antlers are always small and simple, and in those species in which they are variously branched or palmated, this condition is only gradually acquired in several successive annual growths. An interesting parallel has been observed here, as in so many other cases, between the development of the race and that of the individual. The earliest known forms of Deer, those of the Lower Miocene, have no antlers, as in the young of the existing species. The Deer of the Middle Miocene have simple antlers, with not more than two branches, as in existing Deer of the second year. Species occur in the Upper Miocene with three branches to the antlers, but it is not until the Upper Pliocene and Pleistocene times that Deer occur with antlers developed with that luxuriance of growth and beauty of form characteristic of some of the existing species in a perfectly adult state. Among recent *Cervidæ*, antlers are wanting in the genera *Moschus* and *Hydropotes*; they are present in both sexes in *Tarandus* (the Reindeer), and in the male sex only in all others.

2. The "horns" of the *Bovidæ* consist of permanent, conical, usually curved, bony processes, into which air-cells continued from the frontal sinuses often extend, called "horn-cores," ensheathed in a case of true horn, an epidermic development of fibrous structure, which grows continuously, though slowly, from the base, and wears away at the apex, but is very rarely shed entire. The only existing species in which such a process occurs regularly and periodically is

FIG. 113.—Head of Antelope (*Gazella granti*), showing Horns. From Sir V. Brooke, *Proc. Zool. Soc.*, 1878, p. 724.

the American Prong-Buck (*Antilocapra*), in which the horns also differ from those of all others in being bifurcated. Horns are not present at birth, but begin to grow very soon afterwards. The males of all existing *Bovidæ* possess them, and they are also present (though usually not so fully developed) in the females of all except the genera *Portax*, *Tragelaphus*, *Procapra*, *Antilope*, *Æpyceros*, *Saigo*, *Kobus*, *Cervicapra*, *Pelea*, *Nanotragus*, *Neotragus*, and *Tetraceros*.[1]

Another character by which the different members of the *Pecora* can be distinguished is derived from the characters of the molar teeth. Although there is nothing in the general mode and arrangement of the enamel folds, or in the accessory columns, absolutely distinctive between the two principal families, existing species may generally be distinguished inasmuch as the true molars of the *Cervidæ* are "brachyodont," and those of the *Bovidæ* "hypsodont," *i.e.*, the teeth of the former have comparatively short crowns, which, as in most mammals, take their place at once with the neck (or point where the crown and root join) on a level with or a little above the alveolar border, and remain in this

[1] Sir Victor Brooke, *Proc. Zool. Soc.*, 1878, p. 884.

position throughout the animal's life; whereas in the other forms, the crown being lengthened and the root small, the neck does not come up to the alveolar level until a considerable part of the surface has worn away, and the crown of the tooth thus appears for the greater part of the animal's life partially buried in the socket. In this form of tooth (which is almost always most developed in the posterior molars of the permanent series), the constituent columns of the crown are necessarily nearly parallel, whereas in the first-described they diverge from the neck towards the free or grinding surface of the tooth. In the more complete hypsodont form the interstices of the lengthened columnar folds of enamel and dentine are filled up with cementum, which gives stability to the whole organ, and which is entirely or nearly wanting in the short-crowned teeth. The same modification from low to high crowns without essential alteration of pattern is seen in an even still more marked manner in some of the Perissodactyle Ungulates, the tooth of the Horse bearing to that of *Anchitherium* (see HORSE, vol. xii. p. 174) the same relation as that of an Ox does to the early Selenodont Artiodactyles. A parallel modification has been also shown to have taken place in the molar teeth of the *Proboscidea* (see p. 423).

As the hypsodont tooth is essentially a modification of and, as it were, an improvement upon the brachyodont, it is but natural to expect that all intermediate forms may be met with. Even among the Deer themselves, as pointed out by Lartet, the most ancient have very short molars, and the depressions on the grinding surface are so shallow that the bottom is always visible, while in the *Cervidæ* of the more recent Tertiary periods, and especially the Pleistocene and living species, these same cavities are so deep that whatever be the state of the dentition the bottom cannot be seen. Some existing Deer, as the *Axis*, are far more hypsodont than the majority of the family; and, on the other hand, many of the Antelopes (as *Tragelaphus*) retain much of the brachyodont character, which is, however, completely lost in the more modern and highly specialized Sheep and Oxen.

Family CERVIDÆ.

Frontal appendages, when present, in the form of antlers. First molar at least in both jaws brachyodont. Two orifices to the lacrymal duct, situated on or inside the rim of the orbit. An antorbital vacuity of such dimensions as to exclude the lacrymal bone from articulation with the nasal. Upper canines usually present in both sexes, and sometimes attaining a very great size in the male (see fig. 114). Lateral digits of both fore and hind feet almost

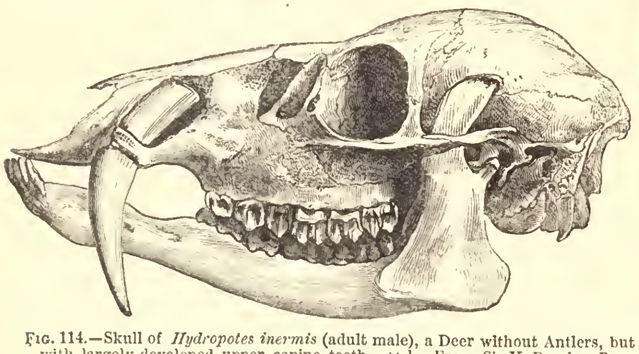

FIG. 114.—Skull of *Hydropotes inermis* (adult male), a Deer without Antlers, but with largely-developed upper canine teeth. × ½. From Sir V. Brooke, *Proc. Zool. Soc.*, 1872, p. 524.

always present, and frequently the distal ends of the metapodals. Placenta with few cotyledons. Gall-bladder absent (except in *Moschus*). This family contains numerous species, having a wide geographical distribution, ranging in the New World from the Arctic Circle as far south as Chili, and in the Old World throughout the whole of Europe and Asia, but absent in the Ethiopian and Australian regions. For the characters of the generic subdivisions and their distribution, see STAG, also DEER, MUNTJAC, and MUSK-DEER.

Family CAMELOPARDALIDÆ.

Frontal appendages consisting of a pair of short, erect, permanent bony processes, ossified from distinct centres, and for a time suturally connected with the frontals, though afterwards ankylosed to them, covered externally with a hairy skin, present in both sexes, and even in the new-born animal. Anterior to these is a median protuberance on the frontal and contiguous parts of the nasal bones, which increases with age, and is sometimes spoken of as a third horn. No upper canines. Molars brachyodont. Lateral digits entirely absent on both fore and hind feet, even the hoofs not developed.

This family contains but a single species, the well-known and very remarkable animal the Giraffe, or Camelopard (*Camelopardalis giraffa*). See GIRAFFE.

Family BOVIDÆ.

Frontal appendages when present in the form of horns. Molars usually hypsodont. Usually only one orifice to the lacrymal canal, situated inside the rim of the orbit. Lacrymal bone almost always articulating with the nasal. Canines absent in both sexes. The lateral toes may be completely absent, but more often they are represented by the hoofs alone, supported sometimes by a very rudimentary skeleton, consisting of mere irregular nodules of bone. Distal ends of the lateral metapodals never present. Gall-bladder almost always present. Placenta with many cotyledons.

The *Bovidæ*, or hollow-horned Ruminants (*Cavicornia*), form a most extensive family, with members widely distributed throughout the Old World, with the exception of the Australian region; but in America they are less numerous, and confined to the Arctic and northern temperate regions, no species being indigenous either to South or Central America. There is scarcely any natural and well-defined group in the whole class which presents greater difficulties of subdivision than this; consequently zoologists are as yet very little agreed as to the extent and boundaries of the genera into which it should be divided. The principal species will be found more particularly described under the headings ANTELOPE, BISON, BUFFALO, CATTLE, CHAMOIS, ELAND, GNU, GOAT, HARTEBEEST, IBEX, MUSK-OX, NYLGHAU, OX, SAIGA, and SHEEP.

GROUP TILLODONTIA.

Here may be noticed a remarkable group of animals, called by Marsh *Tillodontia*, the remains of which are found abundantly in the Lower and Middle Eocene beds of North America. They seem to combine the characters of the *Ungulata*, *Rodentia*, and *Carnivora*. In the genus *Tillotherium* of Marsh (probably identical with the previously described *Anchippodus* of Leidy) the skull resembled

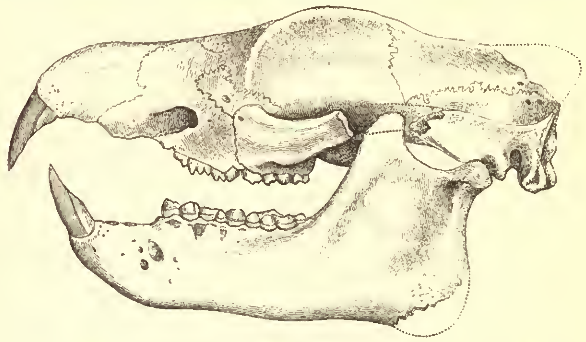

FIG. 115.—Skull of *Tillotherium fodiens*. ¼ nat. size. From Marsh.

that of the Bears, but the molar teeth were of the Ungulate type, while the large incisors were very similar to those of the Rodents. The skeleton resembled that of the Carnivores, but the scaphoid and lunar bones were distinct, and there was a third trochanter on the femur. The feet were plantigrade, and each had five digits, all with long pointed claws. In the allied genus *Stylinodon* all the teeth were rootless. Some were as large as a Tapir.

These, with other similar animals, constituting a group called *Tæniodonta*, are included by Cope in his large order *Bunotheria*, to which also the existing *Insectivora* are referred. The constantly increasing knowledge of these annectant forms adds to the difficulty so often referred to in this article of establishing anything like a definite classification of the heterodont mammals.

ORDER CARNIVORA.

Though the *Carnivora* as at present restricted[1] form a very natural and well-defined order among the *Mammalia*, it is difficult to find any important common diagnostic characters by which they can be absolutely separated; but, as in the case of so many other natural groups, it is by the possession of a combination of various characters that

[1] The *Feræ* of Linnæus included all the then known species of the modern orders *Carnivora*, *Insectivora*, and *Marsupialia*.

they must be distinguished. They are unguiculate, and have never less than four well-developed toes on each foot, with nails more or less pointed, rarely rudimentary or absent. The pollex and hallux are never opposable to the other digits. They are regularly diphyodont and heterodont, and their teeth are always rooted.[1] Their dentition consists of small pointed incisors, usually three in number, on each side of each jaw, of which the first is always the smallest and the third the largest, the difference being most marked in the upper jaw; strong conical, pointed, recurved canines; molars variable, but generally, especially in the anterior part of the series, more or less compressed, pointed, and trenchant; if the crowns are flat and tuberculated they are never complex or divided into lobes by deep inflexions of enamel. The condyle of the lower jaw is a transversely placed half-cylinder working in a deep glenoid fossa of corresponding form. The brain varies much in relative size and form, but the hemispheres are never destitute of well-marked convolutions. The stomach is always simple and pyriform. The cæcum is either absent or short and simple, and the colon is not sacculated or greatly wider than the small intestine. Vesiculæ seminales are never present. Cowper's glands are present in some, absent in other groups. The uterus is bicornuate. The mammæ are abdominal, and very variable in number. The placenta is deciduate, and almost always zonary. The clavicle is often entirely absent, and when present is never complete. The radius and ulna are distinct. The scaphoid and lunar bones are always united into one, and there is never a distinct os centrale in the adult. The fibula is always a distinct slender bone.

The large majority of the species composing this order subsist chiefly upon some variety of animal food, though many are omnivorous, and some few chiefly, though not entirely, vegetable eaters. The more typical forms live altogether on recently-killed warm-blooded animals, and their whole organization is thoroughly adapted to a predaceous mode of life. In conformity with this manner of obtaining their subsistence they are generally bold and savage in disposition, though some species are capable of being domesticated, and when placed under favourable circumstances for the development of such qualities exhibit a very high degree of intelligence and fidelity. The order is naturally divided into two suborders, the members of one being the more typical, and mainly terrestrial in their mode of life, while those of the other are aberrant, having the whole of their organization specially modified for living habitually in water. These are called respectively the True or Fissiped and the Pinniped *Carnivora*.

SUBORDER *CARNIVORA VERA* OR *FISSIPEDIA*.

Generally adapted for terrestrial progression and mode of life, though some may be partially aquatic in their habits. The fore limbs never have the first digit, or the hind limbs the first and fifth digits, longer than the others. Incisors $\frac{3}{3}$ on each side, with very rare exceptions. Cerebral hemispheres more or less elongated; always with three or four gyri on the outer surface forming arches above each other, the lowest surrounding the Sylvian fissure. The molar series of teeth have not the uniform characters of those of the *Pinnipedia*. There is always one tooth in each jaw which is specially modified, and to which the name of "sectorial" or "carnassial" tooth has been applied. The teeth in front of this are more or less sharp-pointed and compressed; the teeth behind it are broad and tuberculated. The characters of the sectorial teeth deserve special attention, as, though fundamentally the same throughout the suborder, they are greatly modified in different genera. The upper sectorial is the most posterior of the teeth which have predecessors, and is therefore reckoned as the last premolar ($\overline{p\ 4}$ of the typical dentition). It consists essentially of a more or less compressed

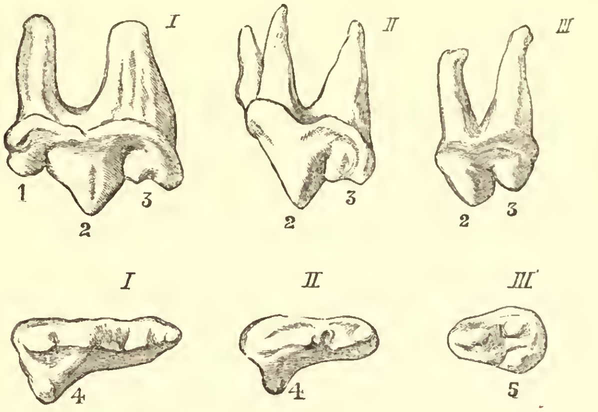

FIG. 116.—Upper Sectorial Teeth of *Carnivora*. I, *Felis*; II, *Canis*; III, *Ursus*. 1, anterior, 2, middle, and 3, posterior cusp of blade; 4, inner lobe supported on distinct root; 5, inner lobe, posterior in position, and without distinct root, characteristic of the *Ursidæ*.

blade supported on two roots and an inner lobe supported by a distinct root (see fig. 116). The blade when fully developed has three cusps (1, 2, and 3), but the anterior is always small, and often absent. The middle lobe is conical, high, and pointed; the posterior lobe has a compressed straight knife-like edge. The inner lobe (4) varies very much in extent, but it is generally placed near the anterior end of the blade, though sometimes it is median in position.

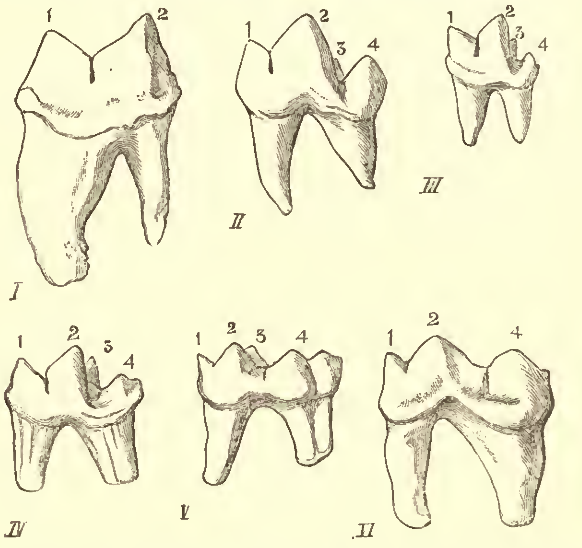

FIG. 117.—Modifications of the Lower Sectorial Tooth in *Carnivora*. I, *Felis*; II, *Canis*; III, *Herpestes*; IV, *Lutra*; V, *Meles*; VI, *Ursus*. 1, anterior lobe of blade; 2, posterior lobe of blade; 3, inner tubercle; 4, heel. It will be seen that the relative size of the two roots varies according to the development of the portion of the crown they have respectively to support.

In the *Ursidæ* alone both inner lobe and root are wanting, and there is often a small internal and posterior cusp (5) without root. In this aberrant family also the sectorial is relatively to the other teeth much smaller than in the rest of the *Carnivora*. The lower sectorial (see fig. 117) is the most anterior of the teeth without predecessors in the milk series; it is therefore reckoned the first true molar ($\underline{m\ 1}$). It has two roots supporting a crown, consisting when fully developed of a compressed bilobed blade (1 and 2), a heel (4), and an inner tubercle (3). The lobes of the blade, of which the hinder (2) is the larger, are separated by a notch,

[1] The tusks of the Walrus, altogether so aberrant in its dentition, are partial exceptions to this statement, but in old individuals the pulp cavity fills up, and they cease to grow.

generally prolonged into a linear fissure. In the most specialized *Carnivora*, as the *Felidæ* (I.), the blade alone is developed, both heel and inner tubercle being absent or rudimentary. In others, as *Meles* (V.) and *Ursus* (VI.), the heel is greatly developed, broad, and tuberculated. The blade in these cases is generally placed obliquely, its flat or convex (outer) side looking forwards, so that the two lobes are almost side by side, instead of anterior and posterior. The inner tubercle (3) is generally a conical pointed cusp, placed to the inner side of the hinder lobe of the blade. The special characters of these teeth are more disguised in the Sea Otter (*Enhydra*) than in any other form, but even in it they can be traced.

The toes are nearly always armed with large, strong, curved, and tolerably sharp claws, ensheathing the ungual phalanges, and held more firmly in their places by broad laminæ of bone reflected over their attached ends from the bases of the phalanges. In some forms, most notably the *Felidæ*, these claws are "retractile." The ungual phalanx, with the claw attached, folds back in the fore foot into a sheath by the outer or ulnar side of the middle phalanx of the digit, being retained in this position when the animal is at rest by a strong elastic ligament. In the hind foot the ungual phalanx is retracted on to the top, and not the side of the middle phalanx. By the action of the deep flexor muscles, the ungual phalanges are straightened out, the claws protruded from their sheath, and the soft "velvety" paw becomes suddenly converted into a most formidable weapon of offence. The habitual retraction of the claws preserves their points from wear in ordinary progression.

The Fissipedal *Carnivora* were divided by Cuvier into two groups, according to the position of the feet in walking,—the *Plantigrada*, or those that place the whole of the soles to the ground, and the *Digitigrada*, or those that walk only on the toes; and the difference between these groups was considered of equal importance to that which separated from them both the *Pinnigrada* or Seals. The distinction is, however, quite an artificial one, and every intermediate condition exists between the extreme typical plantigrade gait of the Bears and the truly digitigrade walk of the Cats and Dogs; in fact, the greater number of the *Carnivora* belong to neither one form nor the other, but may be called "subplantigrade," often when at rest applying the whole of the sole to the ground, but keeping the heel raised to a greater or less extent when walking.

A more natural classification is into three distinct sections, of which the Cats, the Dogs, and the Bears may be respectively taken as representatives, and which are hence called *Æluroidea*, *Cynoidea*, and *Arctoidea*. This division is founded mainly on characters exhibited by the base of the skull, but is corroborated by the structure of other parts.[1] The presence or absence of a bridge of bone, covering the external carotid artery in a part of its course by the side of the alisphenoid bone, and enclosing the "alisphenoid canal," a character to which the late Mr H. N. Turner first drew attention, might seem unimportant at first sight, but it is curiously constant in certain groups, which we have other reasons, derived often from a combination of less easily definable characters, to regard as natural. It is therefore generally mentioned in the following family definitions.

Section ÆLUROIDEA.

The *Æluroidea* or Cat-like forms include the *Felidæ*, *Viverridæ*, *Protelidæ*, and *Hyænidæ*.

[1] See W. H. Flower, "On the Value of the Characters of the Base of the Cranium in the Classification of the order *Carnivora*," *Proc. Zool. Soc.*, 1869, p. 4; St George Mivart, "On the Classification and Distribution of the *Æluroidea*," *ibid.*, 1882, p. 135; and Id., *The Cat, an Introduction to the Study of Backboned Animals, especially Mammals*, 1881.

Family FELIDÆ.

True molars reduced to one above and below, that of the upper jaw very small and transversely extended. Only two inferior premolars. Auditory bulla not externally constricted, but internally divided by a septum. No alisphenoid canal. Carotid canal very minute. Digits 5–4. Dorsal vertebræ 13.

Felis.—The whole structure of the animals of this genus exhibits the carnivorous type in its fullest perfection. Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{3}{2}$, $m\ \frac{1}{1} = \frac{8}{7}$; total 30. The upper anterior premolar, always small, may sometimes be absent without any other modification in the dental or other structures. Such a variation should not therefore be considered as of generic importance. Incisors very small. Canines large, strong, slightly recurved, with trenchant edges and sharp points, and placed wide apart. Premolars compressed and sharp-pointed. The most posterior in the upper jaw (the sectorial) a very large tooth, consisting of a subcompressed blade, divided into three unequal cusps supported by two roots, with a very small inner lobe placed near the front end of the tooth and supported by a distinct root. The upper true molar a very small tubercular tooth placed more or less transversely at the inner side of the hinder end of the last. In the lower jaw the true molar (sectorial) reduced to the blade alone, which is very large, trenchant, and much compressed, divided into two subequal lobes. Occasionally it has a rudimentary heel, but never an inner tubercle. The skull generally is short and rounded, though proportionally more elongated in the larger forms. The facial portion is especially short and broad, and the zygomatic arches very wide and strong. The auditory bullæ are large, rounded, and smooth. Vertebræ: C 7, D 13, L 7, S 3, C 13–29. Clavicles better developed than in other *Carnivora*, but not articulating with either the shoulder bones or sternum. Limbs digitigrade. Anterior feet with five toes, the third and fourth nearly equal and longest, the second slightly and the fifth considerably shorter; the pollex still shorter, not reaching as far as the metacarpo-phalangeal articulation of the second. Hind feet with only four toes. The third and fourth the longest, the second and fifth somewhat shorter and nearly equal; the hallux represented only by the rudimentary metatarsal bone. The claws all very large, strongly curved, compressed, very sharp, and exhibiting the retractile condition in the highest degree. The tail varies greatly in length, being in some a mere stump, in others nearly as long as the body. Ears of moderate size, more or less triangular and pointed. Eyes rather large. Iris very mobile, and with a pupillary aperture which contracts under the influence of light in some species to a narrow vertical slit, in others to an oval, and in some to a circular aperture. Tongue thickly covered with sharp-pointed, recurved horny papillæ. Cæcum small and simple.

As in structure so in habits, the Cats may be considered the most specialized of all the *Carnivora*. All the known members of the genus feed, in the natural state, almost exclusively on warm-blooded animals which they have themselves killed. One Indian species (*F. viverrina*) is said to prey on fish and even freshwater molluscs. Unlike the Dogs, they never associate in packs, and rarely hunt their prey in open ground, but from some place of concealment wait until the unsuspecting victim comes within reach, or with noiseless and stealthy tread, crouching close to the ground for concealment, approach near enough to make the fatal spring. In this manner they frequently attack and kill animals considerably exceeding their own size. They are mostly nocturnal, and the greater number, especially the smaller species, more or less arboreal. None are aquatic, and all take to the water with reluctance, though some may habitually haunt the banks of rivers or pools, because they more easily obtain their prey in such situations. The numerous species of the genus are very widely diffused over the greater part of the habitable world, though most abundant in the warm latitudes of both hemispheres. No species are, however, found in the Australian region, or in Madagascar. Although the Old-World and New-World Cats (except perhaps the Northern Lynx) are all specifically distinct, no common structural character has been pointed out by which the former can be separated from the latter. On the contrary, most of the minor groups into which the genus has been divided have representatives in both hemispheres.

Notwithstanding the considerable diversity in external appearance and size between different members of this extensive genus, the structural differences are but slight, and so variously combined in different species that the numerous attempts hitherto made to subdivide it are all unsatisfactory and artificial. The principal differences are to be found in the form of the cranium, especially of the nasal and adjoining bones, the completeness of the bony orbit posteriorly, the development of the first upper premolar and of the inner lobe of the upper sectorial, the length of the tail, the form of the pupil, and the condition and coloration of the fur, especially the presence or absence of tufts or pencils of hair on the external ears. There is one decidedly aberrant form, which enables us to divide the genus into two sections, to which the rank of genera is sometimes accorded.

1. *Felis* proper.—A distinctly cusped inner lobe to the upper sectorial tooth. Claws completely retractile. There are about

fifty species, of which the following are the most important and best known.

A. *Old-World Species.*

For *F. leo*, see LION; and for *F. tigris*, see TIGER. With regard to *F. pardus*, the Leopard or Panther, it is still a matter of uncertainty whether the large spotted Cats to which these names are given, found chiefly in wooded districts through nearly the whole of Africa and the warmer parts of Asia as far as Japan, belong to one or several species. See LEOPARD. *F. uncia*, the Ounce, inhabits the highlands of Central Asia, from the snowy mountains of Tibet to the southern parts of Siberia, at altitudes of from 9000 to 18,000 feet above the sea. It is about the size of the common Leopard, but lighter in colour, with longer fur and less distinct spots. Its skull differs in shape from that of all the other *Felidæ*, the facial portion being very broad, the nasal bones especially being wide and depressed, and the zygomatic arches very strong and deep. *F. macroclis*, the Clouded Tiger, is a beautifully marked species, with elongated head and body, long tail, and rather short limbs. The canine teeth are proportionally longer than in any existing member of the genus. It is thoroughly arboreal, and is found in the forests of south-east Asia and the islands of Sumatra, Java, Borneo, and Formosa. *F. serval*, the Serval, from South Africa, is yellow with black spots, and has a short tail and large ears. Numerous smaller species called Tiger Cats and Wild Cats, many of them by no means clearly defined zoologically, are found throughout the warmer parts of Asia and Africa. The Wild Cat of Europe, *F. catus*, still inhabits the mountainous and wooded parts of Great Britain. The Domestic Cat is an introduced species, and generally supposed to be derived from *F. maniculata* of Egypt and Syria. Moderate-sized Cats, with short tails, rather long limbs, especially the hinder ones, and tufts or pencils of hair on their ears, are called Lynxes. See LYNX.

B. *New-World Species.*

F. concolor, the Puma or Couguar, commonly called "Panther" in the United States, is about the size of a Leopard, but of an uniform brown colour, spotted only when young, and is extensively distributed in both North and South America, ranging between the parallels of 60° N. and 50° S. *F. onca*, the Jaguar, is a larger and more powerful animal than the last, and more resembles the Leopard in its colours. It also is found in both North and South America, but with less extensive range, reaching northwards only as far as Texas, and southwards nearly to Patagonia. See JAGUAR. *F. pardalis*, and several allied smaller elegantly-spotted species inhabiting the intratropical regions of America, are commonly confounded under the name of Ocelot or Tiger Cat. *F. yaguarundi*, rather larger than the Domestic Cat, with an elongated head and body, and of a uniform brownish-grey colour, ranges from Matamoras to Paraguay. *F. eyra* is a small Cat, very Musteline in form, having an elongated head, body, and tail, and short limbs, and is also of a uniform light reddish-brown colour. It is a native of South America and Mexico. *F. pajeros* is the Pampas Cat. Four species of Lynx are described from North America, but it is doubtful whether these are specifically distinct from each other and from the Lynx of northern Europe.

2. *Cynælurus.*—Sometimes considered as a distinct genus. The Cheetah or Hunting Leopard, *F. jubata*, is distinguished from the other *Felidæ* by the inner lobe of the upper sectorial, though supported by a distinct root, having no salient cusp upon it, by the tubercular molar being more in a line with the other teeth, and by the claws being smaller, less curved, and less completely retractile, owing to the feebler development of the elastic ligaments. The skull is short and high, with the frontal region broad and elevated in consequence of the large development of the frontal air-sinuses. The head is small and round, the body light, the limbs and tail long. Its colour is pale yellowish-brown with small black spots. The Cheetah is less savage and more easily tamed than most of the Cats. In Asia it has been trained for the chase of the Antelope. It has rather an extensive geographical range from the Cape of Good Hope, throughout Africa and the south-western parts of Asia, as far as southern India.

Fossil Felidæ.—Numerous extinct species of the genus are found in Pleistocene, Pliocene, and even later Miocene deposits in Europe, Asia, and America. Among them is the Cave Lion, *F. spelæa*, which can scarcely be separated specifically from *F. leo*, and of which abundant remains are found in caves in England and other parts of Europe. *F. cristata*, from the Siwalik Hills, intermediate in size between a Tiger and Jaguar, is distinguished from the other *Felidæ* by the shortness of the face as compared with the cranial part of the skull. These and many others, mostly of smaller size, present no greater modifications of form than the various existing members of the genus *Felis*, and can therefore be properly included within its limits; but numerous other forms are gradually becoming known, especially through the researches of American palæontologists, which, though evidently animals of the same general type and therefore to be included in the family *Felidæ*, depart so much in various details of structure that they must be placed in different genera. As one of the points in which *Felis* manifests its specialization is the reduction of the number of the molar series of teeth, with concomitant shortening of the jaws, it might be supposed that in the earlier and perhaps ancestral forms these teeth would be more numerous and approach more nearly to the primitive or typical number of the heterodont mammals, viz., seven on each side. This is actually the case. One European form (also recently found in America) to which Gervais has given the name of *Pseudælurus*, of Miocene age, has the dentition of *Felis* with an addition of one premolar in the lower jaw; but others have a still larger number, as *Archælurus debilis* of Cope from the American Miocene, about the size of a Panther, which has four premolars and a tubercular molar in the upper jaw, and three premolars and two molars in the lower jaw. A tubercular molar in the lower jaw, behind the sectorial, also occurs in *Ælurogale*, *Dinictis*, and *Nimravus*. Another tendency to generalization is the existence in some forms, as *Hoplophoneus*, of a posterior lobe or heel to the inferior sectorial, found in nearly all Carnivores except the existing *Felidæ*. On the other hand some of the extinct *Felidæ* show a most remarkable tendency towards a specialization not occurring in any of the surviving members of the family, viz., an enormous development of the upper canines, with which is usually associated an expansion downwards and flattening of the anterior part of the ramus of the lower jaw, on the outer side of which the canine lies, when the mouth is closed. In *Smilodon nœogeus*, the Sabre-toothed Tiger, from the caves of Brazil and also from Pleistocene deposits near Buenos Ayres, an animal about the size of a Tiger, these teeth are 7 inches in length, greatly compressed, and finely serrated on the trenchant anterior edges. Similar serrations are seen on a much fainter scale in the unworn teeth of modern Tigers. Many modifications of this commonly-called "machærodont" type have been met with both in the Old and New World to which the names of *Machærodus*, *Drepanodon*, *Smilodon*, *Hoplophoneus*, *Dinictis*, *Pogonodon*, &c., have been given. A very remarkable form, *Eusmilus*, differs from all other known Felines in having only four incisors in the lower jaw, and a pair of small canines separated by a very long diastema from the next teeth, which consist only of one premolar and one sectorial true molar. The lower jaw is enormously expanded towards the symphysis to protect the large upper canines. This animal then, although of Eocene age, appears to form the culminating development of the sabre-toothed or machærodont dentition, the most specially carnivorous type of structure known.

Cope divides all the known Feline animals into two families, *Felidæ* and *Nimravidæ*,[1] distinguished by the characters of the foramina at the base of the cranium, the former being of more modern origin than the latter, the members of which are all extinct, and which seem to connect the Cats with still more primitive types of *Carnivora*.

Family VIVERRIDÆ.

Premolars $\frac{3}{3}$ or $\frac{4}{4}$. Molars $\frac{1}{1}$ or $\frac{2}{2}$. Auditory bulla externally constricted, and divided by a septum. An alisphenoid canal (with very rare exceptions). Carotid canal distinct as a groove on the side of the bulla. Digits usually 5–5, but sometimes the pollex or hallux or both may be wanting. Dorsal vertebræ 13 or 14. Limited in distribution to the Old World.

The subfamily **Cryptoproctinæ** contains the single genus *Cryptoprocta*. Dentition: $i\ \frac{3}{3},\ c\ \frac{1}{1},\ p\ \frac{4}{4},\ m\ \frac{1}{1} = \frac{9}{9}$; total 36. The teeth generally closely resemble those of the *Felidæ*. The first premolar of both jaws is very minute and early deciduous. The upper sectorial has a very small inner lobe, quite at the anterior part of the tooth. The true molar is very small and placed transversely. The lower sectorial has a large trenchant bilobed blade, and a very minute heel, but no inner tubercle. Skull generally like that of *Felis*, but proportionately longer and narrower. Orbit widely open behind. Vertebræ: C 7, D 13, L 7, S 3, C 29. Body elongated. Limbs moderate in size. Feet subplantigrade; five well-developed toes on each, with sharp, compressed, retractile claws. Ears moderate. Tail long and cylindrical.

The only known species, *C. ferox*, the "Foussa" of the Malagasy, is peculiar to Madagascar, being the largest carnivorous animal in the island. It is about twice the size of the common Cat (5 feet from nose to end of tail), with short close fur of nearly uniform pale brown. Little is as yet known of its habits, except that it is nocturnal, frequently attacks and carries off goats, and especially kids, and shows great ferocity when wounded, on which account it is much dreaded by the natives.

The remaining numerous specific and generic modifications found in the existing animals belonging to this family seem to group themselves mainly into two tolerably distinct groups, distinguishable by the characters of the auditory bulla and neighbouring parts of the base of the skull, and by the structure of the feet. The one form has the genus *Viverra* or Civet Cats for its most typical representative, and the other *Herpestes* or the Ichneumons.

Subfamily **Viverrinæ**.—Auditory bulla oval or rather conical, broad and truncated and not everted behind, narrow in front and

[1] "On the Extinct Cats of America," *American Naturalist*, December 1880.

more or less compressed at the sides. The outer or anterior chamber very small and flat. The meatus with scarcely any inferior lip, its orifice being close to the tympanic ring. Paroccipital process triangular, its apex projecting slightly beyond the bulla. Claws strongly curved and more or less retractile.

Viverra.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{2}{2} = \frac{10}{10}$; total 40. Skull elongated; facial portion small and compressed. Orbits well-defined but incomplete behind. Vertebræ: C 7, D 13, L 7 (or D 14, L 6), S 3, C 22–30. Body elongated and compressed. Head pointed in front; ears rather small. Extremities short. Feet small and rounded. Toes short, five on each foot. First toe both on fore and hind feet much shorter than the others. Palms and soles covered with hair, except the pads of the feet and toes, and in some species a narrow central line on the under side of the sole, extending backwards nearly to the heel. Tail moderate or long. A pair of large glandular follicles situated on the perineum (in both sexes), and secreting in most species an oily substance of a peculiarly penetrating odour.

The numerous species of this genus form a large series, the two extremes of which differ considerably, but the several sections into which they may be divided blend so into one another that it is difficult to differentiate them sharply. (1) *Viverra* proper. This includes the largest species. The teeth are stouter and less compressed than in the other sections. The second upper molar especially larger. The auditory bulla smaller and more pointed in front. Body shorter and stouter; limbs longer; tail shorter, tapering. Under side of tarsus completely covered with hair. Claws longer and less retractile. Fur rather long and loose, and in the middle line of the neck and back especially elongated so as to form a sort of crest or mane. Pupil circular when contracted. Perineal glands greatly developed. These characters apply especially to *V. civetta*, the African Civet, or "Civet Cat" as it is commonly called, an animal rather larger than a common Fox, and an inhabitant of intratropical Africa. *V. zibetta*, the Indian Civet, of about equal size, approaches in many respects, especially in the characters of the teeth and feet and absence of the crest of elongated hair on the back, to the next section. It inhabits Bengal, China, the Malay Peninsula, and adjoining islands. *V. tangalunga* is a smaller but nearly allied animal from the same part of the world. From these three species and the next the civet of commerce, once so much admired as a perfume in England, and still largely used in the East, is obtained. The animals are kept in cages, and the odoriferous secretion collected by scraping the interior of the perineal follicles with a spoon or spatula. (2) *Viverricula.* This section resembles generally the next, but with the whole of the under side of the tarsus hairy. Alisphenoid canal generally absent. *V. malaccensis*, the Rasse, inhabiting India, China, Java, and Sumatra, is an elegant little animal, which affords a favourite perfume to the Javanese. (3) *Genetta.* The Genettes are smaller animals, with more elongated and slender bodies, and shorter limbs than the Civets. Skull elongated and narrow. Auditory bulla large, elongated, rounded at both ends. Teeth compressed and sharp-pointed; a lobe on the inner side of the third upper premolar not present in the previous section. Pupil contracting to a linear aperture. Tail long, slender, ringed. Fur short and soft, spotted or cloudy. Under side of the tarso-metatarsus with a narrow longitudinal bald streak. *V. genetta*, the common Genette, is found in France south of the river Loire, Spain, south-western Asia, and Africa from Barbary to the Cape. *V. felina*, *senegalensis*, *tigrina*, and *pardalis* are other named species, all African in habitat. (4) *Fossa.* *V. fossa*, from Madagascar, may belong to a distinct section or genus, but its structure is very imperfectly known. (5) In some of the smallest species the second upper molar (already reduced to very small dimensions in the Genettes) is absent; in other respects their dentition agrees with section 3. *V. gracilis* and *V. pardicolor*, both from southern Asia, constitute the genus *Prionodon* of Horsfield; *V. richardsonii*, from West Africa, the genus *Poiana* of Gray. The former has the back of the tarsus hairy, the latter has a narrow naked streak as in the Genettes.

All the animals of this genus are, for their size, extremely active, fierce, and rapacious. They feed chiefly on small mammals and birds.

Arctictis.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{2}{2} = \frac{10}{10}$; total 40. The posterior upper molar and the first lower premolar very often absent. Molar teeth generally small and rounded, with a distinct interval between every two, but formed generally on the same pattern as *Parodoxurus.* Vertebræ: C 7, D 14, L 5, S 3, C 34. Body elongated. Head broad behind, with a small pointed face. Whiskers long and numerous. Ears small, rounded, but clothed with a pencil of long hairs. Eyes small. Limbs short. Soles and palms broad, entirely naked. Tail very long and prehensile. Fur long and harsh. Cæcum extremely small. But one species is known, *A. binturong*, the Binturong, an inhabitant of southern Asia from Nepal through the Malay Peninsula to the islands of Sumatra and Java. Although structurally agreeing closely with the Paradoxures, its tufted ears, long, coarse, and dark hair, and prehensile tail give it a very different external appearance. It is slow and cautious in its movements, chiefly if not entirely arboreal, and appears to feed on vegetable as well as animal substances.

Paradoxurus.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{2}{2} = \frac{10}{10}$; total 40. The blunt and rounded form of the cusps of the hinder premolar and the molar teeth distinguishes this genus from most of the members of the family. Vertebræ: C 7, D 13, L 7, S 3, C 29–36. Head pointed in front. Ears small, rounded. Body long. Limbs moderate. Palms and soles almost entirely naked. Claws completely retractile. Tail long, non-prehensile. The Paradoxures or Palm-Civets are less strictly carnivorous than the other members of the family. They are mostly about the size of the common Cat, or rather larger, and are partly arboreal in their habits. The species are rather numerous, and present considerable variations in the details of the form and size of their molar teeth. They are restricted geographically to southern Asia and the Indo-Malayan archipelago. The best known species are *P. bondar*, *P. zeylanicus*, *P. typus*, *P. musanga*, *P. larvata*, and *P. grayi*. *P. virgata* has been separated from the others, and raised into a distinct genus, *Arctogale*, on account of the smallness of the teeth and the elongation of the bony palate. Otherwise it seems not to differ from the others.

Nandinia contains one species, *N. binotata*, a somewhat aberrant Paradoxure, from West Africa. It is rather smaller than the true Paradoxures, has smaller and more pointed molar teeth, and no cæcum. The wall of the inner chamber of the auditory bulla remains through life unossified.

Hemigalea, another modification of the Paradoxure type, contains one species, *H. hardwickii*, from Borneo, an elegant-looking animal, smaller and more slender than the Paradoxures, of light grey colour, with transverse broad dark bands across the back and loins.

Cynogale also contains one species, *C. bennettii*, Gray (described by S. Müller under the name of *Potamophilus barbatus*), from Borneo. This is a curious Otter-like modification of the Viverrine type, having semi-aquatic habits, both swimming in the water and climbing trees, living upon fish, crustacea, small mammals, birds, and fruit. The number and general arrangement of its teeth are as in *Paradoxurus*, but the premolars are peculiarly elongated, compressed, pointed, and recurved, somewhat as in the Seals, though the molars are tuberculated. The head is elongated, the muzzle broad and depressed. Whiskers very long and abundant. Ears small and rounded. Toes short and slightly webbed at the base. Tail short, cylindrical, covered with short hair. Fur very dense and soft, of a dark brown colour, mixed with black and grey.

Subfamily **Herpestinæ.**—Auditory bulla very prominent, and somewhat pear-shaped, the posterior chamber being large, rounded, and generally with its greatest prominence to the outer side. The anterior chamber considerably dilated, and produced into a short inferior wall to the auditory meatus, in which is a depression or vacuity just below the centre of the opening of the meatus. Sometimes this vacuity is continued into the meatus, forming a narrow fissure. The paroccipital process does not project beyond the bulla, but is spread out and lost (in adult animals) on its posterior surface. Toes straight; claws lengthened, exserted, non-retractile.

Herpestes.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, sometimes $\frac{3}{3}$, $m\ \frac{2}{2}$; 40 or 36. Teeth of molar series generally with strongly-developed, sharply-pointed cusps. Skull elongated, constricted behind the orbits. Face short and compressed. Frontal region broad and arched. Post-orbital processes of frontal and malar bones well-developed, generally meeting so as to complete the circle of the orbit behind. Vertebræ: C 7, D 13, L 7, S 3, C 21–26. Head pointed in front. Ears short and rounded. Body very long and slender. Extremities short. Five toes on each foot, the first, especially that on the hind foot, very short. Toes free, or but slightly palmated. Palms naked. Distal portion of soles naked, under surface of tarsus and metatarsus clothed with hair. Tail long or moderate, generally thick at the base, and sometimes covered with more or less elongated hair. The longer hairs covering the body and tail almost always annulated. This genus contains a very large number of animals commonly called Ichneumons, or in India Mongooses, varying in size from that of a large Cat down to a Weasel. They are widely distributed over the African continent and the southern parts of Asia, especially India and the Indo-Malayan archipelago, one species occurring also in Spain. They are mostly terrestrial in their habits, feeding on small mammals and birds, reptiles, especially snakes, eggs of birds and reptiles, and also insects. Some species are partially domesticated, being used to keep houses clear of rats, mice, and snakes. *H. ichneumon* was a sacred animal to the ancient Egyptians. They vary considerably in appearance, some, as *H. galera* (also called *paludinosus* and *robustus*), are larger and heavier, with stouter body, longer limbs, and stronger teeth. Others are small, with very elongated bodies and short legs. The tail also varies somewhat in length, and in the amount of hair with which it is covered. These trivial differences have given rise to the formation by some zoologists of very numerous genera, the characters of which are by no means clearly defined, but the following are the most distinct and generally recognized.

Helogale, premolars $\frac{3}{3}$, contains two small South-African species, *H. parvula* and *H. undulata*.

Bdeogale contains also two small Ichneumon-like animals, *B. crassicauda* and *puisa*, differing from *Herpestes* proper in having only four toes on each foot, both pollex and hallux being absent. The orbit is nearly complete, the tail of moderate length and rather bushy.

Cynictis.—Pollex present, but hallux absent. Skull shorter and broader than in *Herpestes*, rather contracted behind the orbits, which are large and complete behind. Face short. Anterior chamber of the auditory bulla very large. Front claws elongated. *C. penicillata*, from South Africa.

All the foregoing Herpestines have the nose short, with its under surface flat, bald, and with a median longitudinal groove. The remaining forms have the nose more or less produced, with its under side convex, and a space between the nostrils and the upper lip covered with close adpressed hairs, and without any median groove.

Rhinogale.—Toes 5–5. Claws of fore feet short, compressed, acute. Under surface of tarsus hairy. Founded on a single specimen from East Africa, *R. melleri*.

Crossarchus.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{3}{3}$, $m\ \frac{2}{2}$; total 36. Snout elongated. Toes 5–5. Claws on fore feet long and curved. Hallux very short. Under surface of tarsus naked. Tail shorter than the body, tapering. Fur harsh. Species: *C. obscurus*, the Kusimanse, a small burrowing animal from West Africa, of uniform dark-brown colour; *C. fasciatus*; *C. zebra*; *C. gambianus*.

Suricata.—A more distinct genus than any of the above. The dental formula as in the last, but the teeth of the molar series remarkably short in the antero-posterior direction, corresponding with the shortness of the skull generally. Orbits complete behind. Vertebræ: C 7, D 15, L 6, S 3, C 20. Though the head is short and broad, the nose is pointed and rather produced and movable. Ears very short. Body shorter and limbs longer than in *Herpestes*. Toes 4–4, the pollex and hallux being absent. Claws on fore feet very long and narrow, arched, pointed, and subequal. Hind feet with much shorter claws, soles hairy. Tail rather shorter than the body. One species only is known, the Suricate, *S. tetradactyla*, a small grey-brown animal, with dark transverse stripes on the hinder part of the back, from South Africa.

Galidictis, *Galidea*, and *Hemigalidia* are names of three slight generic modifications of the Viverrine type, allied to the *Herpestinæ*, but placed by Mivart in a distinct subfamily, *Galidictinæ*. They are all inhabitants of Madagascar. The best-known, *Galidia elegans*, is a lively Squirrel-like little animal with soft fur and a long bushy tail, which climbs and jumps with agility. It is of a chestnut-brown colour, the tail being annulated with darker brown. *Galidictis vittata* and *striata* chiefly differ from the Ichneumons in their coloration, being grey with parallel longitudinal stripes of dark brown.

Eupleres is another form, also from Madagascar, which has been placed in a subfamily apart. It differs remarkably from all the other *Viverridæ* in the weak development of the jaws and the small

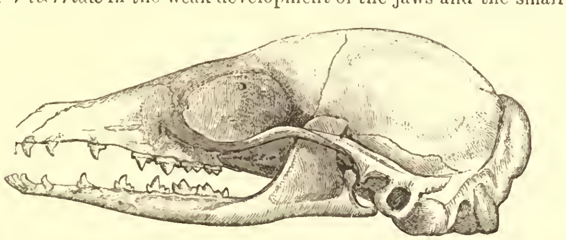

FIG. 118.—Skull of *Eupleres goudoti*. $\frac{4}{5}$ nat. size. Mus. Roy. Coll. Surgeons.

size of the teeth, in consequence of which it was, when first discovered, placed inthe order *Insectivora*. Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{2}{2} = 40$. Vertebræ: C 7, D 13, L 7, S 3, C 20. But one species is known, *E. goudoti*.

Family HYÆNIDÆ.

No alisphenoid canal. Dorsal vertebræ 15. Molars $\frac{1}{1}$. Limited to the Old World.

Subfamily **Protelidæ.**—Auditory bulla divided into two distinct chambers. Premolar and molar teeth very small and simple in character.

This group contains but a single species, belonging to the genus *Proteles*, *P. cristatus*, the Aard-Wolf or Earth-Wolf of the Dutch colonists of the Cape, an animal nearly allied to the Hyænas, but remarkably modified in its dentition, the molar teeth being very small, placed far apart, and almost rudimentary in character (see fig. 119). The canines are long and rather slender. The dental formula is $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, p and $m\ \frac{4}{3\text{ or }4} = \frac{8}{7\text{ or }8}$; total 30 or 32. Vertebræ: C 7, D 15, L 5, S 2, C 24. The fore feet with five toes; the pollex, though short, with a distinct claw. The hind feet with four subequal toes. Claws all strong, blunt, subcompressed, and non-retractile. The general external appearance is very like that of a small striped Hyæna, but the muzzle is more pointed and the ears larger. It has a copious mane of long hair, capable of being

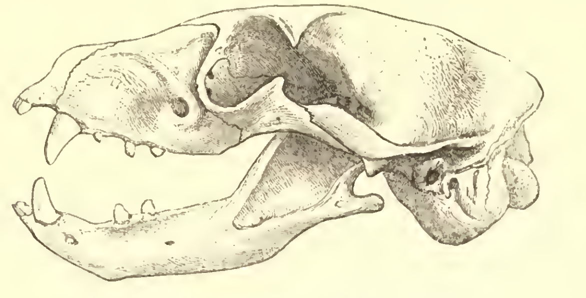

FIG. 119.—Skull and Dentition of *Proteles cristatus*. × $\frac{1}{2}$. Mus. Roy. Coll. Surgeons.

erected, when the animal is excited, along the middle line of the neck and back. It is a native of South Africa, and is a burrowing nocturnal animal, feeding on decomposing animal substances, larvæ, and termites. Observations upon specimens in captivity indicate that it has neither inclination nor power to attack or feed upon living vertebrated animals.

Subfamily **Hyænidæ.**—Auditory bulla not divided by a septum into two chambers.

Hyæna.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{3}$, $m\ \frac{1}{1} = \frac{9}{8}$; total 34. Teeth, especially canines and premolars, very large, strong, and conical. Upper sectorial with a very large, distinctly trilobed blade and a moderately developed inner lobe placed at the anterior extremity of the blade. Molar very small, and placed transversely close to the hinder edge of the last, as in the *Felidæ*. Lower sectorial consisting of little more than the bilobed blade. Zygomatic arches of cranium very wide and strong. Sagittal crest high, giving attachment to very powerful biting muscles. Orbits incomplete behind. Vertebræ: C 7, D 15, L 5, S 4, C 19. Limbs rather long, especially the anterior pair, digitigrade, four subequal toes on each, with stout non-retractile claws. Pollex and hallux only represented by rudimentary metacarpal and metatarsal bones. Tail rather short. A large post-anal median glandular pouch, into which the largely developed anal scent glands pour their secretion.

The three existing species of Hyæna (see HYÆNA) are divisible into two sections to which some zoologists assign generic rank.

1. Upper molar moderately developed and three-rooted. An inner tubercle and heel more or less developed on the lower molar. Ears large, pointed. Hair long, forming a mane on the back and shoulders. *H. striata*, the Striped Hyæna, of northern Africa and southern Asia. *H. brunnea*, of south Africa, in some respects intermediate between this and the next section. 2. Genus *Crocuta*. Upper molar extremely small, two- or one-rooted, often deciduous. Lower molar without trace of inner tubercle, and with an extremely small heel. Ears moderate, rounded. Hair not elongated to form a mane. *H. crocuta* or *Crocuta maculata*, the Spotted Hyæna, from Africa south of the Sahara. In dental characters the first section inclines more to the *Viverridæ*, the second to the *Felidæ*; or the second may be considered as the more specialized form, as it certainly is in its visceral anatomy, especially in that of the reproductive organs of the female.[1]

Extinct Hyænidæ.—Hyænas abounded in Europe from the Upper Miocene to the Pleistocene epoch, and a series of transitional forms from ancient generalized types merging into *Viverridæ*, as *Ictitherium* and *Hyænictis* (with additional tubercular molars), leading by gradual modifications during successive geological ages to the species now existing, have been traced by Gaudry. The Cave Hyæna (*H. spelæa*), once so abundant in Britain and other parts of Europe, is scarcely distinguishable specifically from the existing *H. crocuta* of Africa; and extinct forms found in France, described under the names of *H. prisca* and *H. arvernensis*, are probably the ancestors of *H. striata*. The existing *H. brunnea* seems to have preserved the characters of *H. eximia* of the Upper Miocene of Pikermi in Greece with little modification. There is at present no evidence of the existence of this group in America.

Section CYNOIDEA.

This section contains a single family, *Canidæ*, or Dog-like animals, which appear to hold an intermediate position between the other two sections, retaining also many of the more generalized characters of the ancient members of the order. The structure of the auditory bulla and adjacent parts of the bones of the skull is

[1] The anatomical peculiarities of *Hyæna crocuta* have been fully elucidated in a series of papers by Morrison Watson, in the *Proceedings of the Zoological Society* for 1877, 1878, 1879, and 1881, in which references to previous authors on the subject will be found.

quite intermediate between that of the Æluroid and Arctoid forms. In the number and arrangement of the teeth they more nearly approach the primitive heterodont type than any other existing *Carnivora*. A cæcum is always present, sometimes short and simple, but when long it is folded upon itself in a characteristic manner.

The Dogs form a very compact group, composed of numerous species which closely resemble each other in essential characters, though differing considerably externally. The most marked differences are a slight variation in the number of the true molar teeth, which exceed the usual number in the Cape Long-eared Fox (*Otocyon*), and fall short of it in some other less aberrant forms to which the names of *Icticyon* and *Cyon* have been given, and a diminution in the number of toes in the Cape Hunting Dog (*Lycaon*), which has 4–4, instead of 5–4 as in the remainder of the family. After taking these away, there remain a great number of animals called Dogs, Wolves, Jackals, and Foxes, varying from one another only in the characters of the tail, ears, fur, form of the pupil, and some trifling peculiarities of skull and teeth, upon which some authors have divided them into many genera. These divisions are, however, extremely difficult, if not impossible, to define, on account of the numerous gradual transitions from one form to the other.

Canis.—Pending further investigation, it will perhaps be safest to retain all the species, with the exceptions of *Otocyon* and *Lycaon* mentioned above, in the old genus *Canis*, the most prominent characters of which are the following. Teeth, usually $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{2}{3} = \frac{10}{11}$; total 42. The absence of the last upper molar ($\underline{m\ 3}$), alone distinguishes this from the generalized dentition of heterodonts (see p. 353), and this tooth is occasionally present in one species (*C. cancrivorus*). In certain Asiatic species (*C. primævus* and its allies), which on this account have been separated to form the genus *Cyon* of Hodgson, the last lower molar ($\overline{m\ 3}$) appears to be constantly absent, and in *C. venaticus* (genus *Icticyon*, Lund) not only this but also $\underline{m\ 2}$ is usually not developed. The milk dentition is $di\ \frac{3}{3}$, $dc\ \frac{1}{1}$, $dm\ \frac{3}{3} = \frac{7}{7}$; total 28,—the first permanent premolar having no predecessor. The teeth of both permanent and milk or temporary series are figured at p. 353 (fig. 3). The upper sectorial $\underline{p\ 4}$ consists of a stout blade, of which the anterior cusp is almost obsolete, the middle cusp large, conical, and pointed backwards, and the posterior cusp in the form of a compressed ridge; the inner lobe is very small, and placed quite at the fore part of the tooth. The first molar is more than half the antero-posterior length of the sectorial, and considerably wider than it is long; its crown consists of two prominent conical cusps, of which the anterior is the larger, and a low broad inward prolongation, supporting two more or less distinct cusps and a raised inner border. The second molar resembles the first in general form, but is considerably smaller. The lower sectorial $\overline{m\ 1}$ is a very large tooth, with a strong compressed bilobed blade, the hinder lobe being considerably the larger and more pointed, a small but distinct inner tubercle placed at the hinder margin of the posterior lobe of the blade, and a broad, low, tuberculated heel, occupying about one-third of the whole length of the tooth. The second molar is less than half the length of the first, with a pair of cusps placed side by side anteriorly, and a less distinct posterior pair. The third is an extremely small and simple tooth with a subcircular tuberculated crown and single root.

The cranium is more or less elongated, the facial portion tapering forwards and compressed. The jaws elongated. The zygomata moderately strong. The post-orbital processes of the frontal short, leaving the orbit widely open posteriorly. Vertebræ: C 7, D 13, L 7, S 3, C 17–22. Clavicles present, but very rudimentary. Limbs of moderate proportions, digitigrade. Feet short; five toes on the fore foot, the pollex much shorter than the others, and not reaching to the ground. Four toes on the hind foot, the hallux being represented by a rudiment of the metatarsal.[1] All the toes are provided with exserted non-retractile slightly curved and blunt claws, which, being exposed, become worn at the tips. Tail moderate, or rather long, generally somewhat bushy. The pupil of the eye, when contracted, is in some species round, in others elliptical and vertical.

This extensive genus may be considered as truly cosmopolitan. One or more species are found throughout the American continent from Greenland to Patagonia and the Falkland Isles; and similarly, in the Old World, Europe, Africa, and Asia, with most of the large islands adjacent, and even Australia, have their wild Dogs, though in the last case they probably belong to a feral race, introduced originally by man. They are generally sociable animals, hunting their prey in packs. Many species burrow in the ground; none habitually climb trees. Though mostly carnivorous, feeding chiefly on animals they have chased and killed themselves, many, especially among the smaller species, eat garbage, carrion, insects, and also fruit, berries, and other vegetable substances. The species are very numerous, and, as in most other large genera, very ill-defined, few zoologists agreeing as to which of the many slightly different modifications may be considered as local varieties and which true species. Perhaps the best cranial character by which the different members of the genus can be distinguished is that pointed out by Burmeister, viz., that in the animals generally called Dogs, Wolves, and Jackals the post-orbital process of the frontal bone is regularly smooth and convex above, with its extremity bent downwards, whereas in Foxes the process is hollowed above, with its outer margin (particularly of the anterior border) somewhat raised. This modification coincides in the main with that upon which Professor Huxley has recently[2] based his division of the group into two parallel series, the Thooids or Lupine forms and Alopecoids or Vulpine forms, which he characterizes by the presence of frontal air-sinuses in the former, which not only affects the external form but to a still greater degree the shape of the anterior part of the cranial cavity, and the absence of such sinuses in the latter. The pupil of the eye when contracted is round in most members of the first group, and vertically elliptical in the others, but more observations are required before this character can be absolutely relied upon. The form and length of the tail is often used for the purposes of classification, but its characters do not coincide with those of the cranium, as many of the South American *Canidæ* have the long bushy tails of Foxes and the skulls of Wolves. Taking into account various combinations of these and other minor characters, the species may be arranged in the following groups, which some authors have considered as of generic importance.

A. *Thooid or Lupine Series.*

(1) *Canis* proper contains the largest members of the genus, the true Wolves of the northern parts of both Old and New Worlds (*C. lupus*, &c.), the Jackals of southern Asia and Africa (*C. aureus*, *mesomelas*, &c.), and the various breeds of the domestic Dog (*C. familiaris*), the origin of which is still involved in obscurity. Some naturalists believe it to be a distinct species, descended from one that no longer exists in a wild state; others have sought to find its progenitors in some one of the wild or feral races, either of true Dogs, Wolves, or Jackals; while others again believe that it is derived from the mingling of two or more wild species or races. It is probably the earliest animal domesticated by man, and few if any other species have undergone such an extraordinary amount of variation in size, form, and proportion of limbs, ears, and tail, variations which have been perpetuated and increased by careful selective breeding. See DOG. The Dingo or Australian Dog is met with wild, and also as the domestic companion of the aboriginal people. Dogs were also in the possession of the natives of New Zealand and other islands of the Pacific, where no placental mammals exist naturally, on their discovery by Europeans in the last century. (2) *Cyon*, wild Dogs of the south-east of Asia, distinguished by slight modifications as *C. primævus*, *C. dukhenensis*, and *C. sumatrensis*, differ from the above in wanting the small last lower tubercular molar. (3) *Lycalopex* is a group formed of certain South-American *Canidæ*, distinguished from *Canis* proper by their longer tails and Fox-like aspect:—*C. cancrivorus*, *C. brasiliensis*, *C. melampus*, *C. vetulus*, *C. fulvicaudus*, *C. azaræ*, *C. megellanicus*, *C. griscus*. The last three have been further separated (under the name of *Pseudalopex*) on account of slight differences in the relative size of the molar teeth, and of their pupil being elliptical when contracted. (4) *Nyctereutes* (one species, *C. procyonides*, from Japan and north-east Asia) has no claims to generic distinction but such as are founded upon its long loose fur, short ears, and short bushy tail, which give it some superficial resemblance to a Raccoon. (5) *Icticyon*, with one small species, *C. venaticus*, the Bush Dog, from Guiana and Brazil, with close hair, and short legs and tail, has more reason to be regarded as a distinct form, as it is distinguished from all other Dogs by the reduction of its molar teeth to $\frac{1}{2}$, and their comparatively small size. In consequence of this, and its general external characters, it was formerly placed among the *Mustelidæ*, but its Canine affinities have now been thoroughly established.

B. *Alopecoid or Vulpine Series.*

(6) *Vulpes*, true Foxes. The species or varieties are numerous and widely spread over North America, Eurasia, and Africa:—*C. vulpes*, the common Fox of Europe; *C. niloticus*, *adustus*, and *variegatus*, Africa; *C. flavescens*, *montanus*, *bengalensis*, *japonicus*, *corsæ*, Asia; *C. fulvus*, *macrourus*, *velox*, North America. The tail of the above is clothed with soft fur and long hair, uniformly mixed; from them Baird distinguishes, under the name of *Urocyon*, other species which have a concealed erect mane of stiff hairs along the upper line of the tail. These have also a shorter muzzle and a wide space between the temporal crests; they are *C. virginianus* and *C. littoralis*, both from North America. The Arctic Fox (*C. lagopus*, genus *Leucocyon*, Gray) has the tail very full and bushy and the soles of the feet densely furred below. Its colour changes according to season from bluish-grey to pure white. (7) *Fenneccus*. Certain small elegant African Foxes (*C. cerdo*, *famelicus*, and *chama*), with very

[1] In Domestic Dogs a hallux is frequently developed, though often in a rudimentary condition, the phalanges and claw being suspended loosely in the skin, without direct connexion with the other bones of the foot; it is called by dog-fanciers the "dew claw."

[2] *Proc. Zool. Soc. Lond.*, 1880, p. 238.

large ears and corresponding large auditory bullæ, have been separated under the above name.

Lycaon.—This resembles in most of its characters the Dogs of the Lupine series, but the teeth are rather more massive and rounded, the skull shorter and broader, and it has but four toes on each limb, as in *Hyæna*. The one species, *L. pictus*, the Cape Hunting Dog (fig. 120) from south and east Africa, is very distinct exter-

FIG. 120.—Cape Hunting Dog (*Lycaon pictus*).

nally from all the other *Canidæ*. It is nearly as large as a mastiff, with large, broadly ovate erect ears, and singularly coloured, being not only variable in different individuals, but unsymmetrically marked with large spots of white, yellow, and black. It presents some curious superficial resemblances to *Hyæna crocuta*, perhaps a case of mimetic analogy. It hunts its prey in large packs.

Otocyon.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{3 \text{ or } 4}{4} = \frac{11 \text{ or } 12}{12}$; total 46 or 48. The molar teeth are thus in excess of any other known heterodont mammal. They have the same general characters as in *Canis*, with very pointed cusps. The lower sectorial shows little of its typical characters, having five cusps on the surface; these can, however, be identified as the inner tubercle, the two greatly reduced and obliquely placed lobes of the blade, and two cusps on the heel. The skull generally resembles that of the smaller Foxes, particularly the Fennecs. The auditory bullæ are very large. The hinder edge of the mandible has a very peculiar form, owing to the great development of an expanded, compressed, and somewhat inverted subangular process. Vertebræ: C 7, D 13, L 7, S 3, C 22. Ears very large. Limbs rather long. Toes 5–4. One species, *O. megalotis*, from South Africa, rather smaller than a common Fox.

Professor Huxley looks upon this as the least differentiated or most primitive existing form of *Canis*, regarding the presence of the four molar teeth as a survival of a condition of the dentition exhibited by the common ancestors of the existing *Canidæ* and the existing carnivorous Marsupials. There is, however, at present no palæontological proof of this, as none of the numerous fossil forms of *Canidæ* yet discovered have more than the normal number of molars. One of the best known of these is *Amphicyon*, from the Miocene strata of Europe and America, formerly supposed to have affinities with the Bears, having five toes on each foot, and being possibly plantigrade, but, as the structure of the skull and teeth clearly show, only a generalized Dog, in which the true molars are fully developed. Another genus, *Cynodictis*, of which many modifications have been described by Filhol from the south of France, approaches the *Viverridæ*, and may be a common ancestor of the Cynoid and Æluroid *Carnivora*.

Section ARCTOIDEA.

The section *Arctoidea* includes a considerable number of forms which agree in the essential characteristics of the structures of the base of the cranium and reproductive organs, and in the absence of a cæcum to the intestinal canal. They have no Cowper's glands, and have a rudimentary prostate and a large cylindrical penial bone. All the members of this group have five completely developed toes on each foot.

Family MUSTELIDÆ.

True molars $\frac{1}{2}$ (or $\frac{1}{1}$ in *Mellivora*). No alisphenoid canal. A large group widely diffused, especially in the northern temperate regions of the earth. The different genera are very difficult to arrange in any natural order. They are rather artificially divided, chiefly according to the characters of their feet and claws, into the Otter-like (Lutrine), Badger-like (Meline), and Weasel-like (Musteline) forms.

Subfamily **Lutrinæ.**—Feet short, rounded (except the hind feet of *Enhydra*). Toes webbed. Claws small, curved, blunt. Head broad and much depressed. Upper posterior molars large and quadrate. Kidneys conglomerate. Habits aquatic.

Lutra.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{3}$, $m\ \frac{1}{2}$; total 36. Upper sectorial with a trenchant tricusped blade, and a very large inner lobe, hollowed on the free surface, with a raised sharp edge, and extending along two-thirds or more of the length of the blade. True molar large, with a quadricuspidate crown, broader than long. Skull broad and depressed, contracted immediately behind the orbits. Facial portion very short; brain case large. Vertebræ: C 7, D 14–15, L 6–5, S 3, C 20–26. Body very long. Ears short and rounded. Limbs short. Feet completely webbed, with well developed claws on all the toes. Tail long, thick at the base and tapering, rather depressed. Fur short and close.

The Otters are all more or less aquatic, living on the margins of rivers, lakes, and in some cases the sea, are expert divers and swimmers, and feed chiefly on fish. They have a very extensive geographical range, and so much resemble each other in outward appearance, especially in the nearly uniform brown colouring, that the species are by no means well-defined. See OTTER.

L. sandbachii, a very large species from Demerara and Surinam, with a prominent ridge along each lateral margin of the tail, constitutes the genus *Pteronura* of Gray.

Aonyx.—Feet only slightly webbed; claws exceedingly small or altogether wanting on some of the toes. First upper premolar very small, sometimes wanting. True molars very broad and massive, presenting an approach to the form of the next genus. *A. inunguis*, South Africa; *A. leptonyx*, Java, Sumatra.

Enhydriodon.—*E. sivalensis* is a large extinct Otter-like animal described by Dr Falconer from the Pliocene strata of the Subhimalayan mountains.

Enhydra.—Dentition: $i\ \frac{3}{2}$, $c\ \frac{1}{1}$, $p\ \frac{3}{3}$, $m\ \frac{1}{2}$; total 32. Differs from all other known *Carnivora* in having but two incisors on each side of the lower jaw, the one corresponding to the first (very small in the true Otters) being constantly absent. Though the molar teeth generally resemble those of *Lutra* in their proportions, they differ very much in the exceeding roundness and massiveness of their crowns and bluntness of their cusps. Feet webbed. Fore feet short, with five subequal toes, with short compressed claws. Hind feet very large, depressed, and fin-like. The phalanges flattened as in the Seals. The fifth toe the longest and stoutest, the rest gradually diminishing in size to the first, all with moderate claws. Tail moderate, cylindrical.

One species, *E. lutris*, the Sea-Otter. It is larger than any of the true Otters, and is found only on the coasts and islands of the North Pacific, where it was formerly very abundant, but is gradually becoming more and more rare, on account of the numbers killed annually for their valuable fur. It is said to live on molluscs and crabs as well as fish, and the massive mill-like structure of the grinding teeth, so unlike that of all the known purely piscivorous mammals, would seem to indicate some such diet.

Subfamily **Melinæ.**—Feet elongated. Toes straight. Claws non-retractile, slightly curved, subcompressed, blunt; those of the fore foot especially large. Upper posterior molar variable. Kidneys simple. Habits mostly terrestrial and fossorial.

Mephitis.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{2 \text{ or } 3}{3}$, $m\ \frac{1}{2}$; total 32–34. Upper molar larger than the sectorial, subquadrate, rather broader than long. Lower sectorial with heel less than half the length of the whole tooth. Bony palate terminating posteriorly opposite the hinder border of the last molar tooth. Facial portion of skull short and somewhat truncated in front. Vertebræ: C 7, D 16, L 6, S 2, C 21. Head small. Body elongated. Limbs moderate, subplantigrade. Ears short and rounded. Tail long, abundantly clothed with very long fine hair. Anal glands largely developed; their secretion, which can be discharged at the will of the animal, has an intolerably offensive odour, which circumstance has rendered the Skunks, as they are commonly called, proverbial. They are strictly nocturnal animals, terrestrial and burrowing, feeding chiefly on small mammals, birds, reptiles, insects, worms, roots, and berries. All the known species have a prevalent black colour, varied by white stripes or spots on the upper part. They generally carry the body much arched, and the tail erect, the long loose hair of which waves like a plume over the back. There are many species, all inhabitants of the American continent, over which they have an extensive range. See SKUNK. The South-American species, which have only two upper premolars, and differ in some other characters, have been generically separated under the name of *Conepatus*.

Arctonyx.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{1}{2}$; total 38. Incisor line curved, the outer teeth being placed posteriorly to the others. Lower incisors proclivous. First premolars often rudimentary or absent. Upper molar much larger than the sectorial, longer in the antero-posterior direction than broad. Lower sectorial with a very large, low, tuberculated heel. Cranium elongated and depressed; face long, narrow, and concave above. Bony palate extending as far backwards as the level of the glenoid fossa. Palatal bones dilated. Suborbital foramina very large. Vertebræ: C 7, D 16, L 4, S 4, C 20. Snout long, naked, mobile, and truncated, with large terminal nostrils, much like those of a Pig. Eyes small. Ears very small and rounded. Body compressed, rather than depressed. Limbs of moderate length and digitigrade in walking. Tail moderate, tapering. A full soft under fur, with longer, bristly hairs interspersed. The best-known species is *A. collaris*, the Sand-Bear or *Bhalú-soor* (*i.e.*, Bear-Pig) of the natives, found in the mountains of the north-east of Hindustan and Assam. It is rather larger than the English Badger, higher in its legs, and very Pig-like in general aspect, of a light grey colour, with flesh-coloured snout and feet; nocturnal and omnivorous. Other species or local varieties have been described by A. Milne-Edwards from North China and Tibet.

Mydaus.—Dentition as the last, but the cusps of the teeth more acutely pointed. Cranium elongated, face narrow and produced. Suborbital foramen small, and the palate, as in all the succeeding genera of this group, produced backwards about midway between the last molar tooth and the glenoid fossæ. Vertebræ: C 7, D 14–15, L 6–5, S 3, C 12. Head pointed in front; snout produced, mobile, obliquely truncated, the nostrils being inferior. Limbs rather short and stout. Tail extremely short, but clothed with rather long bushy hair. Anal glands largely developed, and emitting an odour like that of the American Skunks (*Mephitis*). One species, *M. meliceps*, the Teledu, a small burrowing animal, found in the mountains of Java, at an elevation of 7000 or more feet above the sea-level.

Meles.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{1}{2}$; total 38. The first premolar in both jaws extremely minute and often deciduous. Upper molar very much larger than the sectorial, subquadrate, as broad as long. Lower sectorial with a broad, low, tuberculated heel, more than half the length of the whole tooth. The postglenoid processes of the skull are so strongly developed, and the glenoid fossa is so deep, that the condyle of the lower jaw is firmly held in its place even after all the surrounding soft parts are removed. Vertebræ: C 7, D 15, L 5, S 3, C 18. Muzzle pointed. Ears very short. Body stout, broad. Limbs short, strong, subplantigrade. Tail short. The best-known species is the common Badger (*M. taxus*) of Europe and northern Asia, still found in many parts of England, where it lives in woods, is nocturnal, burrowing, and very omnivorous, feeding on mice, reptiles, insects, fruit, acorns, and roots. Other nearly allied species, *M. leucurus* and *M. chinensis*, are found in continental Asia, and *M. anakuma* in Japan.

Taxidea.—Dental formula as in *Meles*, except that the rudimentary anterior premolars appear to be always wanting in the upper jaw. The upper sectorial much larger in proportion to the other teeth. Upper molar about the same size as the sectorial, triangular, with the apex turned backwards. Heel of lower sectorial less than half the length of the tooth. Skull very wide in the occipital region; the lambdoidal crest very greatly developed, and the sagittal but slightly, contrary to what obtains in *Meles*. Vertebræ: C 7, D 15, L 5, S 3, C (?). Body very stoutly built and depressed. Tail short. The animals of this genus are peculiar to North America, where they represent the Badgers of the Old World, resembling them much in appearance and habits. *T. americana* is the common American Badger of the United States. *T. berlandieri*, the Mexican Badger, is perhaps only a local variety.

Mellivora.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{3}{3}$, $m\ \frac{1}{1}$; total 32. Upper sectorial large, with its inner cusp quite at the anterior end of the blade, as in the following genera; molar much smaller and transversely extended, having a very small outer and a larger rounded inner lobe. Heel of lower sectorial very small, scarcely one-fourth of the whole length of the tooth, and with but one cusp. Tubercular molar absent. Vertebræ: C 7, D 14, L 4, S 4, C 15. Body stout, depressed. Limbs short, strong. Head depressed, nose rather pointed. External ears rudimentary. Tail short. The animals of this genus are commonly called Ratels. *M. indica*, from India, and *M. ratel* and *M. leuconota* from South and West Africa, have nearly the same general appearance and size, being rather larger than a common Badger. Their coloration is peculiar, all the upper surface of the body, head, and tail being ash-grey, while the lower parts, separated by a distinct longitudinal boundary line, are black. They live chiefly on the ground, into which they burrow, but can also climb trees. They feed on small mammals, birds, reptiles, and insects, and are said to be very partial to honey.

Helictis.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{1}{2}$; total 38. Upper sectorial with a large bicusped inner lobe. Molar smaller, wider transversely than in the antero-posterior direction. Lower sectorial with heel about one-third the length of the tooth. Skull elongated, rather narrow and depressed. Facial portion especially narrow. Infraorbital foramen very large. Head rather small and produced in front, with an elongated, obliquely truncated, naked snout. Ears small. Body elongated. Limbs short. Tail short or moderate, bushy. Several species are described (*H. orientalis*, *moschata*, *nipalensis*, *subaurantiaca*), all from eastern Asia, small animals compared with the other members of the subfamily, climbing trees with agility and living much on fruit and berries as well as on small mammals and birds.

Ictonyx.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{3}{3}$, $m\ \frac{1}{2}$; total 34. In general characters the teeth much resemble those of the Polecats (*Mustela*), being more delicately cut and sharply cusped than in most of the foregoing. Upper molar smaller than the sectorial, narrow from before backwards. Lower sectorial with a small narrow heel and distinct inner tubercle. General form of body musteline. Limbs short. Fore feet large and broad, with five stout, nearly straight, blunt, and non-retractile claws, of which the first and fifth are considerably shorter than the others. Tail moderate, with longer hairs towards the end, giving it a bushy appearance. Hair generally long and loose. The best-known species of this genus, *I. zorilla*, the Cape Polecat, was placed by Cuvier in the genus *Mustela*, by Lichtenstein in *Mephitis*, and in many characters it forms a transition between these genera. It is about the size of an English Polecat, but conspicuous by its coloration, having broad, longitudinal bands of dark brown, alternating with white. Its odour is said to be as offensive as that of the American Skunks. From the Cape of Good Hope it ranges as far north as Senegal. Another species, *I. frenata*, from Sennaar, has been described.

Subfamily **Mustelinæ.**—Toes short, partially webbed; claws short, compressed, acute, curved, often semiretractile. Upper posterior molar of moderate size, wide transversely. Kidneys simple. Terrestrial and arboreal in habits.

Galictis.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{3}{3}$, $m\ \frac{1}{2}$; total 34. Molars small but stout; upper sectorial with the inner lobe near the middle of the inner border of the tooth. Lower sectorial with heel small, and inner tubercle small or absent. Body long. Limbs short; claws non-retractile. Palms and soles naked. Head broad and depressed. Tail of moderate length. The best-known species, *G. vittata*, the Grison (genus *Grisonia*, Gray), and *G. barbara*, the Tayra (genus *Galera*, Gray), are both South-American; *G. allamandi* is an intermediate form.

Mustela.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{1}{2}$; total 38. Upper sectorial with inner lobe close to the anterior edge of the tooth. Molar nearly as large as sectorial. Lower sectorial with small inner tubercle. Vertebræ: C 7, D 14, L 6, S 3, C 18–23. Body long and slender. Limbs short, digitigrade. Feet rounded; toes short, with compressed, acute, semiretractile claws. Tail moderate or long, more or less bushy. One species is British, *M. martes*, the Pine Marten; the remainder inhabit the northern regions of Europe, Asia, and America. Many of the species, as the Sable (*M. zibellina*), yield fur of great value. See MARTEN.

Putorius.—The dentition differs from that of *Mustela* chiefly in the absence of the anterior premolars of both jaws. The teeth are more sharply cusped, and the lower sectorial wants the inner tubercle. External characters generally similar to those of the Martens, but the body is longer and more slender, and the limbs even shorter. They are all small animals, of very active, bloodthirsty and courageous disposition, living chiefly on birds and small mammals, and are rather terrestrial than arboreal, dwelling among rocks, stones, and outbuildings. Some of the species, as the Stoat or Ermine (*P. ermineus*), inhabiting cold climates, undergo a seasonal change of colour, being brown in summer and white in winter, though the change does not affect the whole of the fur, the end of the tail remaining black in all seasons. This is a large genus, having a very extensive geographical range throughout the Old and New Worlds, and includes the animals commonly known as Weasels, Polecats, Ferrets, and Minks.

Gulo.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{1}{2}$; total 38. Crowns of the teeth very stout. Upper molar very much smaller than the sectorial. Lower sectorial large, with very small heel and no inner tubercle. The dentition, though really but a modification of that of the Weasels, presents a great general resemblance to that of Hyæna. Vertebræ: C 7, D 15, L 5, S 3, C 15. Body and limbs stoutly made. Feet large and powerful, subplantigrade, with large, compressed, much curved, and sharp-pointed claws. Soles of the feet (except the pads of the toes) covered with thick bristly hairs. Ears very small, nearly concealed by the fur. Eyes small. Tail short, thick, and bushy. Fur full, long, and rather coarse. The one species, the Wolverene or Glutton, *G. luscus*, an inhabitant of the forest regions of northern Europe, Asia, and America, much resembles a small Bear in appearance. It is a very powerful animal for its size, climbs trees, and lives on squirrels, hares, beavers, reindeer, and is said to attack even horses and cows.

Family PROCYONIDÆ.

True molars $\frac{2}{2}$, obtusely tuberculated. No alisphenoid canal. Habitat exclusively American.

Procyon.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{2}{2}$; total 40. The molar teeth broad and tuberculated. The upper sectorial with three cusps along the outer margin, and a very broad bicusped inner lobe, giving an almost quadrate form to the crown. First molar with a large tuberculated crown, rather broader than long. Second considerably smaller, with transversely oblong crown. Lower sectorial with an extremely small and ill-defined blade, placed transversely in front, and a large inner tubercle and heel. Second molar as long as the first, but narrower behind, with five obtuse cusps. Vertebræ: C 7, D 14, L 6, S 3, C 16–20. Body stout. Head broad behind, but with a pointed muzzle. Limbs plantigrade, but in walking the entire sole is not applied to the ground as it is when the animal is standing. Toes, especially of the fore foot, very free, and capable of being spread wide apart. Claws compressed, curved, pointed, and non-retractile. Tail moderately long, cylindrical, thickly covered with hair, annulated, non-prehensile. Fur long, thick, and soft. The well-known Raccoon (*Procyon lotor*) of North America is the type of this genus. It is replaced in South America by *P. cancrivorus*.

Bassaris.—A form closely allied to *Procyon*, but of more slender and elegant proportions, with sharper nose, longer tail, and more digitigrade feet, and with teeth otherwise like, but smaller, and more sharply denticulated. It was formerly, but erroneously, placed among the *Viverridæ*. Two species:—*B. astuta*, from the southern parts of the United States and Mexico, and *B. sumichrasti*, from Central America.

Bassaricyon.—This name has recently (1876) been given to a distinct modification of the Procyonine type of which at present only two examples are known, one from Costa Rica and the other from Ecuador, which, appearing to be different species, have been named *B. gabbi* and *B. alleni*. They much resemble the Kinkajou (*Cercoleptes*) in external appearance, but the skull and teeth are more like those of *Procyon* and *Nasua*.

Nasua.—Dentition as in *Procyon*, but the upper canines are larger and more strongly compressed, and the molars smaller. The facial portion of the skull is more elongated and narrow. Vertebræ: C 7, D 14, L 6, S 3, C 22–23. Body elongated and rather compressed. Nose prolonged into a somewhat upturned, obliquely truncated, mobile snout. Tail long, non-prehensile, tapering, annulated. These animals, commonly called Coatis or Coati-Mundis, live in small troops of eight to twenty, are chiefly arboreal, and feed on fruits, young birds, eggs, insects, &c. Recent researches have reduced the number of supposed species to two, *N. narica* of Mexico and Central America, and *N. rufa* of South America from Surinam to Paraguay.

Cercoleptes.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{3}{3}$, $m\ \frac{2}{2} = 36$. Molars with low flat crowns, very obscurely tuberculated. Skull short and rounded, with flat upper surface. Vertebræ: C 7, D 14, L 6, S 3, C 26–28. Clavicles present, but in a very rudimentary condition. Head broad and round. Ears short. Body long and musteline. Limbs short. Tail long, tapering, and prehensile. Fur short and soft. Tongue long and very extensile. But one species of this somewhat aberrant genus is known, *C. caudivolvulus*, the Kinkajou, found in the forests of the warmer parts of South and Central America. It is about the size of a Cat, of a uniform pale, yellowish-brown colour, nocturnal and arboreal in its habits, feeding on fruit, honey, eggs, and small birds and mammals, and is of a tolerably gentle disposition and easily tamed.

Family AILURIDÆ.

Formed for the reception of one genus, resembling the *Procyonidæ* in the number of true molar teeth, but differing in some cranial characters, especially the presence of an alisphenoid canal, and in its Asiatic habitat.

Ailurus.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{3}{4}$, $m\ \frac{2}{2}$; total 38. First lower premolar very minute and deciduous. Molars remarkable for their great transverse breadth, and the numerous cusps of their crowns. Vertebræ: C 7, D 14, L 6, S 3, C 18. Skull high and compressed. Facial portion short. Ascending ramus of mandible extremely high. Head round. Face short and broad. Ears large, erect, pointed. Limbs stout, plantigrade, with large blunt non-retractile claws. Tail nearly as long as body, cylindrical, clothed with long hairs. Fur long and thick. One species, *A. fulgens*, the Panda, rather larger than a Cat, found in the south-east Himalayas, at heights of from 7000 to 12,000 feet above the sea, among rocks and trees, and chiefly feeding on fruits and other vegetable substances. Its fur is of a remarkably rich reddish-brown colour, darker below.

Family URSIDÆ.

True molars $\frac{2}{3}$, with broad, flat, tuberculated crowns. The three anterior premolars of both jaws rudimentary and often deciduous. Fourth upper premolar (sectorial) with no third or inner root. No alisphenoid canal (except in *Ailuropus*). Kidneys conglomerate. Geographical distribution extensive.

Ailuropus.—An interesting annectant form connecting the true Bears with *Ailurus* and with several extinct genera. Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{3}$, $m\ \frac{2}{3}$; total 40. Premolars increasing in size from first to last, and two-rooted except the first. First upper molar with quadrate crown, broader than long. Second larger than the first. Cranium with zygomatic arches and sagittal crest immensely developed, and ascending ramus of mandible very high, giving greater spaces for attachments of temporal muscle than in any other existing member of the order. Facial portion short. Bony palate not extending behind the last molar tooth. An alisphenoid canal. Feet bear-like, but soles more hairy, and perhaps less completely

FIG. 121. *Ailuropus melanoleucus*. From A. Milne-Edwards.

plantigrade. Fur long and thick. Tail very short. One extremely rare species, *A. melanoleucus* (fig. 121), discovered by Père David in 1869, in the most inaccessible mountains of eastern Tibet. Said to feed principally on roots, bamboos, and other vegetables. It is of the size of a small Brown Bear, of a white colour, with ears, spots round the eyes, shoulders, and limbs black.

Ursus.—Dentition: $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{2}{3} = 42$. The three anterior premolars above and below one-rooted, rudimentary, and frequently wanting. Usually the first (placed close to the canine) is present, and after a considerable interval the third, which is situated close to the other teeth of the molar series. The second is very rarely present in the adult state. The fourth (upper sectorial) differs essentially from the corresponding tooth of other Carnivores in wanting the inner lobe supported by a distinct root. Its sectorial characters are very slightly marked. The crowns of both the true molars are longer than broad, with flattened, tuberculated, grinding surfaces. The second has a large backward prolongation or heel. The lower sectorial has a small and indistinct blade and greatly developed tubercular heel. The second molar is of about the same length, but with a broader and more flattened tubercular crown. The third is smaller. The milk teeth are comparatively small, and shed at an early age. Skull more or less elongated. Orbits small and incomplete behind. Palate prolonged considerably behind the last molar tooth. Vertebræ: C 7, D 14, L 6, S 5, C 8–10. Body heavy. Feet broad, completely plantigrade. The five toes on each foot all well-developed, and armed with long compressed and moderately curved, non-retractile claws. Palms and soles naked. Tail very short. Ears moderate, erect, rounded, hairy. Fur generally long, soft, and shaggy.

The Bears are all animals of considerable bulk, and include among them the largest members of the order. Though the species are not numerous, they are widely spread over the earth's surface (but absent from the Ethiopian and Australian regions, and only represented by one species in the Neotropical region), and differ much among themselves in their food and manner of life. They are mostly omnivorous or vegetable feeders, and even the Polar Bear, usually purely carnivorous or piscivorous, devours grass with avidity in summer. The various species may be grouped in the following sections. (1) *Thalassarctos*. Head comparatively small, molar teeth small and narrow. Soles more covered with hair than in the other sections. *U. maritimus*, the Polar or White Bear of the Arctic regions. (2) *Ursus* proper. *U. arctos*, the common Brown Bear of Europe and Asia, a very variable species, to which *U. syriacus* and *isabellinus*, if distinct, are nearly related; *U. horribilis*, the Grizzly Bear, an American representative form; *U. tibetanus*, *japonicus*, and *americanus*, the Black Bears of the Himalayas, Japan, and North America; *U. ornatus*, the Spectacled Bear of the Peruvian Andes. (3) *Helarctos*. Head short and broad. Molar teeth comparatively broad (but the length still exceeding the breadth). Tongue very long and extensile. Fur short and smooth. *U. malayanus*, the Malay Bear or Sun Bear. See BEAR.

Melursus. This differs from the true Bears in the first upper incisor being absent or shed at a very early age, in the very small size of the other teeth, in the very large extensile lips, and in other minor characters. The one species, *M. labiatus*, the well-known Sloth Bear of India, feeds chiefly on black ants, termites, beetles, fruit, honey, &c.

The great Cave Bear, the remains of which are found so abundantly in caves of Pleistocene age in Europe, was a true *Ursus*, and as much or more specialized as any existing species, as it had lost its three anterior premolars in the adult state, but in *Ursus arvernensis* and older species from the Pliocene they were all retained. Still more generalized forms of Bears, presenting various degrees of transition towards a common Carnivorous type, are represented by the genera *Arctotherium* from South America and *Hyænarctos* of Miocene strata of Europe and Asia, and others which are not far removed (at least in dental characters) from such primitive Dog-like types as *Amphicyon*.

Extinct Carnivora of Doubtful Position.

The discovery of fossil remains in Eocene and early Miocene formations both in Europe and North America, shows that numerous species of terrestrial carnivorous animals existed upon the earth during those periods, which cannot be referred to either of the sections into which the order has now become broken up. By some zoologists these have been supposed to be Marsupials, or at least to show transitional characters between the Didelphous and Monodelphous subclasses. By others they are looked upon as belonging altogether to the latter group, and as the common ancestors of existing Carnivores and Insectivores, or perhaps rather as descendants or relatives of such common ancestors, retaining more of the generalized characters than any of the existing species. They shade off almost insensibly into numerous other forms less distinctly carnivorous, to the whole of which, including the modern *Insectivora*, Cope (to whom we are indebted for our principal knowledge of the American extinct species) gives the name of Bunotheria, those more specially related to the existing *Carnivora* forming the suborder *Creodonta*, which is divided into the five families, *Arctocyonidæ*, *Miacidæ*, *Oxyænidæ*, *Amblyctonidæ*, and *Meronychidæ*. These are cases, however, in which the application of the principles of classification adopted in the case of existing species, of which the entire structure is known, and which have become divided into isolated groups by the extinction of intermediate forms, is really impossible. If the generally accepted view of evolution is true, and the extreme modifications pass insensibly into each other by minute gradations (a view the palæontological proof of which becomes strengthened by every fresh discovery), there must be many of these extinct forms which cannot be assigned to definitely characterized groups. There are, however, some which stand out prominently from the others as formed on distinct types, having no exact representatives at present living on the earth. Of these the best-known is that named *Hyænodon*, of which, with the nearly allied *Pterodon*, many species

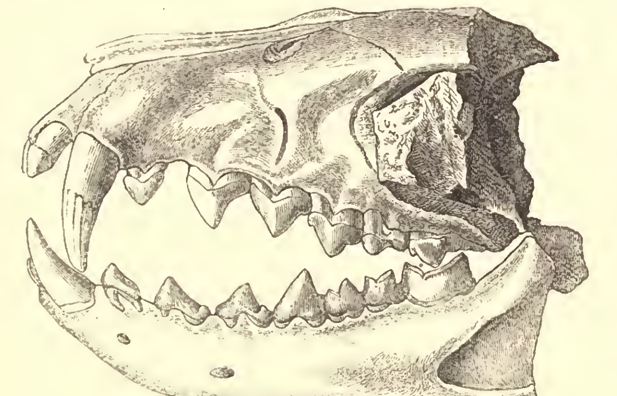

Fig. 122.—Dentition of *Hyænodon leptorhynchus* (Lower Miocene, France). The posterior molar is concealed behind the penultimate tooth.

have been found both in Europe and America. They had the full number of forty-four teeth, grouped in the usual manner, and the incisors, canines, and premolars were formed upon the ordinary Carnivorous type as now seen in the *Canidæ*, the fourth premolar above and the first true molar below being formed upon the "sectorial" plan, but the teeth behind these, instead of being tuberculated as in all existing *Carnivora*, repeated the characters of the sectorial, and also increased in size, especially in the lower jaw, from before backwards. They thus present some resemblance to the teeth of such carnivorous Marsupials as the *Dasyuridæ*; but, as the researches of Filhol have demonstrated, their milk dentition follows precisely the rule of existing placental heterodont mammals, and not that characteristic of the Marsupials. They show, moreover, none of the essential cranial modifications which distinguish true Marsupials. The curious American genus *Oxæna* seems to have been a specialized form of this type, and the European *Proviverra* or *Cynohyænodon* of Filhol) forms a complete transition between it and the *Viverridæ*. In *Arctocyon primævus*, the oldest known Tertiary mammal, from the lowest Eocene beds of La Fère, department of Aisne, France, on the other hand, all the molars were tuberculated, and have been compared with those of the *Procyonidæ* and also *Gymnura*, among the *Insectivora*. The small size of the brain of these early forms is not, as has been supposed, a special Marsupial character, but is common to the primitive forms of all groups of vertebrates. *Mesonyx*, from the Eocene of North America, seems to have been a very generalized form, with flat blunt claws, and long and slender tail. Cope makes the interesting suggestion that this may have been in the ancestral line of the Pinnipeds, but his statement that the scaphoid and lunar bones of the carpus were distinct offers a decided difficulty to the acceptance of this view.

Suborder *PINNIPEDIA*.

These differ from the rest of the *Carnivora* mainly in the structure of their limbs, which are modified for aquatic progression,—the two proximal segments being very short and partially enveloped in the general integument of the body, while the third segment, especially in the hinder extremities, is elongated, expanded, and webbed. There are always five well-developed digits on each limb. In the hind limb the two marginal digits (first and fifth) are stouter and generally larger than the others. The teeth also differ from those of the more typical *Carnivora*. The incisors are always fewer than $\frac{3}{3}$. The molar series consists generally of four premolars and one molar of very uniform characters, with never more than two roots, and with conical, more or less compressed, pointed crowns, which may have accessory cusps, placed before or behind the principal one, but are never broad and tuberculated. The milk teeth are very small and simple, and are shed or absorbed at a very early age, usually either before or within a few days after birth. The brain is relatively large, the cerebral hemispheres broad in proportion to their length, and with numerous and complex convolutions. There is a very short cæcum. The kidneys are divided into numerous distinct lobules. There are no Cowper's glands. Mammæ two or four, abdominal. No clavicles. Tail always very short. Eyes very large and exposed, with flat cornea. The nostrils close by the elasticity of their walls, and are opened at will by muscular action.

The animals of this group are all aquatic in their mode of life, spending the greater part of their time in the water, swimming and diving with great facility, feeding mainly on fish, crustaceans, and other marine animals, and progressing on land with difficulty. They always come on shore, however, for the purpose of bringing forth their young. They are generally marine, but they occasionally ascend large rivers, and some inhabit inland seas and lakes, as the Caspian and Baikal. Though not numerous in species, they are widely distributed over the world, but occur most abundantly on the coasts of lands situated in cold and temperate zones. The suborder is divisible into three well-marked families:—the *Otariidæ* or Sea Bears, which form a transition from the Fissiped *Carnivora* to the Seals; the *Trichechidæ*, containing the Walrus; and the *Phocidæ* or typical Seals.

Family Otariidæ.

When on land the hind feet are turned forwards under the body, and aid in supporting and moving the trunk as in ordinary quadrupeds. A small external ear. Testes suspended in a distinct external scrotum. Skull with post-orbital processes and alisphenoid canal. Palms and soles of feet naked.

Otaria.—Dentition: $i\ \frac{3}{2}$, $c\ \frac{1}{1}$, $p\ \frac{4}{4}$, $m\ \frac{1 \text{ or } 2}{1}$; total 34 or 36. First and second upper incisors small, with the summits of the crowns divided by a deep transverse groove into an anterior and a posterior cusp of nearly equal height; the third large and canine-like. Canines large, conical, pointed, recurved. Molars and premolars, usually $\frac{5}{5}$, of which the second, third, and fourth are preceded by milk teeth shed a few days after birth; sometimes (as in fig. 123) a sixth upper molar (occasionally developed on one side and not the other); all with similar characters, generally uniradicular; crown moderate, compressed, pointed, with a single principal cusp, and sometimes a cingulum, and more or less developed anterior and posterior accessory cusps. Vertebræ: C 7, D 15, L 5, S 4, C 9-10. Head rounded. Eyes large. Pinna of ear small, narrow, and pointed. Neck long. Skin of all the feet extended far beyond the nails and ends of the digits, with a deeply-lobed margin. The nails small and often quite rudimentary, especially those of the first and fifth toes of both feet; the best-developed and most constant are the three middle claws of the hind foot, which are elongated, compressed, and curved.

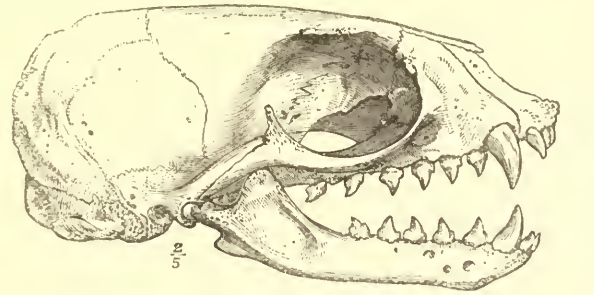

FIG. 123.—Skull and Dentition of *Otaria forsteri*. From Gray, *Proc. Zool. Soc.*, 1872, p. 660.

The *Otariæ*, or Eared Seals, commonly called Sea Bears or Sea Lions, are widely distributed, especially in the temperate regions of both hemispheres, though absent from the coasts of the North Atlantic. As might be inferred from their power of walking on all fours, they spend more of their time on shore, and range inland to greater distances, than the true Seals, especially at the breeding time, though they are obliged always to return to the water to seek their food. They are gregarious and polygamous, and the males are usually much larger than the females, a circumstance which has given rise to some of the confusion existing in the specific determination of the various members of the genus. Some of the species possess, in addition to the stiff, close, hairy covering common to all the group, an exceedingly fine, dense, woolly under fur. The skins of these, when dressed and deprived of the longer harsh outer hairs, constitute the "sealskin" of commerce, so much valued for wearing apparel, which is not the product of any of the true Seals. The best-known species are *O. stelleri*, the Northern Sea Lion, the largest of the genus, from the North Pacific, about 10 feet in length; *O. jubata*, the Southern Sea Lion, from the Falkland Islands and Patagonia; *O. californiana*, from California, frequently exhibited alive in menageries in Europe; *O. ursina*, the common Sea Bear or Fur Seal of the North Pacific, the skins of which are imported in immense numbers from the Prybiloff Islands; *O. pusilla*, from the Cape of Good Hope; *O. forsteri* and others, from the coasts of Australia and various islands scattered over the southern hemisphere. These have been grouped by some zoologists into many genera, founded upon very trivial modifications of teeth and skull.

Family TRICHECHIDÆ.

In many characters the single genus comprising this family is intermediate between the *Otariidæ* and *Phocidæ*, but it has a completely aberrant dentition. It has no external ears, as in the *Phocidæ*; but when on land the hind feet are turned forwards and used in progression, though less completely than in the *Otariidæ*. The upper canines are developed into immense tusks, which descend a long distance below the lower jaw. All the other teeth, including the lower canines, are much alike, small, simple and one-rooted, the molars with flat crowns. The skull is without post-orbital process, but has an alisphenoid canal.

Trichechus, Linn.; *Odobænus*, Brisson (which some modern zoologists have revived).—Dentition of young: $i\,\frac{3}{3}$, $c\,\frac{1}{1}$, p and $m\,\frac{5}{4}$. Many of these teeth are, however, lost early or remain through life in a rudimentary state, concealed by the gums. The teeth which are usually developed functionally are $i\,\frac{1}{0}$, $c\,\frac{1}{1}$, $p\,\frac{3}{3}$, $m\,\frac{0}{0}$; total 18. Vertebræ: C 7, D 14, L 6, S 4, C 9. Head round. Eyes rather small. Muzzle short and broad, with on each side a group of long, very stiff, bristly whiskers. The remainder of the hair covering very short and adpressed. Tail very rudimentary. Fore feet with subequal toes, with five minute flattened nails. Hind feet with subequal toes, the fifth slightly the largest, with cutaneous lobes projecting beyond the ends as in *Otaria*; first and fifth with minute flattened nails; second, third, and fourth with large, elongated, subcompressed pointed nails.

The Walrus or Morse (*T. rosmarus*) is found throughout the circumpolar regions, those of the North Atlantic and North Pacific being considered by some zoologists as distinct species, by others as local varieties. It is gregarious, but, owing to the destruction by the sealers for the sake of its tusks, oil, and hide, it is far less abundant than formerly. The use of the great tusks (which are developed in both sexes, though in the female they are more slender than in the male) appears to be for scraping and digging among the sand and shingle for the molluscs and crustaceans which form its principal sustenance; they are also formidable weapons of defence.

Family PHOCIDÆ.

The true Seals are the most completely adapted for aquatic life of all the Pinnipeds. When on land the hind limbs are extended behind them and take no part in progression, which is effected by a series of jumping movements produced by the muscles of the trunk, in some species aided by the fore limbs only. The palms and soles of the feet are hairy. There is no pinna to the ear, and no scrotum, the testes being abdominal. The upper incisors have simple, pointed crowns, and vary in number in the different groups. All have well developed canines and $\frac{5}{5}$ teeth of the molar series. In those species of which the milk dentition is known, there are three milk molars, which precede the second, third, and fourth permanent molars; the dentition is therefore $p\,\frac{4}{4}$, $m\,\frac{1}{1}$, the first premolar having as usual no milk predecessor. The skull has no post-orbital process and no alisphenoid canal. The fur is stiff and adpressed, without woolly under fur.

Subfamily **Phocinæ**.—Incisors $\frac{3}{2}$. All feet with five well-developed claws. The toes on the hind feet subequal, the first and fifth not greatly exceeding the others in length, and with the interdigital membrane not extending beyond the toes.

Halichœrus.—Dentition: $i\,\frac{3}{2}$, $c\,\frac{1}{1}$, $p\,\frac{4}{4}$, $m\,\frac{1}{1}$; total 34. Molars with large, simple, conical, recurved, slightly compressed crowns, with sharp anterior and posterior edges, but without accessory cusps, except sometimes the two hinder ones of the lower jaw. With the exception of the last one or two in the upper jaw and the last in the lower jaw they are all uniradicular. Vertebræ: C 7, D 15, L 5, S 4, C 14.

One species, *H. grypus*, the Grey Seal of the coasts of Scandinavia and the British Isles.

Phoca.—Dental formula as the last. Teeth smaller and more pointed. Molars with two roots (except the first in each jaw). Crowns with accessory cusps. Vertebræ: C 7, D 14-15, L 5, S 4, C 11-14. Head round and short. Fore feet short, with five very strong, subcompressed, slightly curved, rather sharp claws, subequal in length. On the hind feet the claws much narrower and less curved. The species of this genus are widely distributed throughout the northern hemisphere, and include *P. barbata*, the Bearded Seal; *P. grœnlandica*, the Greenland Seal; *P. vitulina*, the Common Seal; and *P. hispida*, the Ringed Seal of the North Atlantic; *P. caspica*, from the Caspian and Aral Seas; and *P. siberica*, from Lake Baikal. See SEAL.

Subfamily **Stenorhynchinæ**.—Incisors $\frac{2}{2}$. Molars two-rooted, except the first. On the hind feet the first and fifth toes greatly exceeding the others in length, with nails rudimentary or absent.

Monachus.—Dentition: $i\,\frac{2}{2}$, $c\,\frac{1}{1}$, $p\,\frac{4}{4}$, $m\,\frac{1}{1}$; total 32. Crowns of molars strong, conical, compressed, hollowed on the inner side, with a strongly-marked lobed cingulum, especially on the inner side, and slightly developed accessory cusps before and behind. The first and last upper and the first lower molar considerably smaller than the others. Vertebræ: C 7, D 15, L 5, S 2, C 11. All the nails of both fore and hind feet very small and rudimentary. One species, *M. albiventer* (*Pelagius monachus* of some authors), the Monk Seal of the Mediterranean and adjacent parts of the Atlantic.

The other genera of this section have the same dental formula, but are distinguished by the characters of the molar teeth and the feet. They are all inhabitants of the shores of the southern hemisphere.

Stenorhynchus (*Ogmorhinus*, Peters).—All the teeth of the molar series with three distinct pointed cusps, deeply separated from each other; of these the middle or principal cusp is largest and slightly recurved; the other two (anterior and posterior) are nearly equal in size, and have their apices directed towards the middle one. Skull much elongated. One species, *S. leptonyx*, the Sea Leopard, widely distributed in the Antarctic and southern temperate seas.

Lobodon.—Molars with much-compressed elongated crowns, with a principal recurved cusp, rounded and somewhat bulbous at the apex, and with one anterior, and one, two, or three posterior, very distinct accessory cusps. One species, *L. carcinophaga*.

Leptonyx.—Molars small, with simple, subcompressed, conical crowns, with a broad cingulum, but no distinct accessory cusps. *L. weddellii*.

Ommatophoca.—All the teeth very small; those of the molar series with pointed recurved crowns, and small posterior and still less developed anterior accessory cusps. Orbits very large. Nails quite rudimentary on front and absent on hind feet. The skull bears a considerable resemblance to that of the members of the next subfamily, towards which it may form a transition. There is one species, *O. rossii*, of which very little is known.

Subfamily **Cystophorinæ**.—Incisors $\frac{2}{1}$. Teeth of molar series generally one-rooted. Nose of males with an appendage capable of being inflated. First and fifth toes of hind feet greatly exceeding the others in length, with prolonged cutaneous lobes, and rudimentary or no nails.

Cystophora.—Dentition : $i\,\frac{2}{1}$, $c\,\frac{1}{1}$, $p\,\frac{4}{4}$, $m\,\frac{1}{1}$; total 30. The last molar has generally two distinct roots. Beneath the skin over the face of the male, and connected with the nostrils, is a sac capable of inflation, when it forms a kind of hood covering the upper part of the head. Nails present, though small on the hind feet. *C. cristata*, the Hooded or Bladder-Nose Seal of the Polar Seas.

Macrorhinus.—Dentition as the last, but molars of simpler character, and all one-rooted. All the teeth, except the canines, very small relatively to the size of the animal. Hind feet without nails. Vertebræ: C 7, D 15, L 5, S 4, C 11. Nose of adult male produced into a short tubular proboscis, ordinarily flaccid, but capable of dilatation and elongation under excitement. One species, *M. leonina*, the Elephant Seal, or "Sea Elephant" of the whalers, the largest of the whole family, attaining the length of nearly 20 feet. Formerly abundant in the Antarctic Seas, and also found on the coast of California.

EXTINCT PINNIPEDS.

Remains of animals of this group have been found in late Miocene and Pliocene strata in Europe and America, the most abundant and best preserved being those of the Antwerp Crags, the subject of a recent illustrated monograph by Van Beneden. Nothing has, however, yet been discovered which throws any light upon the origin of the group, as all the extinct forms at present known come within the definition of the existing families; and, though annectant forms between these occur, there are as yet no transitions to a more generalized type of mammal. Indeed, all those of which the characters are best known belong to the completely developed Phocine or Trichechine, not to the Otarine, type. The structure of the Pinnipeds is so clearly a modification of that of the terrestrial Carnivores, especially of the Arctoid type, that it is difficult to imagine that they can have had any other origin but one in common with that group; but the separation must have taken place early in the Tertiary epoch, if not before.

Bibliography of Pinnipedia.—J. A. Allen, *History of North American Pinnipeds*, 1880; P. J. Van Beneden, *Ossements fossiles d'Anvers*, pt. i., 1877.

ORDER PRIMATES.

This order in the system of Linnæus includes Man, all the Monkeys, the Lemurs, and the Bats. By common consent of all zoologists the last-named animals have been removed into a distinct order. With regard to the association of the others, there has been, and still is, much difference of opinion.

That all the Monkeys, from the highest Anthropoid Apes to the lowest Marmosets, form a natural and tolerably homogeneous group seems never to have been questioned; but whether the Lemurs on the one hand and Man on the other should be united with them in the same order are points of controversy. With regard to the first, the question has already been referred to in the article LEMUR, in which an account has been given of the characters and the principal modifications of the type. If, in accordance with the traditional views of zoologists, they are still considered to be members of the order *Primates*, they must form a suborder apart from all the others, with which they have really very little in common except the opposable hallux of the hind foot, a character also met with in the Opossums, and which is therefore of very secondary importance.

The history of all the various forms of true Monkeys is very fully given in the article APE. The position of Man alone remains to be considered. In the *Systema Naturæ* of Linnæus he was separated only generically from the Apes, but in the next great work which exercised a widespread influence over the progress of zoological science, the *Règne Animal* of Cuvier, he forms a distinct order under the name of *Bimana*, the Monkeys and Lemurs being associated together as *Quadrumana*. This has been the prevailing arrangement in the zoological systems of the present century, though in the classification of Owen his position is still farther removed from that of the Monkeys, as in it the genus *Homo* forms one of the four primary divisions or subclasses of the *Mammalia*, called *Archencephala*, the *Quadrumana* being united with the *Carnivora*, *Ungulata*, and others in another division called *Gyrencephala*. On the other hand the tendency of most modern systematists, for reasons which have been fully stated by Professor Huxley,[1] is to revert towards the Linnæan position. Considering solely the facts of Man's bodily structure, it can be clearly demonstrated that the points in which he differs from the most nearly resembling Ape are not of greater importance than those by which that Ape differs from other universally acknowledged members of the group; and therefore, in any natural system, if Man is to be made a subject of zoological classification upon the same principles as those applied elsewhere, he must be included in the order which comprises the Monkeys. We say upon the same principles as are applied elsewhere, as zoological classification has never taken into consideration the psychological characteristics which distinguish the subjects of its investigations, but only their tangible and physical structure, otherwise endless confusion would result, at all events with our very imperfect knowledge of animal psychology. The essential attributes which distinguish Man, and give him a perfectly isolated position among living creatures, are not to be found in his bodily structure, and therefore should either be left entirely out of consideration or have such weight given to them as would remove him completely out of the region of zoological classification. To profess to classify Man as if he were one of the animals, as in all points of the structure and functions of his organs he undoubtedly is, to place him in the class *Mammalia*, and then to allow other considerations to influence the judgment as to the particular position he should occupy in the class, is most illogical.

Man, therefore, considered from a zoological point of view, must be included in the order *Primates*, even if the Lemurs are removed from it, as his structural affinities with the Monkeys are far closer than are those of the so-called "Half-Apes." We may, without treading upon debateable ground, go farther, and say that the differences between Man and the Anthropoid Apes are really not so marked as those which separate the latter from the American Monkeys. Perhaps the best exposition of the facts relating to the present condition of the order will be a division into five sections, which may be considered as families, of course without intending to imply that they are exactly equivalent, or that the intervals which separate them are of precisely the same importance, but that they are five distinct groups, all branches from a common stem, and unconnected in the present condition of nature by any intermediate forms. These are—(1) *Hominidæ*, containing Man alone; (2) *Simiidæ*, containing the four genera of Man-like Apes: *Troglodytes*, *Gorilla*, *Simia*, and *Hylobates*; (3) *Cercopithecidæ*, containing all the remaining Old-World Monkeys; (4) *Cebidæ*, containing the American Monkeys having three true molar teeth on each side of each jaw; and (5) *Hapalidæ*, the American Monkeys with two molar teeth, or Marmosets.

The distinctions between *Hominidæ* and *Simiidæ*, of which alone we have to treat at present, as the characters of the other families are given in the article APE, are chiefly relative, being greater size of brain and of brain case as compared with the facial portion of the skull, smaller development of the canine teeth of the males, more complete adaptation of the structure of the vertebral column to the vertical position, greater length of the lower as compared with the upper extremities, and greater length of hallux or great toe, with almost complete absence of the power of bringing it in opposition to the other four toes. The last

[1] *Man's Place in Nature*, 1863, and *Anatomy of Vertebrated Animals*, 1871. See also the more recent investigations of Broca into the comparative structure of Man and the higher Apes, published mostly in the *Revue d'Anthropologie*.

and the small size of the canine teeth are perhaps the most marked and easily defined distinctions that can be drawn between the two groups.

Man is universally admitted to form a single genus, *Homo* of Linnæus, but a question of considerable importance in treating of him from a zoological point of view, and one which has been a subject of much controversy, is whether all men should be considered as belonging to one or to several species. This question is perhaps of less importance now than formerly, when those who maintained a plurality of species associated with the hypothesis plurality of origin. One of the strongest arguments against the view that the various races of Man represent more than one species is that none of those who have maintained it have been able to agree as to how many distinct specific modifications can be defined, almost every number from three to twenty or more having been advocated by different authors. If the distinguishing characters of the so-called species had been so marked, there could not be such a remarkable diversity of opinion upon them. Again, the two facts—(1) that, however different the extremes of any two races may be in appearance (and it must be admitted that, as advocated by many polygenists, the differences are greater than many which are considered specific among other animals), every intermediate gradation can be found through which the one passes into the other, and (2) that all races are fertile *inter se*—are quite conclusive in favour of considering Man as representing a single species in the ordinary sense in which the word is now used, and of treating of all his various modifications as varieties or races.

The great problem at the root of all zoology, the discovery of a natural classification which shall be an expression of our knowledge of the real relationship or consanguinity of different forms, is also applicable to the study of the races of Man. When we can satisfactorily prove that any two of the known groups of mankind are descended from the same common stock, a point is gained. The more such points we have acquired the more nearly shall we be able to picture to ourselves, not only the present, but the past distribution of the races of Man upon the earth, and the mode and order in which they have been derived from one another. But the difficulties in the way of applying zoological principles to the classification of Man are vastly greater than in the case of most animals. When groups of animals become so far differentiated from each other as to represent separate species, they remain isolated; they may break up into further subdivisions—in fact, it is only by further subdivision that new species can be formed; but it is of the very essence of species, as now universally understood by naturalists, that they cannot recombine, and so give rise to new forms. With the varieties of Man it is otherwise. They have never so far separated as to answer to the physiological definition of species. All races, as said above, are fertile with one another, though perhaps in different degrees. Hence new varieties have constantly been formed, not only by the segmentation of portions of one of the old stocks, but also by various combinations of those already established.

Without entering into the difficult question of the method of Man's first appearance upon the world, we must assume for it vast antiquity,—at all events as measured by any historical standard. Of this there is now ample proof. During the long time he existed in a savage state—a time compared to which the dawn of our historical period is as yesterday—he was influenced by the operation of those natural laws which have produced the variations seen in other regions of organic nature. The first Men may very probably have been all alike; but, when spread over the face of the earth, and become subject to all kinds of diverse external conditions,—climate, food, competition with members of his own species or with wild animals,—racial differences began slowly to be developed through the potency of various kinds of selection acting upon the slight variations which appeared in individuals in obedience to the tendency planted in all living things. These differences manifested themselves externally in the colour of the skin, the colour, quality, and distribution of the hair, the form of the head and features, and the proportions of the limbs, as well as in the general stature.

Geographical position must have been one of the main elements in determining the formation and permanence of races. Groups of Men isolated from their fellows for long periods, such as those living on small islands, to which their ancestors may have been accidentally drifted, would naturally, in course of time, develop a new type of features, of skull, of complexion, or hair. A slight set in one direction, in any of these characters, would constantly tend to intensify itself, and so new races would be formed. In the same way, different intellectual or moral qualities would be gradually developed or transmitted in different groups of Men. The longer a race thus formed remained isolated, the more strongly impressed and the more permanent would its characteristics become, and less liable to be changed or lost when the surrounding circumstances were altered, or under a moderate amount of intermixture from other races—the more "true" in fact, would it be. On the other hand, on large continental tracts, where no mountain ranges or other natural barriers form obstacles to free intercourse between tribe and tribe, there would always be a tendency towards uniformity, from the amalgamation of races brought into close relation by war or by commerce. Smaller or feebler races would be destroyed or absorbed by others impelled by superabundant population or other causes to spread beyond their original limits; or sometimes the conquering race would itself disappear by absorption into the conquered.

Thus, for untold ages, the history of Man has presented a shifting, kaleidoscopic scene: new races gradually becoming differentiated out of the old elements, and, after dwelling a while upon the earth, either becoming suddenly annihilated or gradually merged into new combinations; a constant destruction and reconstruction; a constant tendency to separation and differentiation, and a tendency to combine again into a common uniformity—the two tendencies acting against and modifying each other. The history of these processes in former times, except in so far as they may be inferred from the present state of things, is a difficult study, owing to the scarcity of evidence. If we had any approach to a complete palæontological record, the history of Man could be reconstructed; but nothing of the kind is forthcoming. Evidence of the anatomical characters of Man, as he lived on the earth during the time when the most striking racial characteristics were being developed, during the long ante-historic period in which the Negro, the Mongolian, and the Caucasian were being gradually fashioned into their respective types, is entirely wanting, or if any exists it is at present safely buried in the earth, perhaps to be revealed at some unexpected time and in some unforeseen manner. Even the materials from which a history of the modifications of the human species as known to our generation must be constructed are rapidly passing away, as the age in which we live is an age in which, in a far greater degree than any previous one, the destruction of races, both by annihilation and absorption, is going on. Owing to the rapid extension of maritime discovery and commerce, changes such as have never been witnessed before are now taking place in the ethnology of the world, changes especially affecting the island populations among which, more than elsewhere, the solution of many of these problems may be looked for. The subject is, however, attracting the attention of observers of all countries to a greater degree than it ever has before, with the usual result of bringing distrust upon, and dissatisfaction with, the old systems, without as yet establishing anything in their place which meets with universal acceptance. The difficulty of finding distinctive characters capable of strict definition by which races or groups may be differentiated may be inferred from what has been said above. It is rather by the preponderance of certain characters in a large number of members of a group than by the exclusive or even constant possession of these characters in each of its members that the group must be distinguished. Hence, in all cases in which the characters can be expressed by the numerical method, as in the dimensions and proportions of different parts of the body, averages are now largely used by anthropologists. Provided the data upon which these averages are based have been obtained from a sufficient number of individuals, they can be absolutely relied upon to express the prevailing or most characteristic development of each particular feature in any group, and permit satisfactory comparisons between the conditions of that feature in different groups. Great progress is now being made in perfecting the methods of investigation of racial characteristics, and as we are beginning to learn what lines of research are profitable and what are barren, we may hope that the time is not far distant when we may get some clear insight into the knowledge of the natural classification and relationships of the races of Man. (W. H. F.)

INDEX.

MAMMOTH, a name commonly given to one of the numerous extinct forms of Elephant, *Elephas primigenius* of Blumenbach and most subsequent authors.[1] Probably no animal which has not survived to the historic period has left such abundant and well-preserved evidence of its former existence. The discovery of immense numbers, not only, as in the case of most extinct creatures, in the form of fragmentary bones and teeth, but often as more or less entire carcases, or "mummies" as they may be called, with the flesh, skin, and hair *in situ*, in the frozen soil of the tundras of northern Siberia, has for a long time given great interest to the species, and been the cause of many legendary stories among the natives of the lands in which they occur. Among these one of the most prevailing is that the Mammoth was, or still is, an animal which passes its life habitually in burrows below the surface of the ground, and which immediately dies if by any chance it comes into the upper air.

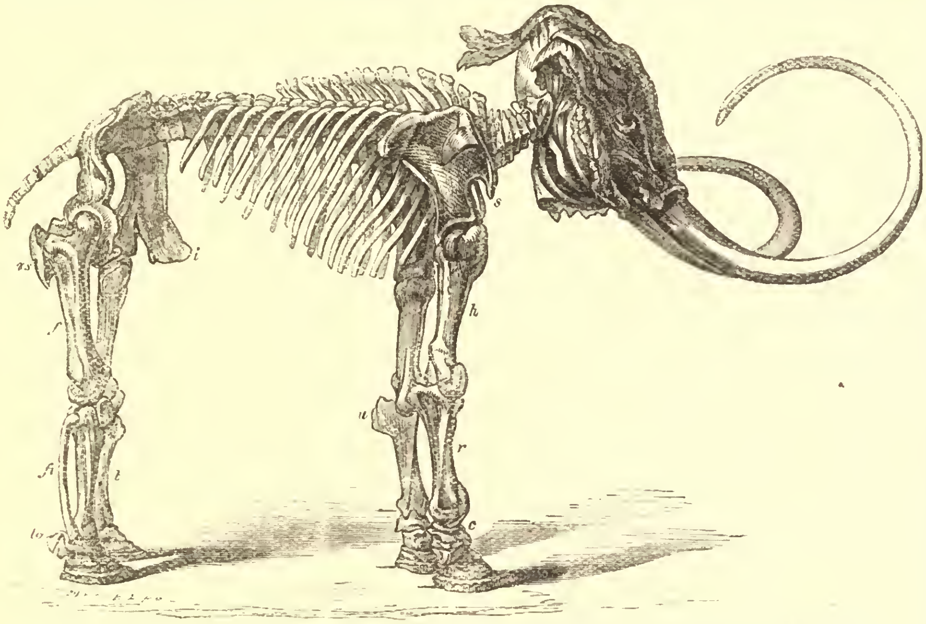

FIG. 1.—Restored Skeleton of Mammoth (*Elephas primigenius*). From Tilesius in *Mém. Acad. Imp. Sc. St Pétersbourg*, t. v. (1815).

The general characteristics of the animals of the order *Proboscidea*, to which the Mammoth belongs, are given in the article MAMMALIA (p. 423). Its position is also there indicated as a member of the most highly specialized section of the group of Elephants, that called by Falconer *Euelephas*, which also contains the modern Asiatic species. Of the whole group it is in many respects, as in the size and form of the tusks, and especially the characters of the molar teeth, the farthest removed from the primitive Mastodon-like type, while its nearest surviving relative, *E. indicus*, has retained the slightly more generalized characters of the Mammoth's contemporaries of more southern climes, *E. columbi* of America, and *E. armeniacus* of the Old World, if, indeed, it can be specifically distinguished from them.

The tusks or upper incisor teeth were doubtless present in both sexes, but probably of smaller size in the female. In the adult males they often attained the length of from 9 to 10 feet measured along the outer curve. Upon leaving the head they were directed at first downwards and outwards, then upwards and finally inwards at the tips, and generally with a tendency to a spiral form not seen in other species of Elephant. Different specimens, however, present great variations in curve, from nearly straight to an almost complete circle.

It is chiefly by the characters of the molar teeth that the various extinct modifications of the Elephant type are distinguished. Those of the Mammoth (see fig. 2) differ from the corresponding organs of allied species in (1) great breadth of the crown as compared with the length, (2) the narrowness and crowding or close approximation of the ridges, (3) the thinness of the enamel and its straightness, parallelism, and absence of "crimping" as seen on the worn surface, or in a horizontal section of the tooth. The molars, as in other Elephants, are six in number on each side above and below, succeeding each other from before backwards. Of these Dr Falconer gave the prevailing "ridge-formula" (or number of complete enamelled ridges in each tooth) as 4, 8, 12, 12, 16, 24, as in *E. indicus*. Dr Leith Adams, working from more abundant materials, has shown that the number of ridges of each tooth, especially those at the posterior end of the series, is subject to very great individual variation, ranging in each tooth of the series within the following limits: 3 to 4, 6 to 9, 9 to 12, 9 to 15, 14 to 16, 18 to 27,—excluding the small plates called "talons" at each end of the tooth. Besides these variations in the number of ridges or plates of which each tooth is composed, the thickness of the enamel varies so much as to have given rise to a distinction between a "thick-plated" and a "thin-plated" variety,—the latter being most prevalent among the specimens from the Arctic regions, and most distinctively characteristic of the species. From the specimens with thick enamel plates the transition to the other species or varieties mentioned above, including *E. indicus*, is almost imperceptible.

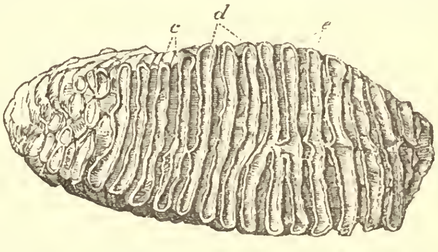

FIG. 2.—Grinding Surface of Upper Molar Tooth of the Mammoth (*Elephas primigenius*). From Owen. *c*, cementum; *d*, dentine; *e*, enamel.

The bones of the skeleton generally more resemble those of the Indian Elephant than of any other known species, but the skull differs, in the narrower summit, narrower temporal fossæ, and more prolonged incisive sheaths, required to support the roots of the enormous tusks. Among the external characters by which the Mammoth was distinguished from either of the existing species of Elephant was the dense clothing, not only of long coarse outer hair, but also of close under woolly hair, of a reddish-brown colour, evidently in adaptation to the colder climate which it inhabited. This character, for a knowledge of which we are indebted to the well-preserved remains found in northern Siberia, is also represented in the rude but

[1] The word Mammoth was introduced into the languages of western Europe about two centuries ago from the Russian, and is thought by Pallas and Nordenskiöld to be of Tartar origin, but others, as Witzen, Strahlenburg, and Howorth have endeavoured to prove that it is a corruption of the Arabic word *Behemoth*, or great beast.

graphic drawings of prehistoric age, found in caverns in the south of France.[1] In size different individuals varied considerably, but the average height does not appear to have exceeded that of either of the existing species of Elephant.

The geographical range of the Mammoth was very extensive. There is scarcely a county in England in which some of its remains have not been found either in alluvial deposits of gravel or in caverns, and numbers of its teeth are from time to time dredged up from the bottom of the sea by the fishermen who ply their trade in the German Ocean, having been washed out of the water-worn cliffs of the eastern counties of England. In Scotland and Ireland its remains are less abundant, but they have been found in vast numbers at various localities throughout the greater part of central Europe (as far south as Santander in Spain and Rome), northern Asia, and the northern part of the American continent, though the exact distribution of the Mammoth in the New World is still a question of debate. It has not hitherto been met with in any part of Scandinavia or Finland.

In point of time, the Mammoth belongs exclusively to the post-Tertiary or Pleistocene epoch of geologists, and it was undoubtedly contemporaneous with man in France, and probably elsewhere. There is evidence to show that it existed in Britain before, during, and after the glacial period.

As before indicated, it is in the northern part of Siberia that its remains have been found in the greatest abundance, and in quite exceptional conditions of preservation. For a very long period there has been from that region a regular export of Mammoth ivory in a state fit for commercial purposes, both eastward to China and westward to Europe. In the middle of the 10th century an active trade was carried on at Khiva in fossil ivory, which was fashioned into combs, vases, and other objects, as related by Abú 'l Kásim, an Arab writer of that period. Middendorff reckoned that the number of tusks which have yearly come into the market during the last two centuries has been at least a hundred pairs, and Nordenskiöld from personal observation considers this calculation as probably rather too low than too high. They are found at all suitable places along the whole line of the shore between the mouth of the Obi and Behring's Straits, and the farther north the more numerous do they become, the islands of New Siberia being now one of the most favourite collecting localities. The soil of Bear Islands and of Liachoff Islands is said to consist only of sand and ice with such quantities of Mammoth bones as almost to compose its chief substance. The remains are not only found around the mouths of the great rivers, as would be the case if the carcases had been washed down from more southern localities in the interior of the continent, but are imbedded in the frozen soil in such circumstances as to indicate that the animals had lived not far from the localities in which they are now found, and they are exposed either by the melting of the ice in unusually warm summers or by the washing away of the sea cliffs or river banks by storms or floods. In this way the bodies of more or less perfect animals, often standing in the erect position, with the soft parts and hairy covering entire, have frequently been brought to light.

References to the principal recorded discoveries of this kind, and to the numerous speculations to which they have given rise, both among the ignorant peasants and learned academicians, will be found in Nordenskiöld's *Voyage of the Vega* (English translation, vol. i. 1881, p. 398 *sq.*) and a series of papers in the *Geological Magazine* for 1880 and 1881, by H. H. Howorth. For the geographical distribution and anatomical characters, see Falconer's *Palæontological Memoirs*, vol. ii., 1868; Boyd Dawkins, "*Elephas primigenius*, its range in space and time," *Quart. Jour. Geol. Soc.*, xxxv. p. 138 (1879); and Leith Adams, "Monograph of British Fossil Elephants," part ii., *Palæontographical Society*, 1879. (W. H. F.)

[1] The best-known of these is the etching upon a portion of tusk found in the cave of La Madelaine in the Dordogne, figured in Christy and Lartet's *Reliquiæ Aquitanicæ*, and in many other works bearing on the subject of the antiquity of man.

MAMMOTH CAVE, in Edmondson county, Kentucky, United States, 37° 14′ N. lat. and 86° 12′ W. long., by rail 85 miles south-south-west of Louisville, was discovered, in 1809, by a hunter named Hutchins, while in pursuit of a wounded bear. Its mouth is in a forest ravine, 194 feet above Green river, and 600 feet above the sea. This aperture is not the original mouth, the latter being a chasm a quarter of a mile north of it, and leading into what is known as Dixon's Cave. The two portions are not now connected, though persons in one can make themselves heard by those in the other. Saltpetre was formerly made from the nitrous earth in which the cave abounded; but it is now mainly turned to account as a place of exhibition.

The cavernous limestone of Kentucky covers an area of 8000 square miles, is massive and homogeneous, and belongs to the Subcarboniferous period. It shows few traces of dynamic disturbance, but has been carved, since the Miocene epoch, into many caverns, of which the Mammoth Cave is the noblest specimen known. The region is undulating, but its valleys are mostly funnel-shaped depressions emptying through fissures into subterranean streams, which feed rivers, often of navigable size, and whose waters are never frozen over, even in severe winters. Such valleys are called sink-holes.

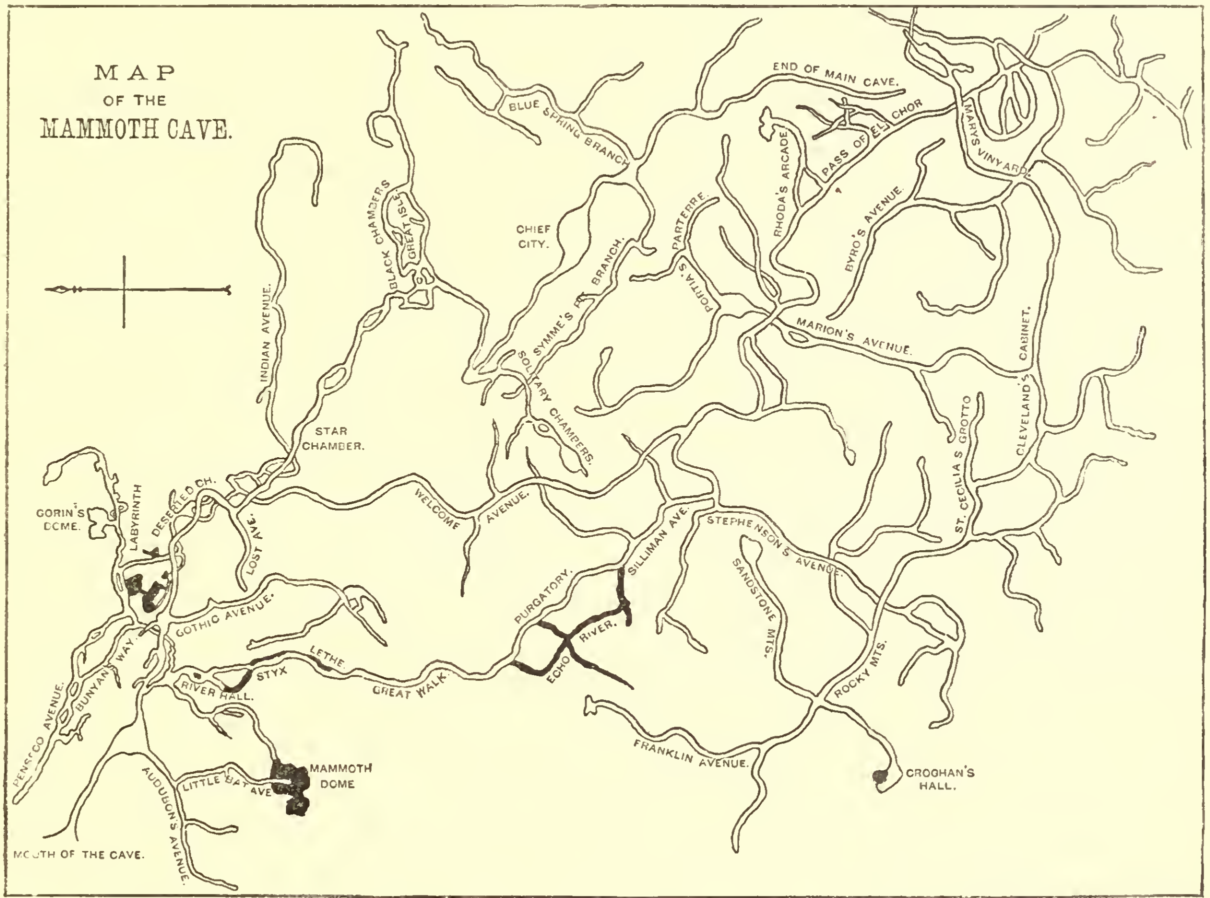
The natural arch that admits one to Mammoth Cave has a span of 70 feet, and from a ledge above it a cascade leaps 50 feet to the rocks below, where it disappears. A winding flight of stone steps leads the way down to a narrow passage, through which the air rushes with violence, outward in summer, and inward in winter. The temperature of the cave is uniformly 54° Fahr. throughout the year, and the atmosphere is both chemically and optically of singular purity. While the lower levels are moist from the large pools that have secret connexion with Green river, the upper galleries are extremely dry. These conditions led, at one time, to the erection of thirteen cottages, at a point about 1 mile under ground, for the use of invalids, especially consumptives. The experiment ended in failure, and only two cottages now remain.

The Main Cave, from 40 to 300 feet wide, and from 35 to 125 feet high, has several vast rooms, *e.g.*, the Rotunda, where are the ruins of the old saltpetre works; the Star Chamber, where the protrusion of white crystals through a coating of the black oxide of manganese creates an optical illusion of great beauty; the Chief City, where an area of 2 acres is covered by a vault 125 feet high, and the floor is strewn with rocky fragments, among which are found numerous half-burnt torches made of canes, and other signs of prehistoric occupancy. Two skeletons were exhumed near the Rotunda; but no other bones of any description have been found. The so-called Mammoth Cave "mummies" (*i.e.*, bodies kept by being inhumed in nitrous earth), with accompanying utensils, ornaments, braided sandals, and other relics, were found in Short and Salt caves near by, and removed to Mammoth Cave for exhibition. The Main Cave, which abruptly ends 4 miles from the entrance, is joined by winding passages, with spacious galleries on different levels; and, although the diameter of the area of the whole cavern is less than 10 miles, the combined length of all accessible avenues is supposed to be about 150 miles.[2]

[2] The present manager, Mr F. Klett, has undertaken the difficult task of a thorough survey, the results of which, so far as completed, are presented in the accompanying map. The portion beyond River Hall is supplemented from an older survey by Stephen, the guide.

The chief points of interest are arranged along two lines of exploration, besides which there are certain side excursions. The "short route" requires about four hours, and the "long route" nine. Audubon's Avenue, the one nearest the entrance, is seldom visited, except by the bats that hang from the walls in clusters like swarms of bees. The Gothic Avenue contains numerous large stalactites and stalagmites, and an interesting place called the Chapel, and ends in a small double dome and cascade. Among the most surprising features of cave scenery are the vertical shafts that pierce through all levels, from the uppermost galleries, or even from the sink-holes, down to the lowest floor. These are styled pits or domes, according to the position occupied by the observer. A crevice behind a block of stone 40 feet long by 20 wide, called the Giant's Coffin, admits the explorer to a place where six pits, varying in depth from 65 feet to 220 feet, exist in an area of 600 yards. This includes Gorin's Dome, which is viewed from a point midway in its side, and is by many regarded as the finest room in the cavern. Others admire more the Mammoth Dome, at the termination of Spark's Avenue, where a cataract falls from a height of 250 feet amid walls wonderfully draped with stalactitic tapestry. The Egyptian Temple, which is a continuation of the Mammoth Dome, contains six massive columns, two of them quite perfect, and 80 feet high and 25 feet in diameter. The combined length of these contiguous chambers is 400 feet. By a crevice above they are connected with an arm of Audubon's Avenue. Lucy's Dome, about 300 feet high, is supposed to be the loftiest of all these vertical shafts. A pit called "the Maelstrom," in Croghan's Hall, is the spot most remote from the mouth of the cave; a son of Prentice, the poet, permitted himself to be lowered 190 feet by a rope to the bottom, in 1859. There are some fine stalactites near this pit, and others in the Fairy Grotto and in Pensico Avenue; but, considering the magnitude of Mammoth Cave, its poverty of stalactitic ornamentation is remarkable. The wealth of crystals is, however, surprising. These are of endless variety and fantastic beauty. Besides the sparkling vault of the Star Chamber (300 feet long and 80 high), there are halls canopied by fleecy clouds, or studded with mimic snowballs, and others displaying various grotesque resemblances on the walls and ceiling.

Cleveland's Cabinet and Marion's Avenue, each a mile long, are adorned by myriads of gypsum rosettes and curiously twisted crystals, called "oulopholites." These cave flowers are unfolded by pressure, as if a sheaf were forced through a tight binding, and



Typographic Etching Co., del. et sc.

the crystal fibres curl outward from the centre of the group. Thus spotless arches of 50 feet span are embellished by floral clusters and garlands, hiding nearly every foot of the grey limestone. The botryoidal formations hanging by thousands in Mary's Vineyard resemble mimic clusters of grapes, as the oulopholites resemble roses. Again there are chambers with drifts of snowy crystals of the sulphate of magnesia, the ceilings so thickly covered with their efflorescence that a loud concussion of the air will cause them to fall like the flakes of a snow storm.

Many small rooms and tortuous paths, where nothing of special interest can be found, are avoided as much as possible on the regular routes; but certain disagreeable experiences are inevitable. There is peril also in the vicinity of the deep pits. The one known as the Bottomless Pit was for many years a barrier to all further exploration, but is now crossed by a wooden bridge. Long before the shaft had been cut as deep as now, the water flowed away by a channel gradually contracting to a serpentine way, so extremely narrow as to be called the Fat Man's Misery. The walls, only 18 inches apart, change direction eight times in 105 yards, while the distance from the sandy path to the ledge overhead is but 5 feet. The rocky sides are finely marked with waves and ripples, as if running water had suddenly been petrified. This winding way conducts one to River Hall, beyond which lie the crystalline gardens that have been described. It used to be said that, if this narrow passage were blocked up, escape would be impossible; but lately an intricate web of fissures, called the Corkscrew, has been discovered, by means of which a good climber, ascending only a few hundred feet, lands 1000 yards from the mouth of the cave, and cuts off one or two miles.

The waters, entering through numerous domes and pits, and falling, during the rainy season, in cascades of great volume, are finally collected in River Hall, where they form several extensive lakes, or rivers, whose connexion with Green river is known to be in two deep springs appearing under arches on its margin. Whenever there is a freshet in Green river the streams in the cave are joined in a continuous body of water, the rise sometimes being 60 feet above the low-water mark. The subsidence within is less rapid than the rise; and the streams are impassable for about seven months in each year. They are navigable from May to October, and furnish interesting features of cave scenery. The first approached is called the Dead Sea, embraced by cliffs 60 feet high and 100 feet long, above which a path has been made, whence a stairway conducts us down to the banks of the River Styx, a body of water 40 feet wide and 400 feet long, crossed by a natural bridge. Lake Lethe comes next—a broad basin enclosed by walls 90 feet high, below which a narrow path leads to a pontoon at the neck of the lake. A beach of the finest yellow sand extends for 500 yards to Echo river, the largest of all, being from 20 to 200 feet wide, 10 to 40 feet deep, and about three-quarters of a mile long. It is crossed by boats. The arched passage-way is very symmetrical, varying in height from 10 to 35 feet, and famous for its musical reverberations,—not a distinct echo, but an harmonious prolongation of sound for from 10 to 30 seconds after the original tone is produced. The long vault has a certain keynote of its own, which, when firmly struck, excites harmonics, including tones of incredible depth and sweetness.

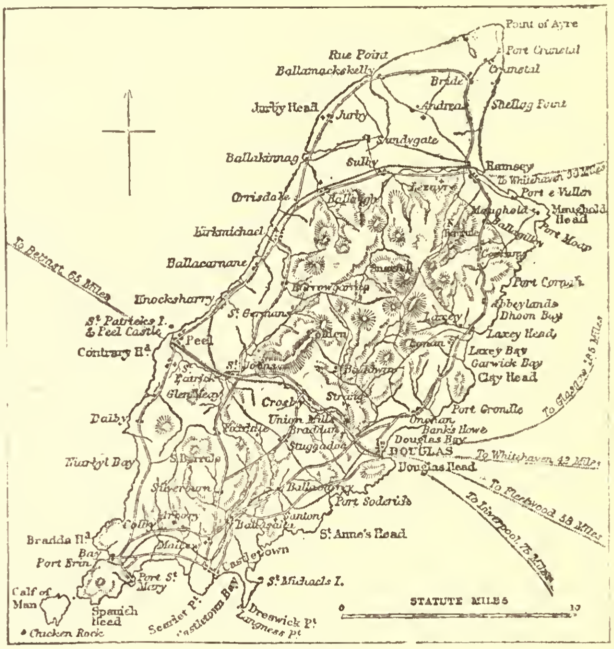
The fauna of Mammoth Cave has been classified by Putman, Packard, and Cope, who have catalogued twenty-eight species truly subterraneous, besides those that may be regarded as stragglers from the surface. They are distributed thus:—*Vertebrata*, 4 species; *Insecta*, 11; *Arachnida*, 6; *Myriapoda*, 2; *Crustacea*, 2; *Vermes*, 3. Ehrenberg adds a list of 8 Polygastric *Infusoria*, 1 fossil infusorian, 5 *Phytolitharia*, and several microscopic fungi. A bed of *Agaricus* was found by the writer near the River Styx; and upon this hint an attempt has been made to propagate edible fungi in this locality. The most interesting inhabitants of Mammoth Cave are the blind, wingless grasshoppers, with extremely long antennæ; blind, colourless crayfish (*Cambarus pellucidus*, Telk.); and the blind fish, *Amblyopsis spelæus*, colourless and viviparous, from 1 inch to 6 inches long. The *Cambarus* and *Amblyopsis* have wide distribution, being found in many other caves, and also in deep wells, in Kentucky and Indiana. Fish not blind are occasionally caught, which are apparently identical with species existing in streams outside. The true subterranean fauna may be regarded as chiefly of Pleistocene origin; yet certain forms are possibly remnants of Tertiary life. The strongly marked divergence of these animals from those found outside convinced the elder Agassiz that they were specially created for the limits within which they dwell. But the opinion now held is that they are modified from allied species existing in the sunlight, and that their peculiarities may all be accounted for on principles of evolution,—the process being accelerated (or retarded) by their migration from the outer world to a realm of absolute silence and perpetual darkness.

The literature of Mammoth Cave is extensive, though scattered through many periodicals, volumes of travels, and scientific reports. See especially Bullitt, *Rambles by a Visitor*, 1844; Collins, *History of Kentucky*, 1847; Forwood, *The Mammoth Cave*, 1870; Packard and Putnam, *Inhabitants of Mammoth Cave*, 1872; Shaler, *Memoirs of Geological Survey of Kentucky*, 1876; Hovey, "In Mammoth Cave," *Scribner's Magazine*, 1880; *Celebrated Caverns*, 1882. (H. C. H.)

MAN. See ANTHROPOLOGY (vol. ii. p. 107 *sq.*) and the articles on the various contributory sciences there referred to. Compare also MAMMALIA, above, p. 444.

MAN, ISLE OF, a dominion of the crown of England, situated in the Irish Sea, almost equidistant from England on the east, Scotland on the north, and Ireland on the west. It lies between 54° 2′ and 54° 25′ N. lat., and between 4° 18′ and 4° 50′ W. long., Douglas on the east coast of the island being distant 58 miles west-north-west from Fleetwood, while Peel on the west coast is 65 miles south-east of Belfast. The greatest length of the island is about 33 miles, and its greatest breadth about 12 miles. The total area is 145,325 acres, or about 227 square miles.

A mountain range occupies the larger portion of the island, extending from Maughold Head to the Calf Islet; the highest summits—Snaefell (2024 feet), North Barrule (1842), and Slieu Chairw (1808)—are in the north-west. These mountains rise abruptly from the narrow tract of almost level ground which forms the extreme northern boundary of the island; and between their lofty chasms are the lovely and picturesque recesses of Ravensdale, Sulby Glen, Glen Aldyn, and Ballure. The fine scenery of the mountains has been made more accessible by the construction of a series of roads, commanding at many points views unsurpassed in the United Kingdom for picturesqueness and variety. In the south-western portion of the mountain range only one summit, that of South Barrule (1585 feet), rises above 1500 feet. From Peel southwards along the western shore the mountains stretch to the very edge of the coast-line, and at the south-western extremity the shore is wildly precipitous, especially at Cronk-ny-Irree-Lhaa, which rises abruptly from the sea to the height of 1449 feet; at Brada Head, near which Brada Hill forms an almost precipitous wall over 700 feet in height; at Calf Islet, surrounded by rugged broken rocks; and at Spanish Head (said to take its name from the destruction which there overtook a portion of the Spanish Armada). Towards the south-eastern shore the mountains slope more gradually towards the sea, the coast of which is generally low and sandy, being indented by several finely rounded bays, including Castletown Bay and Derby Haven. From Derby Haven to Maughold Point the coast is frequently bold and rocky, and the numerous creeks and bays, the largest of which are Douglas Bay and Laxey Bay, greatly add to the charm and variety of the scenery. From Maughold Head round to Peel the coast presents little of special interest, being formed in great part of sand and gravel cliffs, although along the western side the bold clay-slate formation again appears.



Isle of Man.

The largest river in the island is the Sulby, which rises near Snaefell, and, after flowing northwards through a rugged glen to Sulby village, winds eastwards through a level and well-cultivated country to the sea at Ramsey. The Neb or Great River, which is formed by the junction near Slieuwhallin of a stream rising near South Barrule and flowing north by the Foxdale Glen, and of another flowing south from Sartfell by Rhenass, passes west to the Irish Sea at Peel. The Silverburn flows southwards from South Barrule to the Castletown Bay. The Dhu and Glass flowing eastwards unite before entering the sea at Douglas, which takes its name from their union. The streams abound with trout, and fishing is generally permitted without restriction. There are no lakes.

Geology.—The greater part of the island is formed of slaty Silurian rocks of identical formation with the mountainous regions of Cumberland and Westmoreland. No characteristic fossils, however, exist to determine their exact age except one, *Palæochorda major*, found in the Skiddaw slates. The line of strike is from south-west to north-east, and the strata are highly inclined. The mountains for the most part present a smooth rounded appearance, superinduced by prolonged subaerial waste. The clay-slate formation is sometimes broken through by intrusions of granite and other eruptive rocks. The "greenstones" are especially visible at Brada Head, Castletown, Langness, and other points along the coast. A large mass of granite, containing silvery mica, red and white felspar, and gray quartz, rests on the eastern slope of South Barrule mountain, and valuable masses of the same rock appear at the Dhoon river to the north-east of the Laxey lead-mines. Upper Old Red Sandstone and conglomerate occur at Peel on the west coast, and on the south coast, in the neighbourhood of Castletown Bay, chiefly at the peninsula of Langness. It rests on the upturned edges of the slates, and passes imperceptibly into the beds of limestone. The Carboniferous or Mountain Limestone is the only representative of the Carboniferous strata in the island. The limestone contains numerous fossils. At Poolvash it assumes the character of black marble, which is much used for chimneypieces. At Scarlet Point, and thence to Poolvash, interesting evidence exists of volcanic eruptions during the accumulation of the Carboniferous rocks. A great blank in the geological record occurs at the top of the limestone series, for the next strata that appear are the clays and gravels of the Glacial period. These strata occupy the greater portion of the low ground of the island, and consist of boulder clay, drift gravel, and sands. They occasionally reach as far up the mountains as 500 feet, and in the southern districts erratic boulders are sometimes to be observed on the very highest summits. Boulders of granite, for example, have been carried across South Barrule Hill (1585 feet) and dropped on the top of Crook-ny-Irree-Lhaa (1449 feet). The whole of the plain in the north of the island is occupied by Drift deposits, which occasionally form hills above 300 feet in height. Numerous depressions in the plain at one time occupied by lakes are now filled by beds of peat.

Minerals.—The most important minerals are lead, copper, and zinc. The principal mines are those of Laxey, near the Laxey river, which produce lead, copper, and especially sulphide of zinc, which forms more than two-thirds of the total quantity of ore raised from those mines. The galena obtained is very rich in silver. The Foxdale mines, between Castletown and St John's, are also very largely wrought. The amount of copper ore is comparatively small. The mines are rented from the queen as lady of the manor, the lessees paying one-tenth of the produce. In 1852 the total quantity of lead ore obtained was 2415 tons, of lead 1834¼ tons, and of silver 36,700 oz., the value of which was £7646. In 1871 the total quantity of lead ore obtained was 4645 tons, producing 3335 tons of lead and 176,631 oz. of silver; 5768 tons of zinc were also obtained, valued at £19,015, and 267 tons of copper ore, producing 18 tons of copper, valued at £1074. In 1881 Brada Head copper-mine yielded 78 tons of ore, producing 6 tons 5 cwts. of fine copper, valued at £562, 13s.; and at Great Laxey 7567 tons of zinc were raised, giving 3480 tons of the metal, valued at £28,701. The following table gives the produce of the lead-mines in 1881.

Mine.	Lead Ore.	Lead.		Silver.	Value of Ore.		
	Tons.	Tons.	Cwts.	Oz.	£	*s.*	*d.*
Foxdale	3,419	2,500	0	9,080	39,145	10	0
Laxey	1,700	1,275	0	5.250	30,487	0	0
Foxdale, East	400	292	0	9.600	5,362	0	0
Rushen	101	75	7	810	1,050	15	0
Kirk Michael	40	30	0	125	338	0	0
Great Laxey	15	11	5	...	129	15	0
Total	5,675	4,183	12	84,865	76,513	0	0

Rotten-stone and ochre are obtained in the south at Malew and Arbory, the total amount raised in 1881 being 207 tons, valued at £636. Iron is found in small quantities at Foxdale, but the total quantity obtained in 1881 was only 120 tons, valued at £60. Limestone is extensively quarried in the southern districts, both for building purposes and for agriculture. Dolomite occurs in large quantities in the mines at Laxey. There is a valuable granite quarry at Foxdale. Gold in minute particles lies in the bed of a small stream near Barrule. A considerable number of other minerals are found, but the quantity of each is unimportant. The total number of persons employed in the mines in 1881 was 1258.

Climate.—The mean annual temperature is higher than that of any other district occupying the same parallel of latitude, and the variation according to the seasons is remarkably small. The mean annual temperature is a little less than 49° Fahr., the mean temperature of summer less than 59°, and that of winter nearly 42°, giving a difference of only 17°. Rain is frequent but seldom heavy, the annual fall being 41·71 inches, about the same as in the adjacent parts of England and Scotland, but less than in those of Ireland. Thunderstorms are very rare. Many plants, even palms, which in England require artificial heat, grow in some parts of the island throughout winter in the open air, while fuchsias under the same conditions attain to great size and perfection. The air is unusually clear and pure.

Agriculture.—Owing originally to the enterprise of Scotch and English farmers, the land where arable has been brought into a state of high cultivation. Through the use of seaweed in large quantities in the northern districts of the island the sandy and gravelly soil has been greatly enriched, and it now possesses remarkable fertility, its productiveness being increased by the fine climate. The lime obtained in the neighbourhood of Castletown in the south has also been found highly beneficial for the soil in that vicinity. The best land is in these two districts, but even in the mountainous regions in the centre of the island great improvements have taken place. The farms are principally held on lease, and of late years many small holdings have been combined into large farms cultivated on modern principles.

According to the agricultural returns of 1882, the cultivated area comprehended 97,494 acres, 67 per cent. of the whole. The commons and uncultivated lands on the mountains are, moreover, utilized for the pasturage of horses, cattle, and sheep, the evergreen furze forming the principal food of these animals during the winter season. The area under corn crops was 25,211 acres, under green crops 12,046, rotation grasses 37,094, permanent pasture (exclusive of heath or mountain land), 22,836, and fallow 307. Oats occupy about one-half of the total area under corn crops, barley about one-third, and wheat about one-sixth. The wheat, which is of a very fine quality, is cultivated chiefly in the north of the island. The white and red clover and the common grasses grow in great luxuriance, and on account of the good pasturage in winter the supply much exceeds the needs of the island, large quantities being shipped to the neighbouring districts of England. Turnips, which in 1882 occupied 8432 acres, are also largely exported. The dry sandy soil of the island is very favourable for the growth of potatoes, the area planted in 1882 being 3373 acres. The most common rotation of crops is corn, green crop, corn, clover and hay, and pasture.

The total number of horses in 1882 was 5249, of which 3551 were used solely for purposes of agriculture. The native breed of horses is similar to that of North Wales. They are small, but hardy, active, and patient of labour. In 1882 cattle numbered as many as 19,780, an average of nearly 21 to every 100 acres under cultivation, considerably above that of Great Britain, which was 18·4. Of the cattle, 6862, or more than one-third, were cows and heifers in milk or in calf. On account of the large number of summer visitors, dairy farming is specially profitable. The native breed of cattle has very much degenerated, but an improved stock is now general through the importation chiefly of Ayrshires and shorthorns. Sheep in 1882 numbered 55,690, not a very large number considering the mountainous nature of the country, but cattle feeding is generally more profitable than sheep rearing, partly owing to the fine climate. The principal sheep runs are those which have been enclosed by the crown from the common lands. The native breed of sheep, small hardy animals, is gradually being superseded by crosses, and by the introduction of English sheep in the low grounds. The fleece of the native sheep is not valuable, but the mutton is of very fine quality. Pigs are largely kept, the number in 1882 being 4685. The old breed called "purrs" is now nearly extinct.

In 1882 there were 237 acres under orchards, 142 under market gardens, and 6 under nursery grounds. The acreage under woods is not given, but it is very small. Apples, for which the island was at one time famed, are still grown in considerable quantities, and gooseberries, currants, strawberries, and other smaller fruits are largely cultivated. The botany of the island is not specially interesting. The variety of species is not great, although there are a few rare plants.

Fauna.—Like Ireland, the Isle of Man is exempt from venomous reptiles and toads, a circumstance traditionally attributed to the agency of St Patrick, the patron saint of both islands. Frogs are, however, found, and both the sand lizard and the common lizard are met with. Moles are absent, badgers are unknown, and foxes are now extinct. Fossil bones are frequently found of the

Irish elk; and the red deer, as is proved by the references to it in old laws, and the representations of it on Runic monuments, was at one time common, although the species had almost disappeared about the beginning of the 18th century. Hares are less plentiful than formerly, and rabbits are not numerous except on the Calf Islet. Snipe are abundant. There are a few partridges, grouse, and quail, but neither pheasants nor black game. Various species of waterfowl visit the island, including wild geese, wild ducks, plover, widgeon, and teal. The Manx puffin (*Procellaria anglorum*) is becoming scarce, but still frequents the Calf Islet. The peregrine falcon breeds in the precipitous rocks in the neighbourhood of the Calf Islet, and at Maughold Head. The red-legged crow is common, the kingfisher scarce. The cuckoo is a yearly visitant, as is also the lapwing. Wild pigeons and seabirds of great variety frequent the rocks.

A variety of the domestic cat, remarkable for the absence or stunted condition of the tail, is common in the island.

Manufactures and Trade.—Partly perhaps on account of the absence of coal, the manufactures of the island have not attained any importance, the principal being Manx cloth, canvas, nets, ropes, and twine. There is, however, a large export of all kinds of agricultural produce, horses, cattle, and sheep, as well as of lead, lime, and black marble. Much of the trade is still carried on by means of small coasting vessels, but these are being gradually superseded by steamers which ply between Douglas and Liverpool, Barrow, Fleetwood, Silloth, Dublin, Belfast, Whitehaven, and Glasgow. The imports consist principally of provisions from England, timber from Norway, and lean cattle from Ireland. In 1881 the number of vessels engaged in the foreign and colonial trade that entered the ports of the island was 26 of 4885 tons, while 14 of 2916 tons cleared. The number engaged in the coasting trade was—entered, 2288 of 440,158 tons; cleared, 2328 of 436,107 tons. There is daily communication between Douglas and Liverpool.

There are very valuable fishing grounds, especially for herring and cod, round the southern half of the island from Peel to Douglas, and mackerel fishing is also largely prosecuted by the islanders off the coast of Ireland. The Manx fishing boats, decked and undecked, number upwards of seven hundred, employing more than four thousand men. Peel and Port St Mary alone have about three hundred and fifty-seven boats, manned by two thousand five hundred men, the capital invested in boats and nets being for these ports alone about £100,000.

The prosperity of the island, apart from its fishing and agriculture, is mainly dependent on its yearly influx of summer visitors, the annual number being now about 120,000. The season lasts from the middle of May to the middle of September.

Internal Communication.—The roads, which of late years have been greatly improved and extended, are excellent. They are maintained by a system of licences on innkeepers, grocers, and hawkers, and by an impost on carriages, carts, and dogs, and a rate on real property. The highways are under the management of a board appointed by the Tynwald court, a surveyor-general, and parochial surveyors.

The first railway in the Isle of Man was that between Douglas and Peel, opened in 1873. There is now communication by rail between the various towns of the island, and a proposal has also been made for a direct line between Douglas and Ramsey *via* Laxey. The insular government has assisted one of the railway companies by a guarantee. The railways are single narrow-gauge lines, and are worked on the baton system.

Government and Administration.—The government of the island is vested in a governor appointed by the crown, a council which acts as an upper chamber of the legislature, and the House of Keys. The governor and council and the House of Keys together constitute the court of Tynwald; but the approval of the queen of Great Britain in council is essential to every legislative enactment. Acts of the British legislature do not affect the island except it be specially named in them. For the purposes of civil jurisdiction the island is divided into a northern and a southern district, and each of these is again subdivided into three "sheadings," which are analogous to counties.

The governor, who is the representative of the sovereign, is captain-general of the military forces. He presides in the council and in all courts of Tynwald, and is *ex officio* sole judge of the chancery and exchequer courts. The council consists of the lord bishop of the diocese, the attorney-general, the two deemsters, the clerk of the rolls, the water-bailiff, the receiver-general, the archdeacon, and the vicar-general, all of whom are appointed by the crown, except the vicar-general, who is appointed by the bishop. No act of the governor and council is valid unless it is the act of the governor and at least two members of the council. The House of Keys, the representative branch of the legislature of the island, is one of the most ancient legislative assemblies in the world. It consists of twenty-four members elected by male owners or occupiers, and female owners of property. Each of the six sheadings elects three members, the towns of Castletown, Peel, and Ramsey one each, and Douglas, the chief town, three. There is a property qualification required of the members, and the house sits for seven years unless previously dissolved. The Keys were at one time self-elected, but in 1866 they consented to popular election in exchange for the privilege of controlling the expenditure of the surplus revenue of the island, agreeing, however, to pay into the imperial exchequer a fixed sum of £10,000 annually as the island's contribution towards the expenses of the army and navy of the United Kingdom.

In matters of property the court of chancery has the most extensive jurisdiction of any in the island, and is a court both of law and of equity. The governor presides, and is assisted by the clerk of the rolls and the deemsters. The exchequer court takes cognizance of all matters connected with the revenue, and also determines the right of tithe. The common law courts for the southern division are held at Douglas and Castletown alternately, and those for the northern division at Ramsey, once in three months. They are presided over by the deemsters, and take cognizance of all actions, real, personal, and mixed, and of civil matters that require to be determined by a jury. Courts of general jail delivery are held at Castletown, for the trial of prisoners indicted for criminal offences; the governor presides, attended by the deemsters, the clerk of the rolls, and the water-bailiff.

The deemsters or judges of the island (supposed by some to be the successors of the Druidical priests) until the 15th century acted according to unwritten laws, called "breast laws," of which they were the depositaries. They have concurrent jurisdiction over the whole island. Their advice is taken by the governor on all difficult points of law. Each has now a salary of £1000 per annum. Deemster courts are held weekly, alternately at Douglas and Castletown by the deemster for the southern division, and at Ramsey and Peel or Kirk Michael by the deemster of the northern division. They take cognizance in a summary manner of matters of debt, and have jurisdiction in criminal cases. The herring fishery, and the boats employed in it, are placed under the charge of the water-bailiff, who holds courts to redress grievances and enforce the regulations of the fishery. He appoints with a small salary two fishermen, called admirals, to preserve order. The water-bailiff has also civil jurisdiction in questions of salvage, and takes cognizance of suits in maritime matters. The high bailiff's courts are held weekly in Douglas, Castletown, Ramsey, and Peel for the recovery of debts under 40s., and daily for the punishment of drunkenness and offences against public order. The magistrates hold regular courts in each of the towns for the summary trial of breaches of the peace and minor offences. They are appointed by commission under the great seal of England, but their powers are regulated by insular acts of Tynwald. The members of the council and the four high bailiffs are also *ex officio* magistrates. The coroner of the sheading, who is appointed annually by the governor, is a kind of sheriff. Inquests of death are held by the high bailiff and jury. There are about thirty legal practitioners, called advocates, who combine the functions of barrister and solicitor.

The laws of the island still retain much of their ancient peculiarity of character, though modified by acts of Tynwald, and rendered in some respects more in unison with those of England. The criminal law was consolidated and amended by the criminal code of 1872.

The general tenure is a customary freehold devolving from each possessor to his next heir-at-law. The descent of land follows the same rules as the descent of the crown of England. The right of primogeniture extends to females in default of males in the direct line. The interest of a widow or widower, being the first wife or husband of a person deceased, in a life estate is one-half of the lands which have descended hereditarily, and is forfeited by a second marriage; a second husband or second wife is only entitled to a life interest in one-fourth, if there be issue of the first marriage. Of the land purchased by the husband the wife surviving him is entitled to a life interest in one moiety. By a statute of the year 1777 proprietors of land are empowered to grant leases for any term not exceeding twenty-one years in possession without the consent of the wife.

Previous to the Act of Revestment in 1765, the commerce of the island consisted principally in the importing and exporting of contraband goods, the average return of which exceeded half a million sterling per annum, the loss to the British revenue being estimated at £300,000. After this period the customs of the island were regulated by the imperial parliament. The various loans to the insular government were consolidated in 1882, and the funded debt now amounts to £230,000.

For the year ending March 31, 1882, the net revenue of the customs of the island was £70,906, and the expenditure £50,558, leaving a balance of £20,348, which is disposed of thus:—

One-ninth part of the quarter's revenue to 31st March 1882		£1,091
Due exchequer	£10,000	
Less abatement on account of loss on importation of goods	2,000	
		8,000
Expended by War Department, 1881–82		278

Religion and Education.—Christianity is said to have been introduced into the island by St Patrick about the middle of the 5th century. The bishopric of Sodor (*i.e.*, Sudreys, the southern Hebrides) was formerly united with that of Man; and the union continued till the 14th century, the Manx bishops even now retaining the joint title Sodor and Man. Some indeed affirm, but with small evidence to support the statement, that the title of Sodor was derived from the little island off Peel, said to have been at one time called Sodor, now known as St Patrick's Isle, and the seat of the cathedral of St German. The diocese is in the province of York; its bishop has a seat but not a vote in the House of Lords. The bishop is assisted in ecclesiastical matters by an archdeacon, a vicar-general, a registrar, and a sumner-general.

The ecclesiastical courts are the consistory, chapter, and the vicar-general's summary court. The livings of the clergy arise chiefly from tithes; the patronage, from the bishopric downwards, with the exception of four in the gift of the diocesan, is vested in the crown.

Besides King William's College, opened in 1833, providing an education equal to that obtainable at the highest class schools of England, and possessing a considerable number of exhibitions to the universities, there are in the island several other good secondary schools. The parochial schools are also well taught, and there are now board schools, under the insular Education Act, established throughout the island.

Population.—The following table shows the population of each parish and town from 1726 to 1881.

Sheadings, Parishes, and Towns.		Population.					
		1726.	1757.	1821.	1851.	1871.	1881.

In 1880 the death-rate was 21·9 per 1000, and the birth-rate 28·6.

The principal towns of the island are Douglas, Castletown, Ramsey, and Peel. Douglas, the chief town and seat of government, is noticed in vol. vii. p. 376. Castletown, the ancient capital of the island, was until a recent period the residence of the governor. It possesses a good harbour, barracks, and a custom-house. Ramsey, on account of its fine sandy beach and beautiful situation, is a favourite watering-place, and it has also a large shipping trade. Peel, adjoining St Patrick's Islet, is the principal seat of the herring fishery.

Language.—The Manx language is a subdialect of the ancient Celtic, and a dialect of the Irish branch, to which the Scottish Gaelic also belongs. The differences in pronunciation of these languages are not so great as to prevent a native of either country conversing with one of the other, although the differences in orthography perplex even the most learned linguists. The Manx is now spoken only in the north-western parishes and at a few localities along the western coast. The natives generally converse in the English language. Manx is not taught in any of the schools, and it is very probable that it will shortly become utterly extinct. See CELTIC LITERATURE, vol. v. p. 298.

History and Antiquities.—It admits of nearly absolute demonstration that Anglesey and not Man was the *Mona* of Cæsar. By ancient writers the island is called Eubonia. The English name Man is derived from the Manx *Mannin.* Many explanations have been given of the origin of the word, but none of them are better than conjectures.[1] It is inherently probable that the island was occupied by the Romans, and this is confirmed by the discovery of a Roman altar, which is still preserved in Castle Rushen, and of Roman coins in the same vicinity. A cist and urn found in 1852 near Tynwald Hill are supposed to belong to the aboriginal pagan period; another memorial of this period is probably St Patrick's chair, consisting of five upright stones on a stone platform forming a seat. Two of the stones are marked by a cross, but this in all likelihood was done at a period long subsequent to their erection. According to tradition the island was for a considerable period one of the chief seats of the Druids. By the peasantry nearly all the old monuments are attributed to the Druids, but the Runic crosses belong of course to a later period. One of the principal Druidical stone circles is that on the eminence called Mull, near the Calf Islet.

The earliest personage mentioned by tradition and history is Mannanan-Beg-Mac-y-Lheirr, who is described in the statute-book of the island as a paynim, who "kept the land *under mist* by his necromancy." In 517 Maelgwyn, king of North Wales, and nephew of King Arthur, expelled the Scots, and annexed the island to his Welsh dominions. He was succeeded by his son Rhun-ap-Maelgwyn in 560, from whom in 581 the island was reconquered by Aydun M'Gabhran, king of Scotland, who appointed his sister's son Brennus "thane of Man." The Welsh king appears to have recovered it from the Scots about 611, and to have retained possession of it until 630, when it was conquered by Edwin, king of Northumbria. Shortly afterwards it again fell under the dominion of the Welsh, till towards the close of the 9th century it was subdued by Harold Haarfager of Norway. The jarls of Harold for some time threw off his rule, and held independent sway. Of these Jarl Orry succeeded in establishing his rule over Man. His descendants continued to rule till 1077, when Godred Crovan, son of Harold the Black of Iceland, routed the islanders and slew their king, Fingal II. On the death of Godred in 1093, Magnus Barefoot succeeded in obtaining possession of Man, over which he placed the Norwegian jarl Oettar as governor. The inhabitants of the southern district, becoming displeased with Oettar, elected Macmanus in his place; a battle in consequence ensued at Santwart (or Sainthill), in the parish of Jurby, and victory was inclining to the party of Macmanus, when the women of the north, rushing to the scene of action, totally changed the issue of the fight, although not till both leaders were slain. On the death of Magnus, the right of Godred Crovan's line to the kingdom of the Isles was recognized, and Lagman, the son of that conqueror, succeeded to the government. He at length abdicated, and undertook a pilgrimage to Palestine, whence he never returned. Olave II., surnamed the Dwarf, the only surviving son of Godred Crovan, being then a minor, a regent was appointed, who was expelled from the kingdom in the third year of his government. Olave ascended the throne in 1114. He entered into alliance with the kings of England, Ireland, and Scotland, but his reign was disturbed by the pretensions of three natural sons of his brother Harold, by one of whom he was treacherously slain in 1154. On this Godred the Black, Olave's only legitimate son, was recalled from Norway, and the sons of Harold were delivered to condign punishment. During his reign Somerled, thane of Argyll, obtained possession of the island, and Godred had to take refuge in Norway, where he remained till the death of the usurper, on which he regained possession of his throne. His death took place in 1187. Olave III., his only legitimate son, being then a minor, Reginald, another son, was appointed to the government during his minority. The latter endeavoured to secure to himself the throne by doing homage to John of England, and afterwards by acknowledging the supremacy of the pope; a series of struggles was the consequence, till at length Reginald was slain in 1226. In 1237 Olave died in Peel Castle, leaving three sons,—Harold, Reginald, and Magnus; he was succeeded by his son Harold II., who was drowned, with his queen and a numerous retinue of nobility, in 1248, on their return from Norway, where they had been celebrating his marriage with Cecilia, daughter of Haco. His brother Reginald II. assumed the government, but was afterwards slain by Ivar, brother of Reginald the usurper, in 1249. On the death of Reginald II. his brother Magnus was chosen king. John of the Isles landed with an army at Ronaldsway to dispute his claims, but was driven from the island.

From this time the power of the Norwegian kings began to decline, and that of the Scottish sovereigns to revive. Magnus did homage to Alexander III. of Scotland, and held the island from the crown of Scotland. He died in 1265, without issue. In the meantime Magnus VI. of Norway, as the legitimate sovereign of Man, ceded in 1266 to Alexander III. all his claims and interest in the sovereignty and episcopacy of Man for the sum of 4000 marks, and an annual pension of 100 marks. The widow of Magnus (the late king of Man) succeeded, however, in getting Ivar, the assassin of her brother-in-law Reginald, placed on the vacant throne; and Alexander in 1270 sent an army to reduce the island to obedience. After a decisive battle at Ronaldsway, in which Ivar was slain, the kingdom was annexed to the dominions of Alexander. This monarch, in token of his conquest, substituted the quaint device of "the three legs," which still constitutes the national emblem, for the ancient armorial ensign of the island—a ship in full sail, with the motto, "*Rex Manniæ et Insularum.*"

[1] See "Man, its Names and their Origin," by J. M. Jeffcott, in *Manx Society Publications*, 1878.

He placed the island under the government of his nobles or thanes, whose repeated acts of tyrannical oppression at length inspired the inhabitants to throw off the Scottish yoke. Bishop Mark (Marcus Galvadiensis), a Scotchman, however, being informed of their determination, obtained their mutual consent to decide the contest by thirty champions selected from each party. The Manx champions were all killed, and twenty-five of the Scottish warriors shared the same fate. This victory confirmed the conquest of the Scots; the ancient regal government was abolished, and a military despotism established.

The most important relics of the Northmen are the Runic crosses, of which there are about forty, either whole or fragmentary. Nearly one half of these contain Scandinavian inscriptions in the ancient Norse language and in Runic character. There are a very large number at Kirk Michael, but some of the most perfect are those in the churchyards of Ballaugh, Maughold, and Braddan.

During the contentions of Bruce and Baliol, Edward I. of England took possession of the island for a period, while two rival claimants for the throne appeared. One of these was Mary, the daughter of Reginald II.; the other her aunt Affrica or Alfrida, a daughter of Olave II., and sister of Magnus. The latter in 1305 conveyed her right in the island to her husband, Sir Simon de Montacute, whose son Sir William afterwards mortgaged its revenues to Anthony Beck, bishop of Durham and patriarch of Jerusalem. In 1313 Bruce made a descent on the island, and granted it to his nephew Randolph, earl of Murray.

In the reign of Edward III. Mary Waldebeof, daughter of the previous claimant, solicited the assistance of that monarch. The king allowed her title, and by giving her in marriage to William Montacute, earl of Salisbury (the grandson of Sir Simon Montacute and Alfrida), thus united in their persons the rights of the two lines of descendants of Olave the Black to the kingdom of Man. With the aid of the English king, the earl was enabled to expel the Randolphs from the island; and in the year 1344 he was crowned king of Man. In the year 1393 the earl of Salisbury sold to Sir William le Scroop, afterwards earl of Wiltshire, "the Isle of Man, with the title of king, and the right of being crowned with a golden crown." On his attainder for high treason, the island in 1399 was bestowed on Henry Percy, earl of Northumberland, but, he having been attainted and banished, Henry IV. made a grant of it to Sir John Stanley for life. This grant was cancelled, and a new patent passed the Great Seal in 1406, bestowing the island on him and his heirs, to be held of the crown of Great Britain, by presenting to the king a cast of falcons at his coronation. Sir John died in 1414.

The lords of the house of Stanley governed the island chiefly by lieutenants, who occupied the castles of Peel and Rushen. Various tumults arose; and in 1422 fourteen persons were drawn by wild horses, quartered, and beheaded. Eventually authority was delegated by Sir John Stanley the second to Henry Byron, who remodelled the House of Keys, and rendered his regency one of the most popular in the insular history. Sir John died in 1432, and was succeeded by his son Thomas, who was created Baron Stanley by Henry VI., and died in 1460. Thomas his son was created earl of Derby by Henry VII. He died in 1505. This nobleman's son Thomas, the second earl of Derby, relinquished the title of king of Man, as he preferred "being a great lord to being a petty king." Edward, the third earl, son of the last-named Thomas, was a great favourite with Henry VIII. On his death in 1572 he was succeeded by his son Henry, the fourth earl of Derby. He died in 1594, leaving two sons, Ferdinand and William, who in time became lords of Man. The title of William was disputed by the three daughters of Ferdinand; with these, however, he effected a compromise; and in 1610 he obtained an "act for assuring and establishing the Isle of Man in the name and blood of William, earl of Derby," but in 1627 resigned his dignities to his son James, celebrated in history as "the great earl of Derby."

After the execution of this earl in 1651, for bringing aid to Charles II. before the battle of Worcester, the defence of the island was undertaken by the heroic Lady Derby, who was then in Castle Rushen; but William Christian, the receiver-general, on the appearance of a hostile fleet, surrendered the castle without resistance. The island was then granted to General Lord Fairfax, who held it until the Restoration, when it was restored to Charles, the eighth earl (the son of Earl James), in 1660. On the death of Earl Charles in 1672 he was succeeded by his son William, the ninth earl, who took but little interest in his Manx property, and, dying without issue in 1702, was succeeded by his brother James (a younger son of Charles, the eighth earl). At this time the lordship of Man was approaching dissolution. The leases, which had been granted for three lives, having nearly expired, and no provision having been made relative to their renewal, the neglect of agriculture became general, and the people were wholly given up to the fisheries and the pursuit of the contraband trade. In 1703, however, the earl conferred on his Manx subjects the Act of Settlement (very justly called the Manx Magna Charta), by which the lessees of estates were finally established in their possession, and their descent secured in perpetuity, on the payment of certain fines, rents, and dues to the lords. James died in 1736 without issue.

The lordship of Man then devolved on James, second duke of Athole, a descendant of the Lady Amelia Anna Sophia Stanley (youngest daughter of the seventh earl of Derby). In 1725, in order to put an end to the contraband trade of the island, an Act of Parliament was passed authorizing the purchase of all the royalties and revenues of the island; but no result followed till 1765, when proposals for the purchase were revived and the sovereignty and its revenues were surrendered to the crown for £70,000. The duke and duchess reserved the manorial rights, the patronage of the see, and other emoluments and perquisites. By the Act of Revestment the island was more closely united to the crown of England, although its independent form of government has never experienced any material change. An annuity of £2000 had also been granted to the duke and duchess, but, on the ground of inadequate compensation, the fourth duke presented petitions to parliament and the privy council in 1781 and 1790. He did not succeed, however, until the year 1805, when an Act was passed assigning to him and his heirs, as an additional grant, a sum equal to one-fourth of the revenues of the island, which was afterwards commuted for £3000 per annum for ever.

In 1825 an Act passed both houses of parliament, at the instance of the lords of the treasury, authorizing the lords of the treasury to treat with the duke for the purchase of his remaining interest in the island, and in 1829 he was awarded a further sum of £417,144 for his rights in and over the soil as lord of the manor, as follows:—

For the annuity	£150,000
Rents and alienation fines	34,000
Tithes, mines, and quarries; Patronage of the bishopric, with fourteen advowsons, the aggregate value of which was £6000	233,144
Total	£417,144

The ecclesiastical buildings of Man have never been remarkable for architectural beauty. The most important ecclesiastical ruin is St German's cathedral on St Patrick's Isle. The present building, which is roofless and in a very dilapidated condition, dates from 1245, but is supposed to occupy the site of an older building. It is a rude cruciform structure 110 feet long by 70 feet broad. The tower, 68 feet in height, is still entire. The crypt of the cathedral was made use of for an ecclesiastical prison, among its more important captives being Eleanor, wife of Humphrey, duke of Gloucester, uncle of Henry VI. She is alluded to by Shakespeare as living in banishment "with Sir John Stanley in the Isle of Man." St Patrick's church on the same islet is supposed to have been erected in the time of St Patrick. Adjoining it is a round tower similar to those so common in Ireland. Most of the other old churches in Man have been replaced by modern structures, but another very ancient one is Lonan old church, now partly roofless, a very unpretending structure, but said to date from the 6th century. St Trinian's church, also in ruins, is said never to have been roofed, a circumstance accounted for by an interesting legend. Of Rushen Abbey, a house of the Cistercians, founded by Olave, king of Man, in 1134, there now only remain the tower, refectory, and dormitory. The Franciscan friary of Bimakin, founded in 1373, has been partly rebuilt in a rude manner, and is used as a barn. Of the nunnery of Douglas, said to have been founded by Matilda, daughter of Ethelbert, king of the West Saxons, there are now very slight remains, chiefly of the chapel.

The principal castles are Castle Rushen, in Castletown, the ancient residence of the kings of Man, dating probably from the 13th century, and still quite entire; Peel Castle, the ancient stronghold of the island; and Castle Mona, Douglas, erected in 1801 as a residence by the duke of Athole, and now used as a hotel.

The chief sources of the early history of Man are the Norse and Erse Sagas, and the record kept by the monks of Rushen Abbey entitled *Chronicon Manniæ*, which has been edited with learned notes by P. A. Munch, Christiania, 1860. The best general history is that of Train, 2 vols., 1845. Among other works may be mentioned J. G. Cumming, *Isle of Man, its history, physical, ecclesiastical, civil, and legendary*, 1848; Id., *Runic and other Remains of the Isle of Man*, 1857; J. O. Halliwell, *Roundabout Notes on the Isle of Man*, 1863. The publications of the Manx Society are of great value and interest.

MANACOR, a town in the island of Majorca, stands on a slight eminence in a fertile plain, 30 miles east of Palma (40 miles by rail, by way of Inca). It is substantially built, with wide streets and several squares; it has the usual buildings (a parish church, a hospital, schools, and the like), and the former palace of the independent kings of Majorca is pointed out. The neighbourhood produces cereals, fruits, an inferior quality of wine, and some oil; and there is some trade in these, as well as in sheep and cattle The population in 1877 was 14,894.

MANAGUA, the capital of Nicaragua, Central America, lies on the south shore of Lake Managua in 12° 7′ N. lat.

and 86° 12′ W. long. Steamboat communication with Old Leon was opened in 1881, and a railway (32 miles) is in course of construction to Granada. It was mainly owing to the rivalry between Leon and Granada that Managua was chosen as the seat of the national assembly, and apart from the administrative buildings there is little of interest in the place. The population is about 12,000.

MANAKIN, from the Dutch word *Manneken*, applied to certain small birds, a name apparently introduced into English by Edwards (*Nat. Hist. Birds*, i. p. 21) in or about 1743, since which time it has been accepted generally, and is now used for those which form the Family *Pipridæ* of modern ornithologists. The Manakins are peculiar to the Neotropical Region, and are said to have many of the habits of the Titmouse Family (*Paridæ*), living, says Swainson, in deep forests, associating in small bands, and keeping continually in motion, but feeding almost wholly on the large soft berries of the different kinds of *Melastoma*. However, as with most other South American Passerine birds, little is really known of their mode of life; and it is certain that the *Pipridæ* have no close affinity with the *Paridæ*,[1] but belong to the other great division of the Order *Passeres*, to which Garrod assigned the name *Mesomyodi*, and in that division, according to the same authority, constitute, with the *Cotingidæ*,[2] the group *Heteromeri* (*Proc. Zool. Society*, 1876, p. 518). The Manakins are nearly all birds of gay appearance, generally exhibiting rich tints of blue, crimson, scarlet, orange, or yellow in combination with chestnut, deep black, black and white, or olive green; and among their most obvious characteristics are their short bill and feeble feet, of which the outer toe is united to the middle toe for a good part of its length. The tail, in most species very short, has in others the middle feathers much elongated, and in one the outer rectrices are attenuated and produced into threads. They have been divided by various authors into upwards of twenty so-called genera; but Messrs Sclater and Salvin (*Nomenclator*, pp. 53–55) recognize only fifteen, though admitting sixty species, of which fifteen belong to the genus *Pipra* as now restricted, the *P. leucocilla* of Linnæus being its type. This species has a wide distribution from the isthmus of Panama to Guiana and the valley of the Amazon; but it is one of the most plainly coloured of the Family, being black with a white head. The genus *Machæropterus*, consisting of four species, is very remarkable for the extraordinary form of some of the secondary wing-feathers in the males, in which the shaft is thickened and the webs changed in shape, as described and illustrated by Mr Sclater (*Proc. Zool. Society*, 1860, p. 90; *Ibis*, 1862, p. 175[3]) in the case of the beautiful *M. deliciosus*, and it has been observed that the wing-bones of these birds are also much thickened, no doubt in correlation with this abnormal structure. A like deviation from the ordinary character is found in the allied genus *Manacus* or *Chiromachæris*, comprehending six species, and that gentleman believes it enables them to make the singular noise for which they have long been noted (see BIRDS, vol. iii. p. 770), described by Mr Salvin (*Ibis*, 1860, p. 37) in the case of one of them, *M. candæi*, as beginning "with a sharp note not unlike the crack of a whip," which is "followed by a rattling sound not unlike the call of a landrail"; and it is a similar habit that has obtained for another species, *M. edwardsi*, the name in Cayenne, according to Buffon (*Hist. Nat. Oiseaux*, iv. p. 413), of *Casse-noisette*. This view is supported by Mr Layard, who, writing of the last species, says (*Ibis*, 1873, p. 381)—"They make a curious rattling noise (I suspect, by some movement of the oddly shaped wing-feathers), which constantly betrays their presence in the forests," while of the congeneric *M. gutturosus*, Mr J. F. Hamilton remarks (*Ibis*, 1871, p. 305)—"The first intimation given of the presence of one of these birds is a sharp whirring sound very like that of a child's small wooden rattle, followed by two or three sharp snaps." The same observer adds (*loc. cit.*) of a member of the kindred genus *Chiroxiphia*, containing five species, that *C. caudata* is known to the Brazilians as the Fandango-bird from its "habit of performing a dance." They say that "one perches upon a branch and the others arrange themselves in a circle round it, dancing up and down on their perches to the music sung [?] by the centre one." Exception must be taken to this story so far as regards the mode in which the "music" is produced, for these birds have no true song-muscles; but the effect is doubtless as described by Mr Hamilton's informant. (A. N.)

[1] Though Edwards called the species he figured (*ut supra*) a Titmouse, he properly remarked that there was no genus of European birds to which he could liken it.

[2] Excluding, however, the genus *Rupicola*—the beautiful orange-coloured birds well known as the "Cocks of the Rock"—which has usually been placed among the *Cotingidæ*.

[3] The figures are repeated by Mr Darwin (*Descent of Man*, &c., ii. p. 66).

MÁNANTADI, or MANANTODDY, a town in Malabar district, Madras, the trading centre of the Wainád coffee district (11° 48′ N. lat., 76° 2′ 55″ E. long.). The population in 1871, including numerous European coffee planters, with their families, in the neighbourhood, was 10,959. Besides several Government offices, it contains a good club. Early in the century it was a military outpost, and in 1802 the garrison was massacred by the Kotiote rebels.

MANASSEH. The tribe of JOSEPH (*q.v.*), the northern and stronger half of the "sons of Rachel," was divided into two branches, so considerable as themselves to bear the name of tribes, which referred their origin to Manasseh and Ephraim, the two sons of Joseph by his Egyptian wife Asenath. Of the two Manasseh was held to be the elder, but the patriarchal story relates how Jacob predicted the superiority of the younger branch (Gen. xlviii.), which in fact played far the greater part in history, occupying in the early days of the settlement in Canaan the part of the central mountain land (Mount Ephraim) where the head-quarters of armed Israel and the sanctuary of the ark stood (at Shiloh), and in later times holding the kingship, and greatly excelling Manasseh in numerical strength (Deut. xxxiii. 17). During the conquest, perhaps, the separation of the two branches of Joseph was not so well marked as it afterwards became, for the ancient narrative of Josh. xvii. 14 *sq.* represents the whole house of Joseph as acting together, establishing itself in the uncleared forests of the central mountains till it had strength to contend with the iron chariots of the Canaanites about Bethshean, and in the cities of the rich plain of Jezreel. These cities probably were not all subdued till the days of David or Solomon (Jud. i. 27; 1 Sam. xxxi. 10; 1 Kings ix. 15); they ultimately fell to Manasseh, which held the northern part of the hill country of Joseph, overlooking the plain, and finally encroached on lands once reckoned to the less warlike tribes of Asher and Issachar (Josh. xvii. 11). But the line of division between Ephraim and Manasseh was not always the same, and in the time of Gideon, the great hero of Manasseh, and the man under whom the seniority of the tribe had a real meaning, Shechem itself was a Manassite dependency (Jud. viii. 31, ix.; comp. Num. xxvi. 31; Josh. xvii. 2). Besides their western settlements in the fertile glades of northern Samaria, running out into the great plain, the Manassites had broad territories east of the Jordan in the pasture land of Bashan and Gilead, mainly occupied by a clan named Machir, and reckoned as the first-born of Manasseh. On the probability that these territories were colonies from the west see vol. xiii. p. 401.

The outlying Manassites had many struggles with their foreign neighbours; 1 Chron. ii. 23 speaks of the loss of sixty cities to Geshur and the Aramæans (A. V. mistranslates). After suffering much at the hands of Damascus, they were carried into captivity by Tiglath Pileser (734 B.C.). The captivity of their brethren in the west followed some thirteen years later.

The name Manasseh (מְנַשֶּׁה, he who causes to forget) is referred in Gen. xli. 51 to Joseph's joy at the birth of the son who caused him to forget his sorrows and cease to long for his home. Unlike the other tribal names, it occurs as a personal name before the captivity, being that borne by the son and successor of Hezekiah, the godless king whose sins are designated as the decisive cause of the rejection of the kingdom of Judah.

MANATEE, an animal belonging to the order *Sirenia*, for the general characters and position of which see MAMMALIA (p. 389). The name *Manati* was apparently first applied to it by the early Spanish colonists of the West Indies, in allusion to the hand-like use which it frequently makes of its fore limbs; by English writers from the time of Dampier (who gives a good account of its habits) downwards it has been generally spelt "Manatee." It was placed by Linnæus in his heterogeneous genus *Trichechus*, but Storr's name *Manatus* is now generally accepted for it by zoologists. The question of the specific distinction of the African and American Manatees will be treated of further on, but it will be chiefly to the latter and better known form that the following description applies.

The size of the Manatee has been much exaggerated, as there is no trustworthy evidence of its attaining a greater length than 8 or perhaps 9 feet. Its general external form may be seen in the figure at p. 390 of the present volume, taken from a living example in the Brighton Aquarium. The body is somewhat fish-like, but depressed and ending posteriorly in a broad flat shovel-like horizontal tail, with rounded edges. The head is of moderate size, oblong, with a blunt, truncated muzzle, and divided from the body by a very slight constriction or neck. The fore limbs are flattened oval paddles, placed rather low on the sides of the body, and showing externally no signs of division into fingers, but with a tolerably free motion at

FIG. 1.—Front View of Head of American Manatee, showing the eyes, nostrils, and mouth. A, with the lobes of the upper lip divaricated; B, with the lip contracted. From Murie, *Trans. Zool. Soc.*, vol. xi.

the shoulder, elbow, and wrist joints, and with three diminutive flat nails near their extremities. No traces of hind limbs are discernible either externally or internally; and there is no dorsal fin. The mouth is very peculiar, the tumid upper lip being cleft in the middle line into two lobes, each of which is separately movable, as will be described in speaking of its manner of feeding. The nostrils are two semilunar valve-like slits, at the apex of the muzzle. The eyes are very minute, placed at the sides of the head, and with a nearly circular aperture with wrinkled margins. The external ear is a minute orifice situated behind the eye, without any trace of pinna. The skin generally is of a dark greyish colour, not smooth or glistening, like that of the *Cetacea*, but finely wrinkled. At a little distance it appears naked, but a close inspection, at all events in young animals, shows a scanty covering of very delicate hairs, and both upper and under lips are well supplied with short, stiff bristles.

The skeleton is remarkable for the massiveness and extreme density of most of the bones of which it is composed, especially the skull and ribs. The cervical region of the vertebral column is short, and presents the great peculiarity of containing only six bones instead of seven, the number usual in the *Mammalia*,—the only other case being that of one species of Sloth (*Cholœpus hoffmanni*). Another great peculiarity (which, however, seems to be characteristic of all the *Sirenia*) is that the flat ends of the bodies of the vertebræ do not ossify separately, so as to form disk-like epiphyses in the young state. None of the vertebræ are united together to form a sacrum, the rudimentary pelvic bones having no direct connexion with the vertebral column. The number of rib-bearing vertebræ appears to vary in different individuals from fifteen to eighteen, and those of the lumbar and caudal region from twenty-five to twenty-nine. The skull (fig. 2) is exceed-

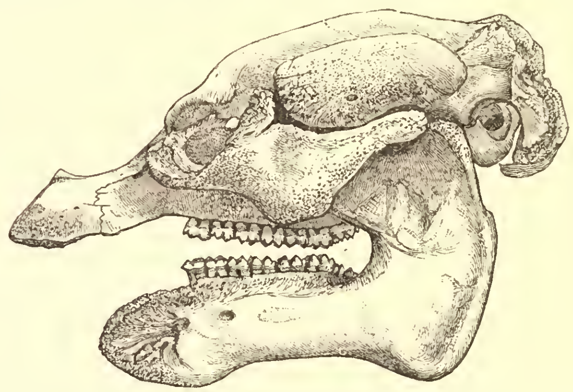

FIG. 2.—Skull of African Manatee (*Manatus senegalensis*). × ⅕. From Mus. Roy. Coll. Surgeons.

ingly different from that of any of the Whales or Dolphins (order *Cetacea*), with which the Manatee was formerly supposed to be allied. The cerebral cavity is rather small as compared with the size of the animal, and of oblong form; its roof is formed of the parietal bones as in ordinary mammals. The squamosal has an extremely large and massive zygomatic process, which joins the largely developed malar bone in front. The orbit is small, but prominent and nearly surrounded by bone. The anterior nares taken together form a lozenge-shaped aperture, which looks upwards and extends backwards considerably behind the orbits. Their sides are formed by the ascending processes of the premaxillæ below, and by the supraorbital processes of the frontals above, no traces of nasals being found in most skulls, though these bones are occasionally present in a most rudimentary condition, attached to the edges of the frontals, far away from the middle line, a position quite unique among the mammalia. In front of the narial aperture the face is prolonged into a narrow rostrum, formed by the premaxillæ, supported below and at the sides by the maxillæ. The under surface of this is very rugous, and in life covered by a horny plate. The rami of the mandible are firmly united together at the symphysis, which is compressed laterally, deflected, and has a rugous upper surface; to this another horny plate is attached, which with that of the upper jaw functionally supplies the place of teeth in the anterior part of the mouth. In the young state there are rudimentary teeth concealed beneath these horny plates, which never penetrate through them, and must therefore be quite functionless, and altogether disappear before the animal is full-grown. There is besides, on each side of the hinder part of both upper and lower jaws, a parallel row of molar teeth, similar in characters from the beginning to the end of the series, with square enamelled crowns raised into tuberculated transverse ridges, something like those of the Tapir and Kangaroo. The upper teeth have two ridges and three roots; the lower teeth have an additional posterior small ridge or talon, and but two roots. These teeth succeed each other from before backwards, as in the *Proboscidea*, those at the front of the mouth being worn out and shed before those at the back are fully developed. There are altogether about eleven on each side of each jaw, but rarely more than six are present at one time. The brain is remarkably simple in structure, its hemispheres exhibiting none of the richness of convolution so characteristic of the *Cetacea*. The stomach is compound, being divided by a valvular constriction into two principal cavities, the first of which is provided with a singular glandular pouch near the cardiac end, and the second with a pair of elongated, conical cæcal sacs or diverticula, the use of which is by no means obvious. The cæcum is bifid. The kidneys are simple. The heart is broad and flat, with the apex deeply cleft between the ventricles. The principal blood-vessels form very extensive and complex *retia mirabilia*. The lungs are remarkably long and narrow, as owing to the very oblique position of the diaphragm the thoracic cavity extends very far back over the abdomen. The mammary glands of the female are two in number, situated just behind and to the inner side of the origin of the pectoral limb. The red corpuscles of the blood are among the largest of those of any members of the class, averaging in diameter, according to Gulliver, $\frac{1}{2400}$ of an inch.

Manatees pass the whole of their life in the water, inhabiting bays, lagoons, estuaries, and large rivers, but the open sea, so congenial to the *Cetacea*, is quite unsuited to their peculiar mode of life. As a general rule they prefer shallow water, in which, when not feeding, they lie near the bottom, supporting themselves on the extremity of the tail, or slowly moving about by the assistance of the fore limbs, the tips of which are just allowed to touch the ground, and only raising the top of the head above the surface for the purpose of breathing at intervals of two or three minutes. In deeper water they often float, with the body much arched, the rounded back close to the surface, and the head, limbs, and tail hanging downwards. The air in the lungs obviously assists them to maintain this position, acting in the same manner as that in the air-sac of fishes. Their food consists exclusively of aquatic plants, on which they browse beneath the water much as terrestrial Ungulates do on the green pastures on shore. They are extremely slow and inactive in their movements, and perfectly harmless and inoffensive, but are subject to a constant persecution from the inhabitants of the countries in which they dwell for the sake of their oil, skin, and flesh. Frequent attempts have of late been made to keep specimens alive in captivity, and sometimes with considerable success, one having lived in the Brighton Aquarium for upwards of sixteen months. It was fed chiefly on lettuce and endives, but would also eat leaves of the dandelion, sow-thistle, cabbage, turnip, and carrot. From this and other captive specimens some interesting observations upon the mode of life of the animal have been made. One of these is the free use it makes of its fore-limbs. From the shoulder-joint they can be moved in all directions, and the elbow and wrist permit of free extension and flexion. In feeding they push the food towards their mouths by means of one of the hands, or both used simultaneously, and any one who has seen these members thus employed can readily believe the stories of their carrying their young about under their arms. Still more interesting and quite unique among Mammals is the action of the peculiar lateral pads formed by the divided upper lip, thus described by Professor Garrod:—"These pads have the power of transversely approaching towards and receding from one another simultaneously (see fig. 1, A and B). When the animal is on the point of seizing (say) a leaf of lettuce, the pads are diverged transversely in such a way as to make a median gap of considerable breadth. Directly the leaf is within grasp the lip-pads are approximated, the leaf is firmly seized between their contiguous bristly surfaces, and then drawn inwards by a backward movement of the lower margin of the lip as a whole." The animal is thus enabled by the unaided means of the upper lip to introduce food placed before it without the assistance of the comparatively insignificant lower lip, the action greatly recalling to the observer that of the mouth of the silkworm and other caterpillars in which the mandibles diverge and converge laterally during mastication. When out of water the Manatee is an extremely helpless animal; and, although statements are frequently met with in books of its voluntarily leaving the water for the purpose of basking or feeding on shore, all trustworthy observations of those acquainted with it, either in a state of nature or in captivity, indicate that it has not the power of doing so. None of the specimens in confinement have been observed to emit any sound.

Manatees, though much less numerous than formerly, are still occasionally found in creeks, lagoons, and estuaries in some of the West India Islands, and at various spots on the Atlantic coast of America from Florida as far south as about 20° S. lat., and in the great rivers of Brazil, almost as high as their sources. They are also met with in similar situations on the opposite African coast, from about 16° N. to 10° S. lat., and as far into the interior as Lake Tchad. Its range may even extend, if native reports obtained by Schweinfurth are correctly interpreted, to the river Keebaly, 27° E. long.

The American Manatee (*M. australis*, Tilesius) was thought by Dr Harlan to be divisible into two species, one inhabiting Brazil and the other the West Indies and Florida. To the northern form he gave the name of *M. latirostris*, but the distinction is not now generally recognized. On better grounds the African Manatee was separated by Desmarest, under the name of *M. senegalensis*, and there are certainly constant although not very important cranial characters by which it can be distinguished from its American congener, among which the following may be cited:—the anterior part of the rostrum is shorter, shallower, and altogether smaller; the orbit is smaller; the zygomatic process is more deep and massive; the malar bone is deeper from above downwards; the upper margin of the anterior nares is narrower and with a smooth and rounded instead of a thin and serrated edge; the upper surface of the frontal is flat, instead of concave; the foramen magnum and occipital condyles are narrower from side to side, and the symphysis of the mandible smaller and shallower.

For an account of the animals most nearly allied to the Manatee, the Rhytina, or "Northern Manatee" as it is sometimes called, and the Dugong, as well as the various extinct kindred forms, see MAMMALIA, pp. 390, 391.

MÁNBHÚM, a district in the lieutenant-governorship of Bengal, India, lying between 22° 37′ and 24° 3′ N. lat., and 85° 51′ and 87° 16′ E. long., is bounded on the N. by Hazáribágh and Bírbhúm, on the E. by Bardwán and Bánkura, on the S. by Singbhúm and Midnapur, and on the W. by Lohárdagá and Hazáribágh. It has an area of 4147 square miles. The headquarters station is at Purulia. Mánbhúm district forms the first step of a gradual descent from the table-land of Chutiá Nágpur to the delta of lower Bengal. In the northern and eastern portions the country is open, and consists of a series of rolling downs, dotted here and there with isolated conical hills. The soil is for the most part composed of hard, dry, ferruginous gravel, but many of the lower levels are filled with good alluvial soil, which yields a fine rice crop. In the western and southern tracts the country is more broken, and the scenery much more picturesque. The principal hills are Dalmá (3407 feet), the crowning peak of a range of the same name; Gangábarí or Gajboro (2220 feet), the highest peak of the Baghmúndí range, about 20 miles south-west of Purulia; and Pánchkot or Pánchet (1600 feet), on the summit of which stands the old palace of the rájás of Pánchet. The hills are all covered with dense jungle. The chief river is the Kasái, which flows through the district from north-west to south-east into Midnapur, and on which a considerable floating trade in *sál* timber is carried on. The useful timber found in Mánbhúm is very limited in quantity, and with the present rate of decrease the supply cannot last many years. Tigers, leopards, bears, wolves, and jackals are not uncommon; various kinds of deer abound; and bison are occasionally met in the south of the district. Elephants come every year from the south-east into the hilly country between Mánbhúm and Singbhúm.

The census of 1872 returned the population at 820,521. The aboriginal tribes numbered about 100,000, Hindus nearly 700,000, and Mohammedans about 30,000. In 1881 the population was 1,042,117. A large proportion of the aborigines are now semi-Hinduized. The most numerous aboriginal tribe are the Santáls; but the Bhúmíj Kols are the characteristic aboriginal race. In Mánbhúm they inhabit the country lying on both sides of the Subarnarekhá. They are pure Mundas, but their compatriots to the east have dropped the title of Munda and the use of their distinctive language, have adopted Hindu customs, and are fast becoming Hindus in religion. The Bhúmíj Kols of the Jungle Mahál's were once the terror of the surrounding districts; they are now a more peaceful tribe, but have lost to a great extent the simplicity and truthfulness of character for which their cognates are generally distinguished. Among high-caste Hindus about 50,000 are Bráhmans and 16,000 Rájputs. The Kevmús, who are agriculturists, form the most numerous caste in the district. The Christian population numbers about 600, most of whom are engaged in agriculture. Mánbhúm is a thoroughly rural district, and contains only two towns with upwards of 5000 inhabitants, namely Purulia and Raghunáthpur, and three others with over 2000, namely Jhálidá, Kásípur, and Mánbázár.

Three principal crops of rice are grown, one sown broadcast early in May on table-lands and the tops of ridges, an autumn crop, and a winter crop, the last forming the chief harvest of the district. Other crops are wheat, barley, Indian corn, pulses, oilseeds, linseeds, jute, hemp, sugar-cane, indigo, pan, and tobacco. Owing to the completeness of the natural drainage floods are unknown, but the country is liable to droughts caused by deficient rainfall. The principal articles of export are oilseeds, pulses, *ghi*, lac, indigo, tasar silk (manufactured near Raghunáthpur), timber, resin, coal, and (in good seasons) rice. The chief imports are salt, piece goods, brass utensils, and unwrought iron. Cotton hand-loom weaving is carried on all over the district. Coal is found at Iharia, a few miles from Parasnáth. The total revenue of Mánbhúm district in 1881 amounted to £25,760, of which £7562 was obtained from land, and £6424 from excise. The schools in 1877 numbered 392, with 9616 pupils. The climate of the district is fairly healthy. The average rainfall for the ten years ending 1880–81 was 55·95 inches.

MANCHA, La. This name, when employed in its widest sense, denotes that bare and monotonous elevated plateau of central Spain which stretches between the mountains of Toledo and the western spurs of the hills of Cuenca, being bounded on the S. by the Sierra Morena and on the N. by the Alcarria, which skirts the upper course of the Tagus. It thus comprises portions of the modern provinces of Toledo, Albacete, and Cuenca, and almost the whole of Ciudad Real. Down to the 16th century the eastern portion was known as La Mancha de Montearagon or de Aragon, and the western simply as La Mancha; afterwards the north-eastern and south-western sections respectively were distinguished by the epithets "Alta" and "Baja" (upper and lower). La Mancha was created a province in 1691; its officially recognized boundaries have since that time varied considerably, and in common parlance it is often now identified with the modern province of Ciudad Real. Ciudad Real, which is bounded on the N. by Toledo and Cuenca, on the E. by Albacete, on the S. by Jaen and Cordova, and on the W. by Badajoz, ranks next to Badajoz and Caceres in point of extent, containing an area of 7840 square miles. The population in 1877 was 260,641. From the scarcity of water and the absence of trees and fences, as also from the circumstance of the rural population being concentrated only at certain points, it as a whole presents to the traveller the arid and cheerless aspect of a desert. The principal river is the Guadiana, which rises in the so-called Ojos ("Eyes") del Guadiana in the north-east, and is joined by the Azuer and the Jabalon on the left, and by the united waters of the Zancara and Giguela on the right. No advantage, unfortunately, is taken of these or any of the other streams in the province for irrigation, the inhabitants depending entirely on the meagre and precarious rainfall. A peculiarity of the province is the facility with which water can be reached by digging; but neither has this resource been turned to much account. The mineral wealth of the province (lead, copper, iron, antimony, coal) is great, the cinnabar mines of Almaden, in particular, which were known to the ancients, being the chief European source for the supply of quicksilver. Saltpetre is obtained in several places, especially in the north (Herencia and Alcazar de San Juan), and there are quarries of fine stone at Santa Cruz and elsewhere. The crops, when not interfered with by drought and locusts, the two scourges of La Mancha, are very large; they include wheat, barley, rye, chick pease, wine (that of Valdepeñas being especially famous), vinegar, and brandy, some oil, saffron, esparto, flax, and silk. The mules reared in the province are considered the best in or out of Spain. There are manufactures of woollen fabrics, lace, earthenware, cutlery, saltpetre, gunpowder, and soap. The lace of Almagro is much appreciated throughout the peninsula. The province is traversed by the Madrid and Cordova Railway, which enters near Alcazar de San Juan and passes through Manzanares and Valdepeñas, entering Jaen at the Venta de Cardenas in the Sierra Morena. The Madrid and Badajoz line passes through Ciudad Real, the capital of the province, which is connected by rail with Manzanares. There are ten judicial partidos,—those of Alcázar de San Juan, Almaden, Almagro, Almodóvar del Campo, Ciudad Real, Daimiel, Infantes, Manzanares, Piedrabuena, and Valdepeñas. The only towns having a population above 10,000 in 1877 were Almodóvar del Campo, Ciudad Real, and Valdepeñas.

MANCHE, a department in the north-west of France, washed by the English Channel (Fr., *La Manche*), from which it derives its name, and made up of the Cotentin, the Avranchin, and part of the Bocage, three districts of the former province of Normandy, lies between 48° 28′ 40″ and 49° 47′ 30″ N. lat., and between 0° 43′ and 1° 54′ 30″ W. long., bounded W., N., and N.E. by the Channel, E. by the department of Calvados, S.E. by Orne, S. by Mayenne and Ille-et-Vilaine. The capital, St Lô, is 159 miles west of Paris. The extreme length from north-west to south-east is 81 miles, the mean breadth from east to west about 28 miles, and the area 2289 square miles.

The department is traversed from south to north by a range of hills, in many parts picturesque, and connected in the south with those of Maine and Brittany. In the country round Mortain, which has been called the Switzerland of Normandy, they rise to a height of 1200 feet, and at Cherbourg their altitude is still from 500 to 600 feet. As a whole the department has an English aspect, with its broken and tide-beaten shores often enveloped in mist, and its ever-verdant meadows. The coast-line, running northward along the bay of the Seine from the rocks of Grand Camp to Cape Barfleur, thence westward to Cape la Hague, and finally southward to the Bay of Mont St Michel, has a length of 200 miles. The Vire and the Taute (which receives the Ouve as a tributary on the left) fall into the sea at the Calvados border, and are united by a canal some miles above their mouths. From the mouth of the Taute a low beach runs to St Vaast la Hougue, where the coast becomes rocky, with sandbanks. Between Cape Barfleur and Cape la Hague lie the roads of Cherbourg, protected by the famous breakwater. The whole western coast is inhospitable; its petty havens, lying behind formidable barriers and reefs, are almost dry at low tide. Great cliffs like the points of Jobourg (420 feet high) and Flamanville alternate with long strands such as that which extends for 30 miles from Cape Carteret to Granville. Between this coast and the Channel Islands the tide, pent up between numerous sandbanks, flows with a terrific force that has given these passages such ill-omened names as *Passage de la Déroute* and the like. The only important harbours are Granville and the haven of refuge of Diélette between Granville and Cherbourg. The chief stream is the Sienne with its tributary the Soulle flowing by Coutances. South of Granville the sands of St Pair are the commencement of the great Bay of Mount St Michel, whose area of 60,000 acres was covered with forest till the terrible tide of the year 709. The equinoctial tides reach a vertical height of nearly 50 feet. Amidst the foam rise the picturesque walls of the abbey, from the summit of a rock 400 feet high. The Sée, which waters Avranches, and the Couesnon (separating Manche from Ille-et-Vilaine) disembogue in the bay.

The climate of Manche is mild and humid from its propinquity to the sea. At Cherbourg, in spite of the northerly exposure, the mean temperature is 3° Fahr. above the mean for that latitude over France. Frosts are never severe; myrtles and fuchsias flourish in the open air. Excessive heat is also unusual; the predominant winds are south-west. Rains are frequent, as the verdure of the country testifies, but they are not violent, the annual rainfall varying from 30 to 34 inches.

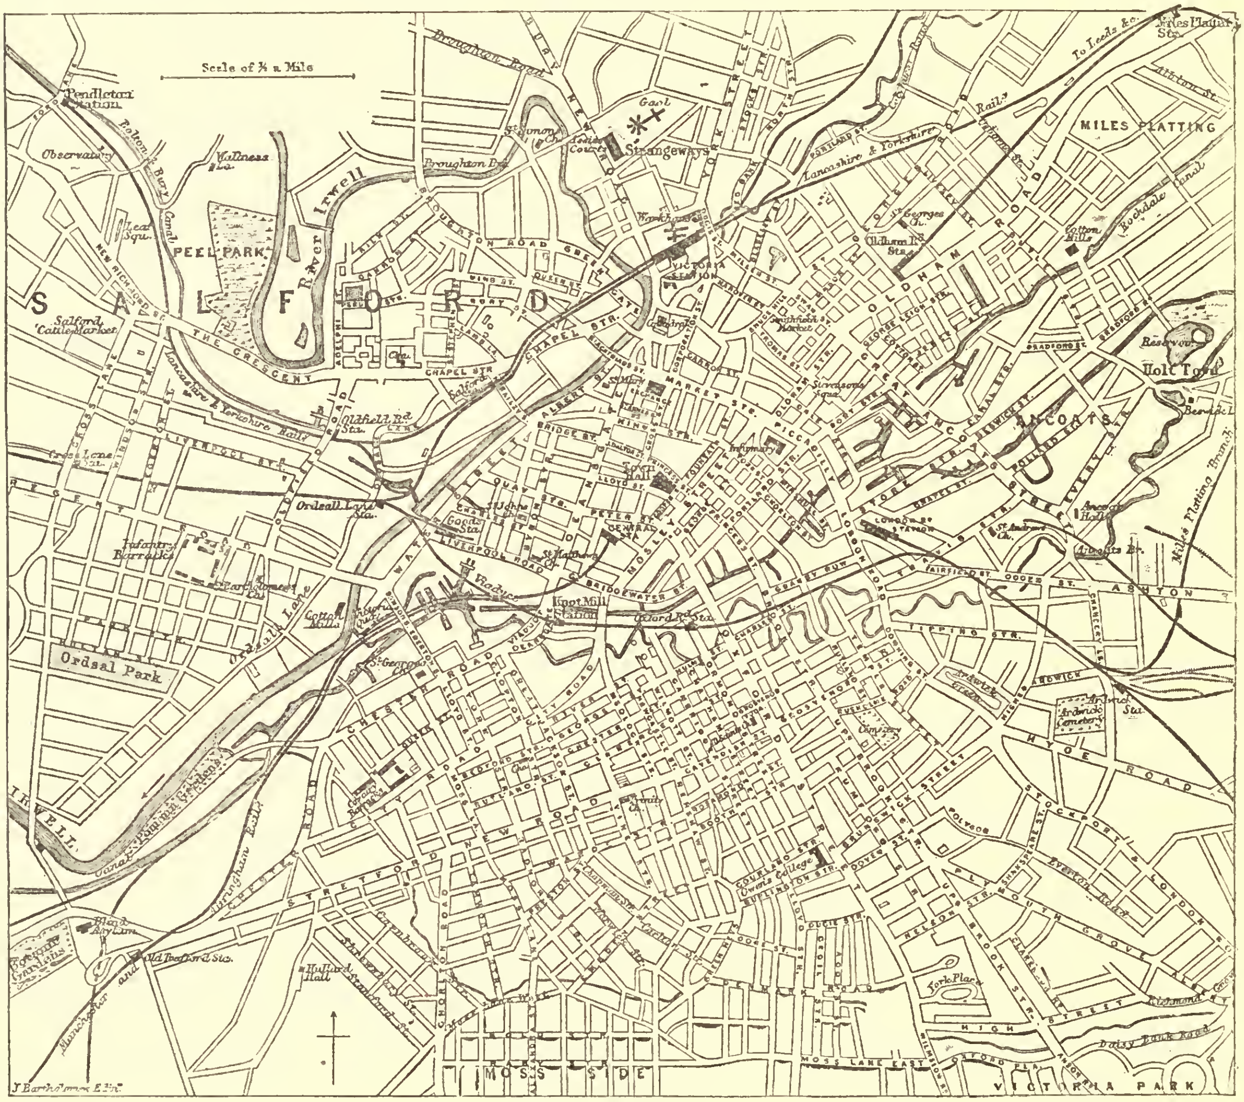
Of the entire area more than the half is arable, 198,000 acres are meadow land, 52,000 are under wood, and 82,000 are heath. The soil is not naturally fertile, but vegetation is promoted by the humidity of the climate and by artificial improvements. The characteristic industry of the department is the rearing of horses and other live stock; the horses number 92,839, besides several thousands of asses and mules, and there are 270,000 horned cattle, 277,000 sheep, upwards of 100,000 pigs, and 40,000 beehives. In 1876 the department yielded 1,458,476 hectolitres of wheat, 83,393 of meslin, 1,014,662 of barley, 427,360 of sarrasin, 484,365 of oats, 52,236 of rye, 683,834 of potatoes, 72,401 of dried legumes, 363,372 of beetroot, and 8758 quintals of hemp; and in the same year there were manufactured 86,088 kilogrammes of linseed oil and 39,380 kilogrammes of colza oil. The arable and meadow lands occupy the eastern portion of the department; legumes are grown in the west, where lands adapted for market gardening purposes are worth as much as 15,000 francs per hectare. Manche has a larger production of cider than any other department of France (upwards of 28,000,000 gallons). Besides apples, pears, plums, cherries, and figs are grown. The fields are lined with rows of oak, elm, and beech, which furnish good timber for building purposes. The aspen, poplar, walnut, and chestnut are also common. Some attempts at reclamation have been made along the sea-shore. The department contains valuable granite quarries in the Cherbourg arrondissement and the Chausay Islands; there are also deposits of carboniferous marble, kaolin, talc, and of calcareous sand ("tangue") used as manure. There are smiths' forges and iron foundries, important brass foundries, and establishments for the manufacture of tools, needles, and other kinds of hardware. The port and arsenal of Cherbourg is very complete in all its appointments. The department has 45 wool-spinning factories with 13,123 spindles, and 6 cotton-spinning mills with 50,000 spindles; and cloth-making, paper-making, tanning, and other industries are carried on. On the coast there are important beds for oyster culture, and the maritime population, when not engaged in the pursuit of the herring, mackerel, or lobster, collect ware and sea-grass. The shipping of Manche amounts to some 4600 vessels, with an aggregate tonnage of 29,000 tons; the exports consist of butter, eggs, poultry, live stock, legumes, meat, fish, horses, grain, stone, brasiery, and hardware. The population in 1876 was 539,910. There are six arrondissements (St Lô, Avranches, Cherbourg, Coutances, Mortain, Valognes), 48 cantons, and 643 communes; the capital is St Lô.

MANCHESTER, a city whose industries are famous throughout the civilized world, is situated in the south-eastern corner of Lancashire, and forms the centre of the towns and villages which constitute the great English cotton district.

The city of Manchester and the borough of Salford are about 180 miles north-west of London, and lie in 53° 29′ N. lat., 2° 14′ 23″ W. long. The sister towns stand for the most part on a level plain, the rising ground being chiefly on the north side. The rivers are the Irwell, the Medlock, the Irk, and the Tib, the last entirely overarched and covered by streets and warehouses. The Irwell, which separates Manchester from Salford, is crossed by a series of bridges; it has here an average width of 91 feet and an average depth of about 7 feet; and it discharges itself into the Mersey, which is about ten miles distant. The chief part of the district, before it was covered with the superficial drift of sand, gravel, and clay, consisted of upper New Red Sandstone with slight portions of lower New Red Sandstone, magnesian marls and upper red marls, hard sandstone and limestone rock, and cold clays and shales of contiguous coal-fields. The town, as its thousands of brick-built houses show, has been for the most part dug out of its own fields of clay. The parliamentary borough of Manchester has an area of 6349 acres; the municipal area is 4294 acres. The parliamentary and municipal boundaries of Salford are identical, and have an area of 5208 acres.

Parks and Statues.—Of the parks and open spaces the principal is the Peel Park in Salford, containing an area of about 40 acres. In its centre is the building containing the Salford library, and also a valuable museum of natural history and a collection of paintings known as the Langworthy gallery (built and endowed by the late Mr E. R. Langworthy, a wealthy Manchester merchant). Among the notable pictures may be named the Last Sleep of Argyll and the Execution of Montrose, by Mr E. M. Ward. Seedley Park, Ordsall Park, and Albert Park have been recently constructed, and are situated in Salford,—where also is the Kersal Moor, a bit of wild moorland, some 21 acres in extent, now under the care of the corporation of Salford. The moor has long been noted for the richness of its flora, about one-eighth of the English flowering plants having been gathered on its very limited area. It has also been the scene of an entomological incident of some interest—the capture of the *Œcophara Woodiella*, of which there is no other recorded habitat. The Queen's Park at Harpurhey is pleasantly situated, notwithstanding that it is now completely surrounded by cottages and manufactories. In the centre is a small museum, the chief interest of which depends upon a series of phrenological casts made by Gall and Spurzheim and completed by Bally. Philips Park is also attractive, notwithstanding its close proximity to some of the densest portions of the town. The principal parks so far named were constructed from money obtained by a public subscription in 1846, but the Alexandra Park at Moss Side has been entirely paid for out of the public rates. It has very good ornamental grounds, but owing to the difficulties of the situation the construction has been somewhat costly. In this connexion may be mentioned the Botanical Gardens, which are situated at Old Trafford, and, although intended chiefly for the subscribers, are open at certain times to the public on liberal terms.

Manchester is not remarkable for the number of its public memorials of the dead; but it possesses some which should not be passed unnoticed. In front of the infirmary are bronze statues of Wellington, Watt, Dalton, and Peel. A bronze statue of Cobden occupies a prominent position in St Ann's Square. The marble statue of the Prince Consort, covered by a Gothic canopy of stone, is placed in Albert Square, in proximity to the town-hall, the enormous proportions of which have the effect of dwarfing what would otherwise be a striking monument. The most picturesque is the bronze statue of Cromwell, on a huge block of rough granite as pedestal. In the Peel Park are statues of Queen Victoria, the Prince Consort, Sir Robert Peel, and Joseph Brotherton.



Plan of Manchester.

Public Buildings.—There are many fine public buildings in Manchester. Among them may briefly be noticed the royal infirmary, consisting of three sides of a quadrangle, one of which owes its existence to the benevolence of Jenny Lind, who gave two concerts in order to raise the necessary funds. The institution will accommodate about two hundred and sixty patients. The royal exchange is a fine specimen of Italian architecture, and was erected in 1869; the great meeting-hall is one of the largest rooms in England, the ceiling having a clear area, without supports, of 120 feet in width. The exchange is seen at its best on market days (Tuesday and Friday), when representatives from all parts of Lancashire, and indeed of the neighbouring counties, are earnestly engaged in buying and selling. The assize courts were built in 1864 from designs by Waterhouse. The style is a mixture of Early English and Decorative, and a large amount of decorative art has been expended on the building. The cost was about £100,000. The New Bailey prison, intended for the criminals of Salford hundred, was built (1787) in accordance with the suggestions of Howard, the prison philanthropist, but in 1868 the present structure, at the rear of the assize courts, was erected. The style of architecture is Norman, and the building, which covers 9 acres, cost £170,000. The city jail is situated in Hyde Road. The old town-hall was built in 1832, in imitation of the Erectheum of Athens, at a cost of £40,000; it is now occupied by the town library. The business of the city is conducted in the new town-hall, probably beyond dispute the most important municipal building in the kingdom, if not in Europe. It was completed in 1877, from designs by Waterhouse, who selected as the style of architecture a form of Gothic, but treated it very freely as purposes of utility required. The edifice covers 8000 square yards, and includes more than two hundred and fifty rooms. The triangular or flat-iron form of the site was a great difficulty, but the architect has skilfully surmounted it. The building consists of continuous lines of corridors surrounding a central courtyard and connected by bridges. The principal tower is 260 feet high, and affords a view which extends over a large part of South Lancashire and Cheshire, and is bounded only by the hills of Derbyshire. It contains a remarkable peal of bells by Taylor of Loughborough, forming an almost perfect chromatic scale of twenty-one bells; each bell has on it a line from section 105 of Tennyson's *In Memoriam*. The great hall is 100 feet long and 50 feet wide, and contains a magnificent organ built by Cavaillé-Coll of Paris. The panels of this room are being filled with mural paintings illustrating the various incidents connected with the history and progress of the city. The total cost of the building has been £1,053,264, inclusive of £201,925 for interest. The branch Bank of England is a Doric building designed by Cockerell. The Salford town-hall is also Doric; and there are besides separate town-halls for the townships of Ardwick, Chorlton, Hulme, Cheetham, Broughton, and Pendleton. The Free Trade hall is a fine structure in the Lombardo-Venetian style, and its great hall will accommodate five thousand people. It is used for public meetings, concerts, &c., and was built by Walters. The young men's Christian association hall was originally used as a natural history museum. The Royal Institution, built by Sir Charles Barry, is a proprietary institution intended for the encouragement chiefly of the fine arts. In the entrance hall are casts of the Elgin Marbles, given by George IV., and a statue of Dalton by Chantrey. There is a small permanent gallery, and periodical exhibitions of pictures are held and courses of lectures delivered. Arrangements have now (1882) been concluded by which the institution will become the property of the town and be managed by a joint committee of members of the town council and others interested in art and literature. The Athenæum, also designed by Barry, was founded by Richard Cobden and others associated with him, for "the advancement and diffusion of knowledge." The institution has, perhaps, not developed exactly on the lines contemplated by its promoters, but it has become one of the most useful in the town. All the advantages enjoyed by members of high-class social clubs, with the addition of facilities for educational classes and the use of an excellent news-room and a well-selected library of 18,000 volumes, are offered in return for a payment which does not amount to a penny a day. The mechanics' institution contains a library of 17,000 volumes, and has connected with it excellent day and evening schools, and classes for technical instruction. The Portico is a good specimen of the older proprietary libraries and news-rooms. It dates from 1806, and has a library of 20,000 volumes. The Memorial Hall was built to commemorate the memory of the Nonconformist ejected ministers of 1662. The Unitarian home missionary board has here its library and rooms for the education of students; and the building is used for a variety of meetings, scientific, educational, musical, and religious. The inconvenience arising from inadequate provision for postal service is, after many years of hesitation, to be remedied by the erection, now (1882) in progress, of a commodious post-office.

Means of Communication.—The opening of the Manchester and Liverpool Railway in 1830 marked an important epoch in the history of modern industry, and since that time Manchester has gradually been connected by rail with every part of the kingdom. The enormous traffic by this means has not, however, entirely superseded the use of the canals, which formerly played so important a part in the cotton industry. The construction of the Bridgewater Canal in 1761 was an event second in importance only to that of the introduction of the railway system. There are three large railway stations, Victoria, London Road, and the Central, and several minor ones. The excellence of the omnibus system of the city was perhaps one principal cause for the somewhat tardy adoption of tramways; but these have now rapidly developed, and ensure facilities for transit between the different parts of the city and also for communication with the neighbouring towns and villages. The establishment of a ship canal to connect Manchester with the sea has been frequently suggested at intervals for the last sixty years, and a scheme of tidal navigation elaborated by Mr Hamilton Fulton is now (1882) being actively discussed.

Water Supply.—This is under the control of the corporation, which supplies not only the citizens but the surrounding populations. The gathering-ground is a series of reservoirs in the valley of Longdendale, chiefly along the course of the river Etherow. Woodhead, the chief reservoir, 20 miles from Manchester, is 777 feet above sea-level, is 72 feet deep, covers an area of 155 acres, and has a capacity of 1,235,000,000 gallons. The present system of waterworks, including the portions now being constructed at Audenshaw and Denton, have an area of reservoirs of 854½ acres, and a capacity of holding 5,914,000,000 gallons. The average daily supply of water was in 1855 8,078,152 gallons; in 1881 it was 18,929,704 gallons. In 1877 the water committee announced that in view of the increased demand it would be necessary to obtain additional or fresh sources of supply. The proposal to utilize Thirlmere in Cumberland for this purpose was vehemently opposed, but the scheme was eventually sanctioned by parliament, and the works have been begun, but have not as yet made rapid progress. Thirlmere is 533 feet above the sea, and it is proposed to raise it by an embankment to 584 feet above the sea. From this height it is estimated that a maximum quantity of 50,000,000 gallons might be withdrawn daily.

Lighting.—The corporation not only manufactures gas for the lighting of the city, but sells it to out-districts. The area of distribution amounts to 42 square miles, and the street mains for the gas supply are 597 miles long. The entire assets of the gas-works were valued in September 1881 at £1,386,942. The average quantity of gas transmitted daily was 2,425,630,000 cubic feet. The revenue from the sale of bye-products is about £90,000. Salford, which is supplied with water by Manchester, has its own gas-works, the property of the ratepayers, and managed by a committee of the town council.

Administration of Justice.—The city has a stipendiary magistrate who, in conjunction with lay magistrates, tries cases of summary jurisdiction in the police courts; these are held in a building erected for the purpose, and having some architectural pretensions. There are also quarter sessions, presided over by a recorder. Separate sessions are held for the Salford hundred. Salford has also a police court with a stipendiary magistrate. Certain sittings of the Court of Chancery for the duchy of Lancaster are held in Manchester. In addition to the county court, there is an ancient civil court known as the Salford Hundred Court of Record. Assizes have been held since 1866.

Churches.—The chief ecclesiastical building in Manchester is the cathedral, which, however, hardly corresponds to the ideas usually associated with that word. It was indeed built simply as a parish church, and, although a fine specimen of Perpendicular Gothic, is by no means what might be expected as the cathedral of an important and wealthy diocese. Though there are remains of older work, the bulk of the building belongs to the early part of the 15th century. The first warden was John Huntington, rector of Ashton, who built the choir. The building, which was noticed for its hard stone by Leland when he visited the town, did not stand time and weather well, and by 1845 some portions of it were rapidly decaying. This led to its restoration by Holden, which was not finished until 1868, when the tower was almost completely renovated in a more durable stone than that formerly used. The total length is 220 feet and the breadth 112 feet; the only parish church exceeding it in this last dimension is said to be that of Coventry. There are several stained-glass windows. In the Ely chapel is the altar tomb of Bishop Stanley, the father of the gallant Sir John Stanley, who fought at Flodden Field. In the stalls there are some curious *miserere* carvings. The tower is 139 feet high, and contains a peal of ten bells, chiefly from the foundry of the Rudhalls. There are two organs, one by Father Smith, and a new one erected at a cost of more than £7000, and enclosed in an oak case designed by the late Sir G. Scott. The church endowments are considerable, and have been the subject of a special act of parliament, known as the Manchester Rectory Division Act of 1845, which provides £1500 per annum for the dean, and £600 to each of the four canons, and divides the residue among the incumbents of the new churches formed out of the old parish. There are about one hundred places of worship in Manchester belonging to the Church of England, but they are not especially remarkable. Of the Roman Catholic churches, the most important are the cathedral church of St John in Salford, of the earliest Decorative character, with a spire 240 feet in height, and the church of the Holy Name, which belongs to the Jesuits, and is remarkable for its costly decoration. Salford is the seat of a Roman Catholic bishopric, as Manchester is the seat of an Anglican one. Most of the Nonconformist bodies have churches in the city and its environs. The meeting-house of the Society of Friends is said to be the largest of the kind in the kingdom, and will seat twelve hundred persons.

Literature and Science.—Manchester possesses numerous associations for the cultivation of literature and science. The oldest of these, the Literary and Philosophical Society, founded in 1781, has a high reputation, and has numbered among its working members John Dalton, Eaton Hodgkinson, William Fairbairn, J. P. Joule, H. E. Roscoe, and many other famous men of science. It has published a lengthy series of memoirs and proceedings. The Manchester Literary Club was founded in 1862, and publishes an annual volume of papers. The Manchester Statistical Society was the first society of the kind established in the kingdom, and has issued *Transactions* containing many important papers. The Scientific Students' Association, the Field Naturalists' and Archæologists' Society, the Microscopical Society, the Botanists' Association, the Geological Society, and the Science Association may also be named. Several printing clubs, the Chetham, Record, Holbein, and English Dialect societies, have their headquarters here. Nine daily papers are published, and the journalism of Manchester takes high rank. The periodicals issued are between fifty and sixty in number.

University and Schools.—There are many educational facilities in Manchester and Salford. The oldest school is the Manchester grammar school, which was founded in 1519 by Hugh Oldham, bishop of Exeter, who was a native of Crumpsall, one of the outskirts of the town. The foundation was done "out of the good mind he bore to the county of Lancashire, perceiving that the children thereof, having pregnant wits, were for the most part brought up rudely and idly; that knowledge might be advanced, and that the children might be better taught to love, honour, and dread God and His laws." The master and usher appointed by the good bishop were to teach freely every child and scholar coming to the school, "without any money or reward taken." Some mills were devised for the maintenance of the school, which was further endowed at both the universities by Sarah, duchess of Somerset, in 1692. The school has been reconstituted on a new basis within recent years, and has now two hundred and fifty free scholars, whilst other pupils are received on payment of low fees. Mr E. R. Langworthy bequeathed to it £10,000 as an endowment for scholarships. Among those educated at the grammar school may be mentioned Thomas De Quincey and the late Mr Harrison Ainsworth.

The Owens College was founded in 1846 by John Owens, who left nearly £100,000 to trustees for an institution in which should be taught "such branches of learning and science as were then and might be hereafter usually taught in English universities." The college was opened in 1851, in a house which had formerly been the residence of Cobden, but in 1872 it was removed to its present home, a handsome Gothic building designed by Waterhouse. An appeal made to the public in 1867 in behalf of the college was heartily responded to, and its capital funds now amount to over £400,000. The building is carefully adapted to its purposes; and the chemical laboratory, a separate structure at the rear, is of the completest description. The first bishop of Manchester, Dr J. Prince Lee, who had an interesting library of some 6000 volumes, bequeathed it to the college, which has also received gifts of books and money from various other quarters, and thus has now the nucleus of an important collection. The Royal School of Medicine, which was founded in 1824, and had acquired the reputation of being one of the most successful of the provincial schools, has been amalgamated with the college. The Medical Society has, by an arrangement with the college authorities, deposited its valuable library of 22,000 volumes in the college rooms. The Manchester museum is now the property of the college, and contains the bulk of the specimens gathered by the Geological Society and by the now extinct Natural History Society. A suitable building for the accommodation of the museum has long been a decided want, and is now (1882) about to be undertaken. The growing importance of the Owens College led to the project for a university charter. The proposal was not received without some opposition, but as the result of lengthy discussions and adjustments a scheme was evolved for a university to consist of affiliated colleges, situated in different towns, but having its centre in Manchester; and the charter of the Victoria University was granted in 1880, with full powers to grant degrees except in medicine—an exception which is to be removed. Among the other educational institutions of the district are the Lancashire Independent college, the Primitive Methodist college, the Baptist institute, the St Bede's college (Roman Catholic), the college for women, the Salford college for working men, the school of art, and many minor institutions. The elementary education is controlled by an elected school board. Salford has also a school board. Very nearly the oldest educational institution in the town is the Chetham hospital, a bluecoat school educating one hundred boys; and almost the latest addition to these institutions is a similar institution founded by the late Alderman Nicholls. The schools for the deaf and dumb are situated at Old

Trafford, in a contiguous building of the same Gothic design as the blind asylum, to which Mr Thomas Henshaw left a bequest of £20,000. There is also an adult deaf and dumb institution, containing a news-room, lecture-hall, chapel, &c., for the use of deaf mutes.

Libraries and Museums.—Manchester is well provided with libraries. The Chetham library is sometimes spoken of as the oldest free library in Europe, and certainly its doors have been open without let or hindrance for more than two centuries, and the building which it occupies is almost the only relic now left of ancient Manchester. What had once been the barons' hall, and afterwards the residence of the clergy, was purchased by the trustees of Humphrey Chetham, and by them applied to the purposes of a blue-coat school and library, provision for the foundation and maintenance of which he had made by will. The library, with its quiet and almost monastic corridors, forms a striking contrast to the busy streets without. The contents now amount to about 40,000 volumes, and include many rare manuscripts and curious books, the gem of the collection undoubtedly being a copy of the historical compilation of Matthew Paris, with corrections in the author's handwriting. There is a large collection of matter relating to the history and archæology of Lancashire and Cheshire. A recent addition to its riches in this department is the extensive series of Lancashire manuscripts bequeathed by the late Canon Raines. The collection of broadsides formed by Mr J. O. Halliwell-Phillips, and the library of John Byrom, rich in mystics and shorthand writers, should also be named. In addition to the library, Chetham left provision for the education of a number of poor boys, and the increase in the value of the endowments has raised the number to one hundred, who receive a good English education and are afterwards put to some useful trade or calling. An additional school has recently been erected from designs by Waterhouse, who has been successful in making the new building harmonize with the quaint and sober architecture of the hospital and library. The Manchester Free Libraries were founded by Sir John Potter, who was instrumental in promoting a public subscription from which a building was bought and stocked with books, and then handed over to the town, by whose municipal authorities the libraries have since been not only maintained but materially increased. There is now a reference library containing about 70,000 volumes, including an extensive series of English historical works and a remarkable collection of books of political economy and trade. The chief object has been to make a good working collection for the student and man of letters. But, although the collection of objects dear to the bibliomaniac has not been considered of first importance, the library now includes some literary curiosities of the first rank, among them specimens of the press of Caxton and Wynkyn de Worde. Affiliated to the central consulting library there are six lending libraries, the Hulme library having 17,000 volumes, Ancoats 15,000, Rochdale Road 15,000, Chorlton and Ardwick 17,000, Cheetham 12,000, and Deansgate 18,000. Each lending library has attached to it a commodious reading-room. There are also libraries in connexion with the Athenæum, the mechanics' institution, the Portico, the Owens College, and other institutions. The sister borough of Salford has also adopted the free library system, and possesses at Peel Park a large reference and lending library, whilst additional lending libraries and news-rooms have been opened at Pendleton, Greengate, and Regent Road.

Recreation.—The city has always been noted for its love of theatrical amusements, and the German element in its population has in the last fifty years largely influenced the taste for music by which it is now distinguished. The theatre royal is a patent theatre, and was opened in 1845, its predecessor having been burned in the previous year. It ranks in size with the large metropolitan theatres, and has connected with it memories of nearly all the great actors of the present and past generation. The Prince's theatre was opened in 1864, and is an elegant and beautifully finished structure. The Queen's theatre is a substantial building with but small architectural pretensions. A theatre has recently been opened in Salford. The concert-hall will hold twelve hundred people. There are many musical societies; and amongst other places of amusement may be mentioned the Belle Vue Zoological Gardens, the Pomona Palace, and numerous music-halls, &c.

Population.—According to the census of 1881, the municipal borough of Manchester contains a population of 341,414 (163,475 males, 177,939 females), while the parliamentary borough has 393,585 (189,005 males, 204,580 females). Salford, on the same authority, has 176,235 (84,610 males, 91,625 females). These figures, however, hardly convey the actual facts of the case. Manchester and Salford are as closely joined as London and Southwark, and are surrounded by populous districts quite as much united as the component parts of what the registrar-general styles "Greater London." There has been a seeming decrease in the population of the city, which in 1871 was stated to contain 355,655 persons; but this appearance is fallacious, for, while the progress of city improvements has reduced the number of inhabited houses in the centre, there has been a large influx into Salford, which has increased by 51,432 persons during the last ten years. The two boroughs, with the urban sanitary districts immediately contiguous, have a population of about 800,000 persons. In the Middle Ages there were in Manchester and Salford probably not more than two or three hundred burgesses and their dependants. In 1588 the population was estimated at 10,000, but the parish is here meant. In 1757 the two towns contained 19,839 persons, who by 1773 had increased to 27,246, and by 1783 to over 39,000. At the first census in 1801 Manchester had 75,275, and Salford 14,477. The last four census statements are:—

	Manchester.	Salford.
1851	303,382	63,850
1861	338,722	102,449
1871	351,189	124,801
1881	341,414	176,235

The increase in rateable value has been equally remarkable. In 1815 Manchester was rated at £357,778; in 1882 the estimate was £2,761,469. The corresponding values for Salford were £54,130 and £801,192.

Sanitary Condition.—Manchester, like other towns, grew more rapidly than the provision for its wise government; but determined efforts have been made in the direction of sanitary improvement. The death-rate in 1840 was 34·3; in 1850, 29·6; in 1860, 28·0; in 1861, 30·4; in 1862, 30·3; in 1869, 28·9; in 1870, 26·52; in 1871, 29·8; in 1877, 25·4; in 1880, 24·7; and for nine months of 1881 it was 23·3. Whatever may be the causes of these fluctuations, it is clear that there is still ample room for further improvement. The air laden with the products of the combustion of coal, and the unspeakably filthy rivers, are urgently in need of energetic remedial action.

Manufactures and Commerce.—As has already been stated, Manchester is the centre of the English cotton industry; but in the town itself of late years the tendency has been more and more in the direction of commerce. Owing to the enhanced value of land, many mills and workshops have been removed to the outskirts and to neighbouring villages and towns, so that the centre of Manchester and an ever-widening circle around is now chiefly devoted not so much to production as to the various offices of distribution. Large and handsome warehouses and shops abound, and there is every evidence of quick and opulent life. It would be a mistake, however, to regard Manchester as solely dependent upon the industries connected with cotton. There are other important manufactures which in another community would be described as gigantic. Wool and silk are manufactured on a considerable scale, though the latter industry has for some years been on the decline. The miscellaneous and multifarious articles grouped under the designation of smallwares occupy many hands. Machinery and tools, using the term with its most comprehensive meaning so as to include alike philosophical instruments and steam-engines, are made in vast quantities. The chemical industries of the city are also on a large scale. In short, there are but few important manufactures that are wholly unrepresented. The proximity of Manchester to the rich coal-fields of Lancashire has had a marked influence upon its prosperity; but for this, indeed, the rapid expansion of its industries would have been impossible.

It would probably be difficult to find a community in any part of the world with which Manchester has no commercial relations. The enterprise of its merchants has kept pace with the energy of its manufacturers, and the products of its looms are to be found in every land, though doubtless the supremacy which its cotton goods have held in the markets of the world tends to become more and more abated by the gradually increasing foreign competition.

From figures laid before the Manchester Statistical Society, the money extent of trading operations at this centre has been calculated at about £207,000,000 in 1872 and £318,000,000 in 1881. These figures, though to be taken with certain reservations, indicate approximately the extent of the activity of the city.

The commercial institutions of Manchester are too numerous for detailed description. Its chamber of commerce has for more than sixty years held a position of much influence in regard to the trade of the district and of the nation. There are eleven joint-stock banks, seven of which have their head offices in the town; these banks, besides numerous branches in the surrounding district, have sixteen branches in the town; and there are several private bankers.

Municipality.—The affairs of the town are regulated by a council consisting of sixty-four representatives of the fifteen wards into which the city is divided. The body corporate of sixteen aldermen and forty-eight councillors, who are presided over by the mayor, has shown much enterprise and public spirit in the energy with which it has prosecuted public improvements, and in the business ability with which it has managed the vast undertakings connected with the lighting and water supply of the town. The town council of Salford consists also of sixteen aldermen and forty-eight councillors, and there are fourteen wards.

History.—Very little is known with certainty of the early history of Manchester. It has, indeed, been conjectured, and with some probability, that at Castlefield there was a British fortress, which was afterwards taken possession of by the soldiers of Agricola. It is at all events certain that a Roman station of some importance existed in this locality, and a fragment of the wall still exists. In the last century considerable evidences of Roman occupation were still visible; and from time to time, in the course of excavation (especially during the making of the Bridgewater Canal), Roman remains have been found. The coins were chiefly those of Vespasian, Antoninus Pius, Trajan, Hadrian, Nero, Domitian, Vitellius, and Constantine. The period succeeding the Roman occupation is for some time legendary. As late as the 17th century there was a floating tradition that Tarquin, an enemy of King Arthur, kept the castle of Manchester, and was killed by Launcelot of the Lake. The mention of the town in authentic annals is very scanty. It was probably one of the scenes of the missionary preaching of Paulinus; and it is said (though by a chronicler of comparatively late date) to have been the residence of Ina, king of Wessex, and his queen Ethelberga, after he had defeated Ivor, somewhere about the year 689. Nearly the only point of certainty in its history before the Conquest is that it suffered greatly from the devastations of the Danes, and that in 923 Edward, who was then at Thelwall, near Warrington, sent a number of his Mercian troops to repair and garrison it. In Domesday Book Manchester, Salford, Rochdale, and Radcliffe are the only places named in South-East Lancashire, a district now covered by populous towns. Large portions of it were then forest, wood, and waste lands. Twenty-one thanes held the manor of Salford among them. The church of St Mary and the church of St Michael in Manchester are both named in Domesday, and some difficulty has arisen as to their proper identification. Most antiquaries have considered that the passage refers to the town only, whilst others think it relates to the parish, and that, while St Mary's is the present cathedral, St Michael's would be the present parish church of Ashton-under-Lyne. Manchester and Salford are so closely allied that it is impossible to dis-associate their history. Salford received a charter from Ranulph de Blundeville, in the reign of Henry III., constituting it a free borough, and Manchester in 1301 received a similar warrant of municipal liberties and privileges, from its baron, Thomas Gresley, a descendant of one to whom the manor had been given by Roger of Poictou, who was created by William the Conqueror lord of all the land between the rivers Mersey and Ribble. The Gresleys were succeeded by the De la Warres, the last of whom was educated for the priesthood, and became rector of the town. To avoid the evil of a non-resident clergy, he made considerable additions to the lands of the church, in order that it might be endowed as a collegiate institution. A sacred guild was thus formed, whose members were bound to perform the necessary services at the parish church, and to whom the old baronial hall was granted as a place of residence. The manorial rights passed to Sir Reginald West, the son of Joan Greslet, and he was summoned to parliament as Baron de la Warre. The West family, in 1579, sold the manorial rights for £3000 to John Lacy, who, in 1596, resold them to Sir Nicholas Mosley, whose descendants enjoyed the emoluments and profits to be derived from them until the middle of the present century (1845), when they were purchased by the present town council of Manchester for a sum of £200,000. The lord of the manor had the right to tax and toll all articles brought for sale into the market of the town. But, though the inhabitants were thus to a large extent taxed for the benefit of one individual, they had a far greater amount of local self-government than might have been supposed, and the court leet, which was then the governing body of the town, had, though doubtless in a somewhat rudimentary form, nearly all the powers and functions now possessed by municipal corporations. This court had not only control over the watching and watering of the town, the regulation of the water supply, and the cleaning of the streets, but also had power, which at times was used freely, of interfering with what would now be considered the private liberty of their fellow-citizens. Some of the regulations adopted, and presumably enforced, sound grotesquely at the present day. Thus, no single woman was allowed to be a householder; no person might employ other than the town musicians; and the amount to be spent at wedding feasts and other festivities was carefully settled. Under the protection of the barons the town appears to have steadily increased in prosperity, and it early became an important seat of the textile manufactures. Fulling mills were at work in the district in the 13th century; and documentary evidence exists to show that woollen manufactures were carried on in Ancoats at that period. In 1641 we hear of the Manchester people purchasing linen yarn from the Irish, weaving it, and returning it for sale in a finished state. They also brought cotton wool from Smyrna to work into fustians and dimities. An Act passed in the reign of Edward VI. regulates the length of cottons called Manchester, Lancashire, and Cheshire cottons. These, notwithstanding their name, were probably all woollen textures. It is thought that some of the Flemish weavers who were introduced into England by Queen Philippa of Hainault were settled at Manchester; and Fuller has given an exceedingly quaint and picturesque description of the manner in which these artisans were welcomed by the inhabitants of the country they were about to enrich with a new industry, one which in after centuries has become perhaps the most important industry of the country. The Flemish weavers were in all probability reinforced by religious refugees from the Low Countries. Leland, writing in 1638, describes Manchester as the "fairest, best builded, quickest, and most populous town of Lancashire." The right of sanctuary had been granted to the town, but this was found so detrimental to its industrial pursuits that after very brief experience the privilege was taken away. The college of Manchester was dissolved in 1547, but was refounded in Mary's reign. Under her successor the town became the head-quarters of the commission for establishing the Reformed religion.

In the civil wars, the town was besieged by the Royalists under Lord Strange, but was successfully defended by the inhabitants under the command of a German soldier of fortune, Colonel Rosworm, who complained with some bitterness of their ingratitude to him. An earlier affray between the Puritans and some of Lord Strange's followers is said to have occasioned the shedding of the first blood in the disastrous struggle between the king and parliament. The year 1689 witnessed that strange episode, the trial of those concerned in the so-called Lancashire plot, which ended in the triumphant acquittal of the supposed Jacobites. That the district really contained many ardent sympathizers with the Stuarts was, however, shown in the rising of 1715, when the clergy ranged themselves to a large extent on the side of the Pretender, and was still more clearly shown in the rebellion of 1745, when the town was taken possession of by Prince Charles Edward Stuart, and a regiment, known afterwards as the Manchester regiment, was formed and placed under the command of Colonel Francis Townley. In the fatal retreat of the Stuart troops the Manchester contingent was left to garrison Carlisle, and surrendered to the duke of Cumberland. The officers were taken to London, where they were tried for high treason and beheaded on Kennington Common.

The variations of political action in Manchester had been exceedingly marked. In the 16th century, although it produced both Catholic and Protestant martyrs, it was earnestly in favour of the Reformed faith, and in the succeeding century it became indeed a stronghold of Puritanism. Yet the descendants of the Roundheads who defeated the army of Charles I. were Jacobite in their sympathies, and by the latter half of the 18th century had become imbued with the aggressive form of patriotic sentiment known as anti-Jacobinism, which showed itself chiefly in dislike of reform and reformers of every description. A change was, however, imminent. The distress caused by war and taxation, towards the end of the last and the beginning of the present century, led to bitter discontent, and the anomalies existing in the parliamentary system of representation afforded only too fair an object of attack. While single individuals in some portions of the country had the power to return members of parliament for their pocket boroughs, great towns like Manchester were entirely without representation. The injudicious conduct of the authorities, also, led to an increase in the bitterness with which the working classes regarded the condition of society in which they found themselves compelled to toil with very little profit to themselves. Their expressions of discontent, instead of being wisely regarded as symptoms of disease in the body politic, were looked upon as crimes, and the severest efforts were made to repress all expression of dissatisfaction. This foolish policy of the authorities reached its culmination in the affair of Peterloo, which may be regarded as the starting point of the modern reform agitation. This was in 1819, when an immense crowd assembled on St Peter's Fields (now covered by the Free Trade hall and warehouses) to petition parliament for a redress of their grievances. The authorities had the Riot Act read, but in such a manner as to be quite unheard by the mass of the people; and drunken yeomanry cavalry were then turned loose upon the unresisting mass of spectators. The yeomanry appear to have used their sabres somewhat freely; several people were killed and many more injured; and, although the magistrates received the thanks of the prince regent and the ministry, their conduct excited the deepest indignation throughout the entire country. Naturally enough, the Manchester politicians took an important part in the reform agitation, and when the Act of 1832 was passed, the town sent as its representatives the Right Hon. C. P. Thomson, vice-president of the Board of Trade, and Mr Mark Philips. With one notable exception, this was the first time that Manchester had been represented in parliament since its barons had seats in the House of Peers in the earlier centuries. In 1654 Mr Charles Worsley and Mr R. Radcliffe were nominated to represent it in Cromwell's parliament. Worsley was a man of great ability, and must ever have a conspicuous place in history as the man who carried out the injunction of the Protector to "remove that bauble," the mace of the House of Commons. The agitation for the repeal of the corn laws had its headquarters at Manchester, and the success which attended it, not less than the active interest taken by its inhabitants in public questions, has made the city the home of various projects of reform. The "United Kingdom Alliance for the suppression of the liquor traffic" was founded there in 1853, and during the continuance of the American War the adherents both of the North and of the South deemed it desirable to have organizations to influence public opinion in favour of their respective causes. A charter of incorporation was granted in 1838; a bishop was appointed in 1847; and the town became a city in 1853. The Lancashire cotton famine, caused by the civil war in America, produced much distress in the Manchester district, and led to a national movement to help the starving operatives. The relief operations then organized are amongst the most remarkable efforts of modern philanthropy.

Although several excellent books have been written on subjects connected with the town, there is no adequate modern history. The *History of Manchester*, by the Rev. John Whitaker, appeared in 1771; it is a mere fragment, and, though containing much important matter, requires to be very discreetly used. The following may be recommended:—Reilly, *History of Manchester*, 1861; Procter, *Manchester in Holiday Dress* (1866), *Memorials of Manchester Streets* (1874), *Memorials of Byegone Manchester*, 1880; Buxton, *Botanical Guide to Manchester*, &c., 2d ed., 1859; Axon, *Handbook of the Public Libraries of Manchester and Salford*, 1877; Grindon, *Manchester Flora*, 1859; Baines, *History of Lancashire*, 2d ed., 1868-70. (W. E. A. A.)

MANCHESTER, a town of the United States, in Hartford county, Connecticut, with a station on the New York and New England Railroad, 8 miles east of Hartford. Its spinning and weaving mills turn out annually 2,000,000 yards of gingham and 90,000 pairs of stockings; and its paper mills (upwards of a dozen in number) produce not only vast quantities of book paper but Government and bank-note paper for several nations. At South Manchester, 2½ miles distant, and reached by a branch line, are the silk factories of Messrs Cheney, which cover about 8 acres, and give employment to one thousand operatives. The factory village has been laid out by a landscape gardener; and connected with it are a public hall, a library and reading-room, and a free school. The population of the town has increased from 4223 in 1870 to 6462 in 1880.

MANCHESTER, a city of the United States, one of the shire towns of Hillsborough county, New Hampshire, is situated mainly on the left bank of the Merrimac, in a broad plain about 90 feet above the level of the river, in 42° 35′ N. lat. and 71° 31′ W. long., 16 miles from Concord and 46 north-west of Boston. It is a terminus of several railroads, as well as a principal station on the Boston, Lowell, and Concord line. The general plan is regular and spacious; there are several large and ornamental squares, and the main thoroughfare, Elm Street, is 100 feet wide, more than a mile long, and bordered by the trees from which it takes its name. Towards the river the frontage consists of great brick-built factories and substantial tenements for the accommodation of the operatives. A city-hall (rebuilt after the fire in 1842), the county court-house, the State reform school (for one hundred and fifty pupils), two opera-houses, and a Roman Catholic convent (St Ann's) and orphan asylum are among the buildings of note. The city library (24,000 volumes), founded by private enterprise in 1844 as the Manchester Athenæum, became public property in 1854. Water from Lake Massabesic (4 miles distant and 2300 acres in extent) was introduced into the town in 1874, at a cost of nearly $1,000,000, and is stored in a reservoir capable of containing 16,000,000 gallons. It is almost exclusively to the water-power furnished by the Blodgett Canal (built in 1816 round the Amoskeag Falls, which have a descent of 47 feet) that Manchester owes its prosperity as a manufacturing centre. The Amoskeag Company (dating from 1831), the Stark mills (1838), the Manchester mills (1839), the Langdon mills (1857), and the Amory mills (1880) are the leading establishments; they possess an aggregate capital of $7,650,000, work 12,000 looms and 409,000 spindles, and make 143 miles of web daily. Locomotive engines (produced at the rate of fourteen per month), steam fire-engines, edge tools, circular saws, files, sewing machines, carriages, leather, boots and shoes, paper, and ale all likewise form important items in the local industry. Manchester is governed by a mayor, a board of aldermen (one member for each of the eight wards), and a common council (three members for each ward). The assessed value of property in 1881 was $19,175,408; and the city debt $965,550. The population, which was 13,932 in 1850, stands in the succeeding decades at 20,107, 23,536, and 32,630, and is stated in 1882 at 36,500.

Originally settled in the close of the 17th century by Scotch Presbyterians and Massachusetts Puritans, Derryfield, as it was then called, though incorporated in 1751, continued for upwards of seventy years to be a place of less than one hundred inhabitants, with neither minister nor lawyer, and so dependent on the river fisheries that the eels were known as the "Derryfield beef." The name Manchester was legally recognized in 1810, and a city charter was granted in 1846. The city has recently been described as paying nearly one-ninth of the State tax and producing one-eighth of the manufactured goods made in the State, as embracing one-tenth of the population of the State, as the fourth city of the Union in the value of its cotton and woollen manufactures, and the third city in New England in increase during the last decade.

MANCHURIA is the name by which the territory in the east of Asia occupied by the Manchus is known in Europe. By the Chinese it is called the country of the Manchows, or, as it is pronounced by the natives, of the Manchus, an epithet meaning "Pure," chosen by the founder of the dynasty which now rules over Manchuria and China as an appropriate designation for his family. Manchuria as it has existed for upwards of two centuries, that is to say since it has had an historical existence, is a tract of country lying in a north-easterly and south-westerly direction between 38° 40′ and 49° N. lat. and 120° and 133° E. long., and is wedged in between China and Mongolia on the west and north-west, and Corea and the Russian territory on the Amur on the east and north. Speaking more definitely, it is bounded on the N. by the Amur, on the E. by the Usuri, on the S. by the Gulf of Leaou-tung, the Yellow Sea, and Corea, and on the W. by the river Nonni and a line of palisades which stretch from Kwan-chung-tsze to the Great Wall of China. The territory thus defined is about 800 miles in length and 500 miles in width, and contains about 390,000 square miles. It is divided into three provinces, viz., Tsitsihar or Northern Manchuria, Kirin or Central Manchuria, and Leaou-tung or Southern Manchuria. Physically the country is divided into two regions, the one a series of mountain ranges occupying the northern and eastern portions of the kingdom, and the other a plain which stretches southwards from Moukden, the capital, to the Gulf of Leaou-tung. Speaking generally, the mountains run in a direction parallel with the lie of the country, and are interspersed with numerous and fertile valleys, more especially on the southern and eastern slopes, where the summer sun brings to rich perfection the fruits of the soil fertilized by the showers of the south monsoon.

The principal range of mountains is the Shan-a lin, the Chinese *Chang pih Shan*, "the long white mountains," which runs in a north-easterly direction from the shores of the Gulf of Leaou-tung to the mouth of the Amur river. In its course through Northern Manchuria it forms the watershed of the Sungari, Hurka, and Usuri rivers, and in the south that of the Ya-lu, Ta-yang, and many smaller streams. It also forms the eastern boundary of the great plain of Leaou-tung. The mountains of this range reach their greatest height on the south-east of Kirin, where their snow-capped peaks rise to the elevation of from 10,000 to 12,000 feet. The scenery among them is justly celebrated for the grandeur of its beauty, more especially in the neighbourhood of Haiching, Siu-yen, and the Corean Gate. Another range forms a parallel line to the Shan-a-lin mountains on their west, and runs from the neighbourhood of the junction of the Hurka and Sungari rivers, passing Kirin, to the plain on the north side of Moukden.

The three principal rivers of Manchuria are the Sungari, Hurka, and Usuri already mentioned. Of these the Sungari, which is the largest, rises on the northern slopes of the Shan-a-lin range, and runs in a north-westerly direction to its junction with the Nonni, from which point it turns north-east until it empties itself into the Amur. It is navigable by native junks above Kirin, to which city also the Russians have succeeded in travelling on it by steamer. In its long course it varies greatly both in depth and width, in some parts being only a few feet deep and spreading out to a width of more than a mile, while in other and mountainous portions of its course its channel is narrowed to 300 or 400 feet, and its depth is increased in inverse ratio. The Usuri rises in about 44° N. lat. and 131° E. long., and, after running a north-easterly course for nearly 500 miles, it also loses itself in the Amur. The Hurka takes its rise, like the Sungari, on the northern slopes of the Shan-a-lin range, and not far form the sources of that river. It takes a north-easterly course as far as the city of Ninguta, at which point it turns northward, and so continues until it joins the Sungari at San-sing. It is navigable by junks between that city and Ninguta, though the torrents in its course make the voyage backwards and forwards one of considerable difficulty. Next in importance to these rivers are the Leaou and Ta-yang, the former of which rises in Mongolia, and after running in an easterly direction for about 400 miles enters Manchuria in about 43° N. lat., and turning southward empties itself into the Gulf of Leaou-tung. In bygone days large junks were able to sail up it as far as New-chwang, but owing to the silting up of the bed it is not now navigable for any but small boats beyond Ying-tsze, where the foreign settlement is situated. The Ta-yang rises on the southern slopes of the Shan-a-lin mountains, and flows southward into the Yellow Sea.

Moukden, or as it is called by the Chinese Shing-yang, the capital city of Manchuria, is situated in the province of Leaou-tung, in 41° 40′ N. lat. and 130° 30′ E. long. It occupies a fine position on the river Shin, an affluent of the Leaou, and is a city with considerable pretensions to grandeur. The city wall presents a handsome appearance, and is pierced by eight gates. Like Peking, the town possesses a drum tower and a huge bell. The streets are broad and well laid out, and the shops are well supplied with both native and foreign goods. The population is estimated at about 200,000, including that of the suburbs, the richest and most extensive of which are on the western and southern faces of the city. Leaou-yang, which was once the capital of the country, also stands in the province of Leaou-tung, but it is not now a place of much importance. Such trade as there is is carried on in the centre of the city, the remaining portions being open, having been turned into vegetable gardens. The other cities in the province are King-chow-foo on the west of the Gulf of Leaou-tung; Kin-chow, on the western extremity of the Leaou-tung peninsula; Kai-chow, on the north-western shore of the same peninsula; Hai-ching, on the road from Ying-tsze to Moukden; Ki-yuen, a populous and prosperous city in the north of the province; and Hing-king, on the northern slope of the Shan-a-lin mountains, which is famous rather from the fact that it was the original seat of the founders of the present dynasty than for any pretensions to present importance. The most important commercial place, however, is the treaty port of Ying-tsze, which is situated at the head of the Gulf of Leaou-tung. The main street, which is lined with shops and warehouses, is 2 miles in length, and the trade there carried on is very considerable. According to the custom-house returns the value of the foreign imports and exports in the year 1880 was £691,954 and £1,117,790 respectively, besides a large native trade carried on in junks. The population of the whole province of Leaou-tung is estimated to be about 12,000,000.

The province of Kirin, or Central Manchuria, is bounded on the N. and N.W. by the Sungari, on the S. by Leaou-tung and Corea, on the W. by the line of palisades already spoken of, and on the E. by the Usuri and the maritime Russian provinces. It contains an area of about 135,000 square miles, and is entirely mountainous with the exception of a stretch of plain country in its north-western corner. This plain produces large quantities of indigo and opium, and is physically remarkable for the number of isolated conical hills which dot its surface. These sometimes occur in a direct line at intervals of 15 or 20 miles, and elsewhere are scattered about "like dish-covers on a table." Kirin, the capital of the province, is situated in about 43° 40′ N. lat. and 126° 50′ E. long., and occupies a magnificent position, being surrounded on the north, west, and south by a semicircular range of mountains with the broad stream of the Sungari flowing across the front. The local trade is considerable, and is benefited by the presence of large junk-building yards, which, owing to the abundance and cheapness of wood, have been established there, and from which the place has derived its Chinese name of Chuen-chang or "shipyard." The town has a well-to-do appearance, and in summer time the houses and shops are gaily decorated with flowers brought from the sunny south. Ashehoh, on the Ashe, with its population of 40,000; Petuna, *Sinice* Sing-chung, on the Sungari, population 30,000; San-sing, near the junction of the Sungari and Hurka; La-lin, 120 miles to the north of Kirin, population 20,000; and Ninguta, are the other principal cities in the province.

Tsi-tsi-har, or Northern Manchuria, which contains about 195,000 square miles, is bounded on the N. and N.E. by the Amur, on the S. by the Sungari, and on the W. by the Nonni and Mongolia. This province is thinly populated, and is cultivated only along the lines of its rivers. The only towns of any importance are Tsitsihar and Mergen, both situated on the Nonni.

Four principal highways traverse Manchuria. The first runs from Peking to Kirin *via* Moukden, where it sends off a branch to Corea. At Kirin it bifurcates, one branch going to San-sing, the extreme north-eastern town of the province of Kirin, and the other to Poissiet on the coast *via* Ninguta. The second road runs from the treaty port of Ying-tsze through Moukden to Petuna in the north-western corner of the Kirin province and thence to Tsitsihar, Mergen, and the Amur. The third also starts from Ying-tsze, and strikes southward to Kin-chow at the extremity of the Leaou-tung peninsula. And the fourth connects Ying-tsze with the Gate of Corea.

The great plain in Leaou-tung is in many parts swampy, and in the neighbourhood of the sea, where the soil emits a saline exudation such as is also common in the north of China, it is perfectly sterile. In other parts fine crops of millet and various kinds of grain are grown, and on it trees flourish abundantly.

The climate over the greater part of the country varies between the two extremes of heat and cold, the thermometer ranging between 90° in the summer and 10° below zero in the winter. As in the north of China, the rivers are frozen up during the four winter months. After a short spring the heat of summer succeeds, which in its turn is separated by an autumn of six weeks' duration from snow and ice. The trees and plants are much the same as those common in England, and severe as the weather is in winter the less elevated mountains are covered to their summits with trees. The wild animals also are those known in Europe, with the addition of tigers and panthers. Bears, wild boars, hares, wolves, foxes, and wild cats are very common, and, in the north, sables are found in great numbers. One of the most noticeable of the birds is the Mongolian lark (*Melanocoryphya mongolica*), which is found in a wild state both in Manchuria and in the desert of Mongolia. This bird is exported in large numbers to northern China, where it is much prized on account of the extraordinary power it possesses of imitating the songs of other birds, the different tones of the barks of dogs, and the mews and hisses of cats, as well as all the noises peculiar to the neighbourhood in which it lives. The Manchurian crane is common, as also are eagles, cuckoos, laughing doves, &c. Insects, of which there are, according to the Russians, one thousand different species, abound, owing to the swampy nature of much of the country. The rivers are well stocked with fish, especially with salmon, which forms a common article of food among the people. In such immense shoals do these fish appear in some of the smaller streams that numbers are squeezed out on to the banks and there perish. This fact possibly gave rise to the legend of a certain Prince whose royal mother became pregnant by the influence of the rays of the sun, and who brought forth an egg from which the prince was sprung. His supernatural origin excited the alarm of the king's ministers, who advised that he should be put to death, but his mother, having warning of their intention, sent him away privately. This Manchurian Phaeton thereupon wandered forth, and in his travels came to a river having neither bridge nor ferry. In his difficulty he cried for help to his father the Sun, and instantly fishes rose to the surface of the water and formed themselves into such close array that the prince was able to walk to the opposite bank on their backs.

In minerals Manchuria is very rich: coal, gold, iron (as well as magnetic iron ore), and precious stones are found in quantities which suggest that if better appliances were employed than are now in use the returns might be very large.

Of the crops grown by the people indigo and opium are the most lucrative. The indigo plant is grown in large quantities in the plain country to the north of Moukden, and is transported thence to the coast in carts, each of which carries rather more than a ton weight of the dye. The poppy is cultivated wherever it will grow, the crop being far more profitable than that of any other product. Cotton, tobacco, pulse, millet, wheat, and barley are other crops grown by the Manchurian farmers.

History.—Manchow, or more correctly Manchu, is, as has been said, not the name of the country but of the people who inhabit it. The name is a modern one, having been adopted by a ruler who rose to power in the beginning of the 13th century. Before that time the Manchus were more or less a shifting population, with no fixed location, and, being broken up into a number of tribes, they went mainly under the distinctive name of those clans which at different periods exercised lordship over them. Thus under the Chow dynasty (1122–225 B.C.) we find them spoken of as Sewshin, and at subsequent periods they were known as Yih-low, Wuhkeih, Moh-hoh, Pohai, Nüchin, and according to the Chinese historians also as K'etan. Throughout their history they appear as a rude people, the tribute they brought to the Chinese court consisting of stone arrow-heads, hawks, gold, and latterly ginseng. Assuming that, as the Chinese say, the K'etans were Manchus, the first appearance of the Manchus, as a people, in China dates from the beginning of the 10th century, when K'etans having first conquered the kingdom of Pohai crossed the frontier into China and established the Leaou or Iron dynasty in the northern portion of the empire. These invaders were in their turn overthrown two centuries later by another invasion from Manchuria. These new conquerors were Nüchins, and, therefore, direct ancestors of the Manchus. On assuming the imperial yellow in China, their chief adopted the title of Kin or "Golden" for his dynasty. "Iron" (Leaou), he said, "rusts, but gold always keeps its purity and colour, therefore my dynasty shall be called Kin." In a little more than a century, however, the Kins were driven out of China by the Mongols under Jenghiz Khan. But before the close of their rule a miraculous event occurred on the Shan-a-lin mountains which is popularly believed to have laid the seeds of the greatness of the present rulers of the empire. Three heaven-born maidens, so runs the legend, were bathing one day in a lake under the Shan-a-lin mountains when a passing magpie dropped a ripe red fruit into the lap of one of them. The maiden ate the fruit, and in due course a child was born to her, whom she named Aisin Gioro, or the Golden. When quite a lad Aisin Gioro was elected chief over three contending clans, and established his capital at Otole near the Shan-a-lin mountains. His reign, however, was not of long duration, for his subjects rose against him and murdered him, together with all his sons except the youngest, Fancha, who, like the infant Haitu in Mongolian history, was miraculously saved from his pursuers. Nothing is recorded of the facts of Aisin Gioro's reign except that he named the people over whom he reigned Manchu, or "Pure." His descendants, through the rescued Fancha, fell into complete obscurity until about the middle of the 16th century, when one of them, Norhachi by name, a chieftain of a small tribe, rose to power. Taking advantage of the shifting scenes of Manchurian politics, Norhachi played with skill and daring the rôle which had been played by Jenghiz Khan more than three centuries before in Mongolia. With even greater success than his Mongolian counterpart, Norhachi drew tribe after tribe under his sway, and after numerous wars with Corea and Mongolia, he established his rule over the whole of Manchuria. Being thus the sovereign of an empire, he, again like Jenghiz Khan, adopted for himself the title of Ying-ming, "Brave and Illustrious," and took for his reign the title of T'een-ming. Thirteen years later, in 1617, after numerous border fights with the Chinese, Norhachi drew up a list of "seven hates," or indictments, against his southern neighbours, and, not getting the satisfaction he demanded, declared war against them. The progress of this war, the hastily patched up peace, the equally hasty alliance and its consequences, being matters of Chinese history, have been treated of under the article CHINA.

At the present day the Manchus are rapidly dying out before the quietly advancing Chinese settlers. By far the greater number of the present inhabitants of Manchuria are Chinamen. The Chinese system of education is adopted everywhere throughout the country; the Chinese language is taught in all the schools; and Manchuria promises to become before long as much a Chinese province as Chih-le or Shantung.

See *Journeys in North China, Manchuria, and Eastern Mongolia*, by the Rev. Alexander Williamson; *The Manchus*, by Rev. John Ross; *Man-chow yuen lew kaou.* (R. K. D.)

MANDÆANS, also known as Sabians, Nasoræans, or St John's Christians,[1] an Oriental sect of great antiquity, interesting to the theologian as almost the only surviving example of a religion compounded of Christian, heathen, and Jewish elements on a type which is essentially that of ancient Gnosticism.

The Mandæans, who can never have been numerous, and are now much decayed, are found in the marshy lands of South Babylonia (al-baṭáiḥ), the ancient refuge of so many strange sects, particularly in the neighbourhood of Basrah (or Bussorah), and in Khúzistán (Disful, Shuster).[2] They speak the languages of the localities in which they are settled (Arabic or Persian), but the language of their sacred books is an Aramaic dialect, which has its closest affinities with that of the Babylonian Talmud, written in a peculiar character suggestive of the old Palmyrene.[3] The existence of the Mandæans has been known since the middle of the 17th century, when the first Christian missionaries, Ignatius a Jesu[4]

[1] The first of these names (not Mendæans or Mandaites) is that given by themselves, and means γνωστικοί, followers of Gnosis (מאנדאייא, from מאנדא, Hebr. מַדָּע). The Gnosis of which they profess themselves adherents is a *personification*, the æon and mediator "knowledge of life" (see below). The title Nasoræans (Náṣóráyé), according to Petermann, they give only to those among themselves who are most distinguished for knowledge and character. Like the Arabic Naṣára, it is originally identical with the name of the half heathen half Jewish-Christian Ναζωραῖοι, and indicates an early connexion with that sect. The inappropriate designation of St John's Christians arises from the early and imperfect acquaintance of Christian missionaries, who had regard merely to the reverence in which the name of the Baptist is held among them, and their frequent baptisms. In their dealings with members of other communions the designation they take is Sabians, in Arabic Ṣubbá' (sing. Ṣábi'), from צבע=צְבָא, to baptize, thus claiming the toleration extended by the Koran (Sur. 5, 73; 22, 17; 2, 59) to those of that name.

[2] Recent accounts (1882) represent them as shrunk to 200 families, and seeking a new settlement on the Tigris, to escape the persecutions to which they are exposed.

[3] See Nöldeke's admirable *Mandäische Grammatik*, Halle, 1875.

[4] *Narratio originis, rituum, et errorum Christianorum S. Joannis*, Rome, 1652.

and Angelus a Sancto, began to labour among them at Basrah; further information was gathered at a somewhat later date by Pietro della Valle[1] and Thevenot,[2] and in the following century by Kaempfer, Chardin, and Niebuhr. In recent times they have been visited by Petermann[3] and Albert Socin, and last of all Liouffi[4] published in 1880 a full and accurate account of the manners and customs of the sect, taken from the lips of a converted Mandæan himself. For our knowledge of their doctrinal system, however, we must of course still depend chiefly upon the sacred books already mentioned, consisting of fragments of very various antiquity derived from an older literature.[5] Of these the largest and most important is the *Sidrá rabbá* or "Great Book," known also as *Ginzá* (treasure), consisting of two unequal parts, of which the larger is called "yaminá" (to the right hand) and the smaller "s'málá" (to the left hand), because of the manner in which they are bound together. In Petermann's edition the former occupies three hundred and ninety-five large quarto pages and the other only one hundred and thirty-eight. The former is intended for the living; the latter consists chiefly of prayers to be read at the burial of priests. As regards doctrine, the work is exhaustive; but it is characterized throughout by diffuseness, and often by extreme obscurity, besides being occasionally self-contradictory, as might be expected in a work which consists of a number of unconnected paragraphs of various authorship and date. The last section of the "right-hand" part (the "Book of Kings") is one of the older portions, and from its allusion to "the Persian and Arabian kings" may be concluded to date from somewhere between 700 and 900 A.D. Many of the doctrinal portions may in substance well be still older, and date from the time of the Sassanids. None of the MSS., however, are older than the 16th century.[6]

The following sketch represents, as far as can be gathered from these heterogeneous sources, the principal features of the Mandæan system. The ground and origin of all things is Pírá, or more correctly Pérá rabbá, "the great abyss" (either Persian Pír, "old," or from פער, "to split," comp. the Gnostic βυθός), associated with whom, and forming a triad with him, are the primal æons Ayar zívá rabbá, "the great shining æther," and Máná rabbá d'ĕkárá, "the great spirit of glory," usually called simply Máná rabbá. The last-named, the most prominent of the three, is the king of light properly so called, from whom the development of all things begins. From him emanates Yardĕná rabbá, "the great Jordan," which, as the higher world soul, permeates the whole æther, the domain of Ayar. Alongside of Máná rabbá frequent mention is made of D'múthá, his "image," as a female power; the name "image of the father" arises out of the same conception as that which gives rise to the names of σιγή and ἔννοια among the Greek Gnostics. Máná rabbá called into being the highest of the æons properly so-called, Hayyé Ḳadmáyé, "Primal Life," and then withdrew into deepest secrecy, visible indeed to the highest but not to the lowest æons (comp. Σοφία and Προπάτωρ), yet manifesting himself also to the souls of the more pious of the Mandæans after their separation from the body. Primal Life, who is properly speaking the Mandæan god, has the same predicates as the primal spirit, and every prayer, as well as every section of the sacred books, begins by invoking him.[7] The extremely fantastic delineation of the world of light by which Hayyé Ḳadmáyé is surrounded (see for example the beginning of *Sidrá rabbá*) corresponds very closely with the Manichæan description of the abode of the "king of the paradise of light." The king of light "sits in the far north in might and glory." The Primal Light unfolds himself by five great branches, viz., "the highest purest light, the gentle wind, the harmony of sounds, the voice of all the æons, and the beauty of their forms," all these being treated as abstractions and personified. Out of the further development and combination of these primary manifestations arise numerous æons ('Uthré, "splendours," from עתר, "is rich"), of which the number is often stated to be three hundred and sixty. They are divided into a number of classes (kings, hypostases, forms, &c.); the proper names by which they are invoked are many, and for the most part obscure, borrowed doubtless, to some extent, from the Parsee angelology. From the First Life proceeds as a principal emanation the "Second Life," Hayyé Tinyáné, generally called Yúshamín. This last name is evidently meant to be Hebrew, "Jehovah of the heavens," the God of the Jews being of a secondary rank in the usual Gnostic style. The next emanation after Yúshamín is "the messenger of life" (Mandá d'hayyé, literally γνῶσις τῆς ζωῆς), the most important figure in the entire system, the mediator and redeemer, the λόγος and the Christ of the Mandæans, from whom, as already stated, they take their name. He is occasionally also called the primal man, Gabrá Ḳadmáyá, as in the Kabbala and by Mani. Yúshamín desired to raise himself above the Primal Light, but failed in the attempt, and was punished by removal out of the pure ætherial world into that of inferior light. The one world is separated from the other by water channels (H'fíké Mayyé). Mandá on the other hand continues with the First Life and Máná rabbá, and is called his "beloved son," the "first born, "high priest," and "word of life." Mandá makes his appearance in the visible world in a series of incarnations beginning with the three brothers Hibil, Shithil, and Anúsh (late Judæo-Babylonian transformations of the well-known names of the book of Genesis), and ending with John the Baptist. Of the first three the most highly honoured is Hibil, almost invariably referred to as "the brilliant Hibil"; he is the alter ego of Mandá, his image in this present world, having the same predicates and the same activities, and is the Jesus Christ of the Mandæans. The Second Life, Yúshamín, has as the last of three sons Hayyé t'lítáyé, the "Third Life," the most distinguished of

[5] Mandæan MSS. occur in the British Museum, the Bodleian Library, the Bibliothèque Nationale of France, and also in Rome, Weimar, and Berlin.
[6] The first printed edition and translation of the *Sidrá rabbá*, by Matth. Norberg (*Codex Nazaræus, liber Adami appellatus*, 3 vols., Copenhagen, 1815–16, followed by a lexicon in 1816, and an onomasticon in 1817), is so defective as to be quite useless; even the name Book of Adam is unknown to the Mandæans. Petermann's *Thesaurus s. Liber magnus, vulgo "Liber Adami" appellatus, opus Mandæorum summi ponderis* (2 vols., Leipsic, 1867), is an excellent metallographic reproduction of the Paris MS. A critical edition still remains a desideratum. Next in importance to the *Sidrá rabbá* is the *Sidrá d'Yahyá*, or "Book of John," otherwise known as the *D'ráshé d'Malké*, or "Discourses of the Kings," which has not as yet been printed as a whole, although portions have been published by Lorsbach and Tychsen (see *Museum f. bibl. u. orient. Lit.*, 1807, and Stäudlin's *Beitr. z. Phil. u. Gesch. d. Relig u. Sittenlehre*, 1796 *sq.*). The *Kolástá* (Ar., *Kholáṣa*, "Quintessence"), or, according to its fuller title *'Enyáné uleráshé d'maṣbáthá umassekthá* ("Songs and Discourses of Baptism and the Ascent," viz., of the soul after death) has been admirably lithographed by Euting (Stuttgart, 1867). It is also known as *Sidrá d'neshmátha*, "Book of Souls," and besides hymns and doctrinal discourses contains prayers to be offered by the priests at sacrifice and at meals, as well as other liturgical matter. The Mandæan marriage service occurs both in Paris and in Oxford as an independent MS. The *Díwán*, hitherto unpublished, contains the ritual for atonement. The *Asfar malwáshé*, or "Book of the Zodiac," is astrological. Of smaller pieces many are magical and used as amulets.
[7] The use of the word "life" in a personal sense is usual in Gnosticism; compare the Ζωή of Valentin, and el-ḥayát el-muallama, "the dark life," of Mani in the *Fihrist*.

the ʿUthré, hence usually called their father (Abá d' ʿUthré, Abáthúr). His usual epithet is "the Ancient" (ʿAṭíḳá); and he is also called "the deeply hidden and guarded." He stands on the borderland between the here and the hereafter, like the mysterious πρεσβύτης τρίτος or *senex tertius* of Mani, whose becoming visible will betoken the end of the world. Abáthúr sits on the furthest verge of the world of light that lies towards the lower regions, and weighs in his balance the deeds of the departed spirits who ascend to him. Beneath him was originally nothing but a huge void with muddy black water at the bottom, in which his image was reflected, becoming ultimately solidified into P'táhíl, his son, who now partakes of the nature of matter. The demiurge of the Mandæans, and corresponding to the Ialdabaoth of the Ophites, he at the instance of his father frames the earth and men,—according to some passages in conjunction with the seven bad planetary spirits. He created Adam and Eve, but was unable to make them stand upright, whereupon Hibil, Shithil, and Anúsh were sent by the First Life to infuse into their forms spirit from Máná rabbá himself. Hibil, at the instance of the supreme God, also taught men about the world of light and the æons, and especially gave them to know that not P'tahíl but another was their creator and supreme God, who as "the great king of light, without number, without limit," stands far above him. At the same time he enjoined the protoplasts to marry and people the world. P'tahíl had now lost his power over men, and was driven by his father out of the world of light into a place beneath it, whence he shall at the day of judgment be raised, and after receiving baptism be made king of the ʿUthré with divine honours.

The underworld is made up of four vestibules and three hells properly so-called. The vestibules have each two rulers, Zartay and Zartanay, Hag and Mag, Gaf and Gafan, Anatan and Kin. In the highest hell rules alone the grisly king Sh'dúm, "the warrior"; in the story immediately beneath is Giv, "the great"; and in the lowest is Krún or Karkúm, the oldest and most powerful of all, commonly called "the great mountain of flesh" (Túrá rabbá d'besrá), but also "the first-born of darkness." In the vestibules dirty water is still to be met with, but the hells are full of scorching consuming fire, except Krún's domain, where is nought but dust, ashes, and vacancy. Into these regions descended Hibil the brilliant, in the power of Máná rabbá, just as in the Manichæan mythology the "primal man," armed with the elements of the king of light, descends to a contest with the primal devil. Hibil lingers, gradually unfolding his power, in each of the vestibules, and finally passing from hell to hell reaches Karkúm. Hibil allows himself to be half swallowed by the monster, but is unhurt, and compels his antagonist to recognize the superiority of Máná rabbá, the God of light, and to divulge his profoundest secret, the hidden name of darkness. Armed with this he returns through the successive hells, compelling the disclosure of every secret, depriving the rulers of their power, and barring the doors of the several regions. From the fourth vestibule he brought the female devil Rúhá, daughter of Kin, and set her over the whole four. This Rúhá, the mother of falsehood and lies, of poisoning and fornication, is an anti-Christian parody of the Rúhá d'Ḳudshá (Holy Spirit) of the Syriac Church. She is the mother of Ur, the personified fire of hell, who in anger and pride made a violent onset on the world of light (compare the similar occurrence in the Manichæan mythology), but was mastered by Hibil and thrown in chains down to the "black water," and imprisoned within seven iron and seven golden walls. By Ur, Rúhá, while P'táhíl was engaged in his work of creation, became mother of three sets of seven, twelve, and five sons respectively; all were translated by P'táhíl to the heavenly firmament (like the Archons of Mani), the first group forming the planets and the next the signs of the zodiac, while the third is as yet undetermined. Of the names of the planets Estera (Istar, Venus, also called Rúhá d'Ḳudshá, "holy spirit"), Enba (Nebo, Mercury), Sín (moon), Kéwán (Saturn), Bíl (Jupiter), and Niríg (Nirgal, Mars) reveal their Babylonian origin; Il or Il Il, the sun, is also known as Ḳádúsh and Adúnay (the Adonai of the Old Testament); as lord of the planetary spirits his place is in the midst of them; they are the source of all temptation and evil amongst men. The houses of the planets, as well as the earth and a second world immediately to the north of it, rest upon anvils laid by Hibil on the belly of Ur.

In the Mandæan representation the sky is an ocean of water, pure and clear, but of more than adamantine solidity, upon which the stars and planets sail. Its transparency allows us to see even to the pole star, who is the central sun around whom all the heavenly bodies move. Wearing a jewelled crown, he stands before Abáthúr's door at the gate of the world of light; the Mandæans accordingly invariably pray with their faces turned northward. The earth is conceived of as a round disk, slightly sloping towards the south, surrounded on three sides by the sea but on the north by a high mountain of turquoises; behind this is the abode of the blest, a sort of inferior paradise, inhabited by the Egyptians drowned along with Pharaoh in the Red Sea, whom the Mandæans look upon as their ancestors, Pharaoh himself having been their first high priest and king. The total duration of the earth they fix at four hundred and eighty thousand years, divided into seven epochs, in each of which one of the planets rules. The *Sidrá Rabbá* knows of three total destructions of the human race by fire and water, pestilence and sword, a single pair alone surviving in each case. In the Mandæan view the Old Testament saints are false prophets; such are Abraham, who arose six thousand years after Nú (Noah) during the reign of the Sun, Míshá (Moses), in whose time the true religion was professed by the Egyptians, and Shlímún (Solomon) bar Davith, the lord of the demons. Another false prophet and magician was Yishu M'shíhá, who was in fact a manifestation of the planet Mercury. Forty-two years before his day, under King Pontius Pilate, there had appeared the true prophet Yahyá or John son of Zechariah, an incarnation of Hibil, of whose birth and childhood fantastic stories are told. Yahyá by a mistake gave baptism to the false Messiah, who had feigned humility; on the completion of his mission, after undergoing a seeming execution, he returned clothed with light into the kingdom of light. As a contemporary of Yahyá and the false Messiah Hibil's younger brother Anúsh ʿUthrá came down from heaven, caused himself to be baptized by Yahyá, wrought miracles of healing and of raising the dead, and brought about the crucifixion of the false Messiah. He preached the true religion, destroyed Jerusalem ("Urashlam," *i.e.*, "the devil finished it"), which had been built by Adúnay, dispersed over the world the Jews who had put Yahyá to death, and previous to his return into the worlds of light sent forth three hundred and sixty prophets for the diffusion of the true religion. All this speaks of intense hatred alike of Jews and Christians; the fasts, celibacy, and monastic and anchoret life of the latter are peculiarly objectionable to the Mandæans. Two hundred and forty years after the appearing of the false Messiah there came to the world sixty thousand saints out of Pharaoh's world to take the place of the Mandæans, who had been completely extirpated; their high priest had his residence in Damascus. The last false prophet was M'hammad or Ahmat bar Bisbat (Mohammed), but Anúsh, who remained close beside him and his immediate successors, prevented hostilities against the true believers, who claim to have had in Babylonia, under the Abbasides, four hundred places of worship. Subsequent persecutions compelled their withdrawal to 'Ammárah in the neighbourhood of Wásit, and ultimately to Khúzistán. At the end of the world the devil Ur will swallow up the earth and the other intermediate higher worlds, and thereupon will burst and fall into the abyss of darkness, where, along with all the worlds and powers of darkness, he will ultimately cease to be, so that thenceforward the universe will consist of but one everlasting world of light.

The chief depositaries of these Mandæan mysteries are the priests, who enjoy a high degree of power and social regard. The priesthood has three grades. (1) the Sh'kandá or deacon is generally chosen from episcopal or priestly families, and must be without bodily blemish. The candidate for orders must be at least nineteen years old and have undergone twelve years' preparation; he is then qualified to assist the priesthood in the ceremonies of religion. (2) The Tarmídá (*i.e.*, "Talmídá," initiated") or priest is ordained by a bishop and two priests or by four priests after a long and extremely painful period of preparation. (3) The Ganzivrá ("treasurer") or bishop, the highest dignitary, is chosen from the whole body of the Tarmídás after a variety of tests, and possesses unlimited authority over the clergy. A supreme priestly rank, that of Rísh 'ammá, or "head of the people," is recognized, but only in theory; since the time of Pharaoh this sovereign pontificate has only once been filled. The priestly dress, which is all white, consists of drawers, an upper garment, and a girdle with the so-called tágá or "crown"; in all ceremonies the celebrants must be barefoot. By far the most frequent and important of the religious ceremonies is that of baptism (maṣbúthá), which is called for in a great variety of cases, not only for children but for adults, where consecration or purification is required, as for example on all Sundays and feast days, after contact with a dead body, after return from abroad, after neglect of any formality on the part of a priest in the discharge of his functions. In all these cases baptism is performed by total immersion in running water, but during the five days' baptismal festival the rite is observed wholesale by mere sprinkling of large masses of the faithful at once. The Mandæans observe also with the elements of bread (pehtá) and wine (mambúgá, lit. "fountain") a sort of eucharist, which has a special sanctifying efficacy, and is usually dispensed at festivals, but only to baptized persons of good repute who have never willingly denied the Mandæan faith. In receiving it the communicant must not touch the host with his finger; otherwise it loses its virtue. The hosts are made by the priests from unleavened fine flour. A peculiar act of piety is for a layman under the guidance of the bishop to receive the masseḳtha ("elevation"), and thereby become a sort of ascetic, a shalmáná tábá ("really perfect"). The Mandæan places of worship, being designed only for the priests and their assistants, are excessively small, and very simply furnished; two windows, a door that opens towards the south so that those who enter have their faces turned towards the pole star, a few boards in the corner, and a gabled roof complete the whole structure; there is neither altar nor decoration of any kind. The neighbourhood of running water (for baptisms) is essential. At the consecration of a church the sacrifice of a dove (the bird of Venus) has place among the ceremonies. Besides Sundays there are six great feasts: (1) that of the New Year (Naurúz rabbá), on the first day of the first month of winter; (2) Dehwá h'níná, the anniversary of the happy return of Hibil Zívá from the kingdom of darkness into that of light, lasting five days, beginning with the 18th of the first month of spring; (3) the Marwáná, in commemoration of the drowned Egyptians, on the first day of the second month of spring; (4) the great five days' baptismal festival (pantshá), the chief feast, kept on the five intercalary days at the end of the second month of summer,—during its continuance every Mandæan, male and female, must dress in white and bathe thrice daily; (5) Dehwá d'daimáná, in honour of one of the three hundred and sixty 'Uthras, on the first day of the second month of autumn; (6) Kanshe Zahlá, the preparation feast, held on the last day of the year. There are also fast days called m'battal (Arab.), on which it is forbidden to kill any living thing or eat flesh. The year is solar, and has twelve months of thirty days each, with five intercalary days between the eighth and the ninth month. Of the seven days of the week, next to Sunday (habshabá) Thursday has a special sacredness as the day of Hibil Zívá. As regards secular occupation, the present Mandæans are goldsmiths, ironworkers, and house and ship carpenters. They practise polygamy, the *Sidrá Rabbá* laying great stress upon the duty of procreation, but few of them are rich enough to maintain more than two wives. In the 17th century, according to the old travellers, they numbered about 20,000 families, but at the present day they hardly number more than 1200 souls. In external appearance the Mandæan is distinguished from the Moslem only by a brown coat and a parti-coloured headcloth with a cord twisted round it. They have some peculiar death-bed rites: a deacon with some attendants waits upon the dying, and as death approaches administers a bath first of warm and afterwards of cold water; a holy dress, consisting of seven pieces (rastá), is then put on; the feet are directed towards the north and the head turned to the south, so that the body faces the pole star. After the burial a funeral feast is held in the house of mourning.

The Mandæans are strictly reticent about their theological dogmas in the presence of strangers; and the knowledge they actually possess of these is extremely small. The foundation of the system is obviously to be sought in Gnosticism, and more particularly in the older type of that doctrine (known from the serpent symbol as Ophite or Naassene) which obtained in Mesopotamia and Further Asia generally. But it is equally plain that the Ophite nucleus has from time to time received very numerous and often curiously perverted accretions from Babylonian Judaism, Oriental Christianity, and Parsism, exhibiting a striking example of religious syncretism. In the Gnostic basis itself it is not difficult to recognize the general features of the religion of ancient Babylonia, and thus we are brought nearer a solution of the problem as to the origin of Gnosticism in general. It is certain that Babylonia, the seat of the present Mandæans, must be regarded also as the cradle in which their system was reared; it is impossible to think of them as coming from Palestine, or to attribute to their doctrines a Jewish or Christian origin. They do not spring historically from the disciples of John the Baptist (Acts xviii. 25; xix. 3 *sq.*; *Recog. Clem.*, i. 54); the tradition in which he and the Jordan figure so largely is not original, and is therefore worthless; at the same time it is true that their baptismal praxis and its interpretation place them in the same religious group with the Hemerobaptists of Eusebius (*H. E.*, iv. 22) and Epiphanius (*Hær.*, xvii.), or with the sect of disciples of John who remained apart from Christianity. Their reverence for John is of a piece with their whole syncretizing attitude towards the New Testament. Indeed, as has been seen, they appropriate the entire personale of the Bible from Adam, Seth, Abel, Enos, and Pharaoh to Jesus and John, a phenomenon which bears witness to the close relations of the Mandæan doctrine, at the time of its formation, both with Judaism and Christianity,—not the less close because they were relations of hostility. The history of religion presents other examples of the degradation of holy to demonic figures on occasion of religious schism. The use of the word "Jordan," even in the plural, for "sacred water," is precisely similar to that by the Naassenes described in the *Philosophumena* (v. 7); there ὁ μέγας Ἰορδάνης denotes the spiritualizing, sanctifying fluid which pervades the world of light. The notions of the Egyptians and the Red Sea, according to the same work (v. 16), are used by the Peratæ much as by the Mandæans. And the position assigned by the Sethians (Σηθιανοί) to Seth is precisely similar to that given by the Mandæans to Abel. Both alike are merely old Babylonian divinities in a new Biblical garb. The genesis of Mandæism and the older gnosis from the old and elaborate Babylonio-Chaldæan religion is clearly seen also in the fact that the names of the old pantheon (as for example those of the planetary divinities) are retained, but their holders degraded to the position of demons,—a conclusion confirmed by the fact that the Mandæans, like the allied Ophites, Peratæ, and Manichæans, certainly have their original seat in Mesopotamia and Babylonia. Great caution is necessary, in the present state of our knowledge, in the use made of the results of cuneiform decipherment in relation to Babylonian mythology; but so much seems clear, that the trinity of Anu, Bil, and Ea in the old Babylonian religion has its counterpart in the Mandæan Píra, Ayar, and Máná rabbá. The D'múthá of Máná is the Damkina, the wife of Ea, mentioned by Damascius as Δαύκη, wife of Ἀός. Mandá d'hayyé and his image Hibil Zívá with his incarnations clearly correspond with the old Babylonian Marduk, Merodach, the "first-born" son of Ea, with his incarnations, the chief divinity of the city of Babylon, the mediator and redeemer in the old religion. Hibil's contest with darkness has its prototype in Marduk's battle with chaos, the dragon Tiamat, which (another striking parallel) partially swallows Marduk, just as is related of Hibil and the Manichæan primal man. Other features are borrowed by the Mandæan mythology under this head from the well-known epos of Istar's *descensus ad inferos*. The sanctity with which water is invested by the Mandæans is to be explained by this fact that Ea has his seat "in the depths of the world sea."

Compare K. Kessler's article "Mandäer" in Herzog-Plitt's *Real-encyklopädie*, and the same author's paper, "Ueber Gnosis u. altbabylonische Religion," in the *Abhandh. d. fünften internationalen Orientalisten-congresses zu Berlin* (Berlin, 1882). (K. K.)

MANDALAY, the capital of Independent Burmah, is situated about 2 miles from the left bank of the Irawadi river, in 21° 59′ N. lat. and 96° 8′ E. long. It was founded by the king of Burmah, who transferred to it the seat of government from Amarapura in 1860. The city proper is laid out in a square, each side of which is a little over a mile in length. It is enclosed by a crenellated brick wall 26 feet high and 3 feet thick; the twelve gates (three on each side) are surmounted with wooden watch-towers. A deep wet moat, 100 feet broad, with its escarp 60 feet from the walls, extends along all four sides; it is crossed by five bridges. The palace of the king occupies the central space of the city; the walls of its enclosure are laid symmetrically with those of the city, and each face is about 370 yards in length. The outer fence consists of a stockade of teak-wood posts 20 feet high, and within it are three successive enclosures, bounded by brick walls. The palace is built within the inner enclosure; and its front, which faces the east, contains the great hall of audience, 260 feet long, composed of teak timber, elaborately carved and gilded, erected on a terrace of brickwork 10 feet high. It is in the form of a colonnade, the central part running back, forming a nave with two side aisles. At the extremity of this nave is a space like a chancel (said to be the exact centre of the city) where stands the throne, over which rises a graceful gilded spire, visible from all parts of the city and surrounding country. Another feature of the complex palace buildings is the lofty campanile. Around the palace walls a wide space has been laid out as an esplanade, on the further margin of which are situated most of the houses of the princes, ministers of state, and court officials. The city may be said to consist of two parts, intramural and extramural; the streets in the former run parallel with the walls, dividing the building sites into rectangular blocks. The majority of the houses are constructed of bamboos and bamboo matting, slightly raised from the ground on posts, with here and there a few brick and wooden buildings. The streets inside the city are very wide, the principal ones being lined with tamarind trees. In the suburbs the roads are laid out with something of the same regularity as in the city, but are of less width, with the exception of the principal road, the Kuladan or foreign quarter, inhabited chiefly by Armenians, Mughals, and the few European residents. The number of houses in the city and suburbs is said to be, in round numbers, 12,000; and the population is roughly estimated at 65,000. Monasteries and pagodas are dotted about in open spaces, both within and without the walls. Silk-weaving is the principal manufacture.

See Fytche, *Burma Past and Present*, 1878.

MANDAMUS, Writ of, in English law, is usually described as a high prerogative writ, containing a command in the name of the king, and issuing from the King's Bench, directed to persons, corporations, and inferior courts, ordering them to do a specific act within the duty of their office. Direct orders from the sovereign to subjects commanding the performance of particular acts were common in early times, and to this class of orders mandamus originally belonged. It became customary for the Court of King's Bench, in cases where a legal duty was established but no sufficient means existed for enforcing it, to order performance by this writ. At all times, accordingly, mandamus has been regarded as of the nature of an equitable interference supplementing the deficiencies of the common law. When the object sought could be equally well obtained by other means, as by an action, or by any other form of proceedings, then mandamus would not lie. A further condition of mandamus at common law was that it lay only for the performance of acts of a public or official character. The enforcement of merely private obligations, such as those arising from contracts, was not within its scope. Further, the interference of the court could only be obtained when there was no doubt of the existence of the duty, or when performance had been demanded and refused. Nor would the writ be issued when performance had become impossible. By the Common Law Procedure Act, 1854, the plaintiff in any action other than replevin and ejectment was entitled to claim a writ of mandamus to compel the defendant to discharge any duty in which the plaintiff might show that he was personally interested, or from the non-performance of which he might sustain damage. The duties so enforceable must, however, be of a public character. By the Judicature Act, 1873, a mandamus may be granted by an interlocutory order of the court in all cases in which it shall appear to the court to be just and convenient, and subject to such terms and conditions, if any, as the court shall think just. Under this section it has been held that the court (which now includes what was formerly the Court of Chancery) has power to issue a writ of mandamus in any cause or matter pending before it, but when the cause is at an end the power is gone. And it has also been held that, when the circumstances are such as would form ground for an application for the old prerogative writ of mandamus, the application must be made to the Queen's Bench division, which has taken the place of the Court of Queen's Bench on the old system. The jurisdiction of the Court of Chancery to compel specific performance of contracts has some resemblance to mandamus in the domain of semi-public law. For a collection of the cases in which the prerogative writ of mandamus will or will not lie, reference may be made to Tapping *On Mandamus*, and to Selwyn's *Nisi Prius*, art. "Mandamus."

The writ has passed into the law of the United States. "There is in the federal judiciary an employment of the writ substantially as the old prerogative writ in the King's Bench practice, also as a mode of exercising appellate jurisdiction, also as a proceeding ancillary to a judgment previously rendered, in exercise of original jurisdiction, as when a circuit court having rendered a judgment against a county issues a mandamus requiring its officers to levy a tax to provide for the payment of the judgment." And in the various States mandamus is used under varying regulations, mandate being in some cases substituted as the name of the proceeding. See Abbott's *Law Dictionary*.

MANDATE (Mandatum). The contract of *mandatum* in Roman law was constituted by one person (the *mandatarius*) promising to do something gratuitously at the request of another (the *mandator*), who undertakes to indemnify him against loss. The jurist distinguished the different cases of mandatum according as the object of the contract was the benefit of the mandator or a third person singly, or the mandator and a third person, the mandator and the mandatarius, or the mandatarius and a third person together. When the benefit was that of the mandatarius alone, the obligations of the contract were held not to arise, although the form of the contract might exist, the commission being held to be merely advice tendered to the mandatarius, and acted on by him at his own risk. Mandatum was classified as one of the contracts established by consent of the parties alone; but, as there was really no obligation of any kind until the mandatarius had acted on the mandate, it has with more propriety been referred to the contracts created by the supply of some fact (*re*). The obligations of the mandatarius under the contract were, briefly, to do what he had promised according to his instructions, observing ordinary diligence in taking care of any property entrusted to him, and handing over to his principal the results of his action, including the right to sue in his name. On the other hand, the principal was bound to recoup him his expenses and indemnify him against loss through obligations he might have incurred.

The essentials and the terminology of the contract are preserved in most modern systems of law. But in English law mandate, under that name, can hardly be said to exist as a separate form of contract. To some extent the law of mandatum corresponds partly to our law of principal and agent, partly to that of principal and surety. Story, disputing the assertion that "in the laws of England the contract of mandatum is of no use," points out that "the common law does not indeed comprehend under that appellation all the contracts of mandate according to the civil law,—such, for example, as mere naked acts of agency, where there is no bailment of anything to the agent. But for the most part the principles applicable to all the various classes of mandate have a place in our law, although they may be differently named." The difference, however, is more than one of name. English law in this as in other cases reaches its end by a different method through different principles from those of the civil law, though the end may be the same.

Mandate is retained by Story and others to signify the contract more generally known as gratuitous bailment. It is restricted, as he points out, to personal property, and it implies the delivery of something to the bailee, both of which conditions are unknown in the mandatum of the civil law. Mandate in this later sense is further distinguished from deposit in that the custody of the thing is the principal object of the latter contract, while in the former it is something to be done with respect to the thing, though Story holds that custody and performance concur in both contracts,—this by way of correction of Sir W. Jones's distinction that mandate consists in feasance and deposit in custody.

MANDEVILLE, Bernard de (1670–1733), is generally known as an ethical writer of debasing and degrading tendency, but he was at least as much of a humorist as a philosopher, and set up as an analyst of "what is," repeatedly disavowing all pretensions as a lawgiver of "what ought to be." He was a foreigner by birth, a native of Rotterdam, where his father practised as a physician for thirty years. A remarkably eloquent schoolboy exercise, *De Medicina Oratio Scholastica*, was printed for him at Rotterdam in 1685. He studied for six years at Leyden, and took his degree in medicine in 1691, his inaugural thesis being *De Chylosi Vitiata*. Immediately afterwards he came over to England "to learn the language," which he did to some purpose, writing it with such mastery as to throw doubts upon his foreign extraction. He settled in London as a physician. The *Fable of the Bees* is the general title of the miscellaneous work by which he is known to fame. This work includes the fable proper, *The Grumbling Hive, or Knaves Turned Honest* (some two hundred doggerel couplets, published as a sixpenny pamphlet and pirated as a halfpenny sheet in 1705); *Remarks* on the fable and *An Inquiry into the Origin of Moral Virtue*, added to the edition of 1714; *An Essay on Charity Schools*, and *A Search into the Origin of Society*, added to the edition of 1723. Owing to a curious misprint in an edition published after Mandeville's death, a wrong date is commonly assigned to the *Grumbling Hive*, and the contemporary point of it consequently missed. It appeared during the heat of the bitterly contested elections of 1705, when the question before the country was whether Marlborough's war with France should be continued. The cry of the high Tory advocates of peace was that the war was carried on purely in the interests of the general and the men in office; charges of bribery, peculation, hypocrisy, every form of fraud and dishonesty, were freely cast about among the electors. It was amidst this excitement that Mandeville sought and found an audience for his grimly humorous paradox that "private vices are public benefits,"—that individual self-seeking, ambition, greed, vanity, luxury, are indispensable to the prosperity and greatness of a nation. "Fools only strive to make a great an honest hive." The bees of his fable grumbled as many Englishmen were disposed to do,—"cursed politicians, armies, fleets," whenever there came a reverse, and cried, "Had we but honesty!" Jove at last in a passion swore that he would "rid the bawling hive of fraud," and filled the hearts of the bees with honesty and all the virtues, strict justice, frugal living, contentment with little, acquiescence in the insults of enemies. Straightway the flourishing hive declined, till in time only a small remnant was left; this took refuge in a hollow tree, "blest with content and honesty," but destitute of arts and manufactures. The *Grumbling Hive* was in fact a political *jeu d'esprit*, full of the impartial mockery that might be expected from a humorous foreigner, and with as much ethical theory underlying it as might be expected from a highly educated man in an age of active ethical speculation. The underlying theory was made explicit in the *Remarks* and the *Inquiry into the Origin of Moral Virtue*, published in 1714. But his purpose in dwelling on the text that private vices are public benefits was still rather the invention of humorous paradoxes than the elaboration of serious theory. Dr Johnson, who owned that Mandeville "opened his views into real life very much," considered that the fallacy of his argument lay in his defining neither vices nor benefits. But such a criticism as this overlooks the hinge on which all Mandeville's paradoxes turn. He does define virtue and vice very precisely, in accordance with the current orthodoxy of the time. He "gives the name of virtue to every performance by which man, contrary to the impulse of nature, should endeavour the benefit of others, or the conquest of his own passions, out of a rational ambition of being good"; while "everything which, without regard to the public, man should commit to gratify any of his appetites" is vice. His paradoxical humour has ample scope in tracing how much vice and how little virtue there is in the world, when the terms are thus strictly defined. He finds self-love (a vice by the definition) masquerading in many virtuous disguises, lying at the root of asceticism, heroism, public spirit, decorous conduct,—at the root, in short, of all the actions that pass current as virtuous. These actions are not virtuous by the definition, because not performed solely "out of a rational ambition of being good." "This is the way," Dr Johnson says, "to try what is vicious, by ascertaining whether more evil than good is produced by it on the whole." Mandeville would at once have admitted this, but his definition compelled him, in determining virtue and vice, to consider also the motive. And having regard to the motive, "the nearer we search into human nature, the more we shall be convinced that the moral virtues are the political offspring which flattery begot upon pride." Man, "an extraordinary selfish and headstrong as well as a cunning animal," has been induced to subordinate his own appetites to the good of others, by the dexterous management of politicians and moralists, who have worked upon his pride to persuade him that self-indulgence is worthy only of the brutes, and altogether "unbecoming the dignity of such a sublime creature as himself." When Mandeville, in the 1723 edition of the fable, applied his analysis of self-regarding motives to the institution of charity schools, at that time a highly fashionable form of munificence, a great outcry was made against his doctrines; his book was presented to the justices by the grand jury of Middlesex as being of an immoral and pernicious tendency, and a copy was condemned to be burnt by the common hangman. Mandeville's defence of himself was that his remarks were "designed for the entertainment of people of knowledge and education," and that his inquiry could hardly be intelligible except to those accustomed to matters of speculation; and he claimed that he had "diverted persons of great probity and virtue and unquestionable good sense." The truth is that, to be rightly understood, the prose part of Mandeville's fable must be read in connexion with Lord Shaftesbury's ethical writings; the intention to ridicule the amiable but somewhat feebly reasoned theories of that moralist is most apparent in the *Search into the Origin of Society*, but many lurking references may be detected elsewhere. If Mandeville were taken seriously, he would certainly be open to the charge of conveying the impression that those who restrain their appetites and sacrifice personal interests for the public good make fools of themselves, and are the dupes of a designing society. But his main purpose seems to have been to entertain himself and others at the expense of more serious but less quick-witted theorizers.

Besides his political and philosophical parerga, Mandeville wrote, in 1711, a medical treatise, *Of the Hypochondriack and Hysterick Passions*—their symptoms, causes, and cures. The treatise is in the form of a dialogue, and is "interspersed with instructive discourses on the real art of physic itself, and entertaining remarks on the modern practice of physicians and apothecaries." In this, with the same entertaining style and clear and subtle judgment, he protests against and ridicules speculative therapeutics, and pleads for patient diagnosis and careful observation and record of facts. His own theories about the animal spirits and their connexion with "the stomachic ferment" are fanciful enough, but he shows an intimate acquaintance with the scientific methods of Locke, and a warm admiration for Sydenham. *The Virgin Unmasked*; *Free Thoughts on Religion, the Church, and National Happiness*; *An Inquiry into the Causes of the frequent Executions at Tyburn*; *An Inquiry into the Origin of Honour, and Usefulness of Christianity in War*—are titles of other works of Mandeville; but all that is characteristic of him as a thinker and humorist may be found in the *Fable of the Bees*. (W. M.)

MANDEVILLE, JEHAN DE, the name claimed by the compiler of a singular book of travels, written in French, and published between 1357 and 1371. By aid of translations into many other languages it acquired extraordinary popularity, while a few interpolated words in a particular edition of the English version have gained for Mandeville in modern times the spurious credit of being "the father of English prose."

In his preface the compiler calls himself a knight, and states that he was born and bred in England, of the town of St Albans; had crossed the sea on Michaelmas Day 1322; had travelled by way of Turkey (Asia Minor), Armenia the little (Cilicia) and the great, Tartary, Persia, Syria, Arabia, Egypt upper and lower, Libya, great part of Ethiopia, Chaldæa, Amazonia, India the less, the greater, and the middle, and many countries about India; had often been to Jerusalem; and had written in Romance as more generally understood than Latin. In the body of the work we hear that he had been at Paris and Constantinople; had served the sultan of Egypt a long time in his wars against the Bedouins, had been freely addressed by him on the corruption of contemporary Christendom, had been vainly offered by him a princely marriage and a great estate on condition of renouncing Christianity, and had left Egypt under Sultan Melech Madabron, *i.e.*, Muẓaffar or Mudhaffar[1] (who reigned in 1346–47); had been at Mount Sinai, and had visited the Holy Land with letters under the great seal of the sultan, which gave him extraordinary facilities; had been in Russia, Livonia, Cracow, Lithuania, "en roialme daresten" (? de Daresten or Silistria), and many other parts near Tartary, but not in Tartary itself; had drunk of the well of youth at Polombe (Quilon on the Malabar coast), and still seemed to feel the better; had taken astronomical observations on the way to Lamary (Sumatra), as well as in Brabant, Germany, Bohemia, and still farther north; had been at an isle called Pathen in the Indian Ocean; had been at Cansay (Hangchow-fu) in China, and had served the emperor of China fifteen months against the king of Manzi; had been among rocks of adamant in the Indian Ocean; had been through an haunted valley, which he places near Millestorach (= Millescorath, *i.e.*, Malasgird in Armenia); had been at many great feats of arms, but had been incapable of performing any himself; had been driven home against his will in 1357 by arthritic gout (despite the well of youth!); and had written his book as a consolation for his "wretched rest." The paragraph which states that he had had his book confirmed at Rome by the pope is, however, an interpolation of the English version.

This recital is of itself enough to provoke some little questioning, and on investigating the sources of the book it will presently be obvious that part at least of the personal history of Mandeville is mere invention. Under these circumstances the truth of any part of that history, and even the genuineness of the compiler's name, become matter for serious doubt. No contemporary corroboration of the existence of such a Jehan de Mandeville seems to be known. Some French MSS., not contemporary, give a Latin letter of presentation from him to Edward III., but this is so hopelessly vague that it might have been penned by any writer on any subject. At Liége, in the abbey of the Guilelmites, now pulled down, there certainly was in the 16th century a tomb of a man in armour said to be Mandeville; but the old French inscription showed no name, and the arms were quite unlike those of the Mandevilles, earls of Essex; while the Latin inscription, stating that the tomb was Mandeville's, and that he died at Liége on November 17, 1372, is not only apparently much later in style, but confounds him with a physician called "ad Barbam," who is said in a printed Latin edition of Mandeville to have met him first at Cairo and again at Liége, and to have persuaded and helped him to write his travels.[2]

Leaving this question, there remains the more complex one whether the book contains, in any measure, facts and knowledge acquired by actual travels and residence in the East. We believe that it may, but only as a small portion of the whole, and that confined entirely to the section of the work which treats of the Holy Land, and of the different ways of getting thither, as well as of Egypt, and in general of what we understand by the Levant.

The prologue indeed points almost exclusively to the Holy Land as the subject of the work. The mention of more distant regions comes in only towards the end of this prologue, and (in a manner) as an afterthought. As regards the writer's claim to have travelled in those more distant regions, it is somewhat astonishing to find that any modern editor could have regarded this as possibly founded in truth. And the apology sometimes made for the book, as only a compilation of what was regarded as truth in the writer's age, is not tenable in the face of the frequent assertion (explicit or implicit) that he had himself been in the remotest regions spoken of, and had witnessed some of the most marvellous circumstances that he details. To this we shall recur later, for the bearing of these statements can only be appreciated when the true derivation of the matter about the further East shall have been exhibited.

By far the greater part of these more distant travels, extending in fact from Trebizond to Ormus, India, the Indian Archipelago, and China, and back again to western Asia, has been appropriated from the narrative of Friar Odoric (written in 1330). These passages, as served up by Mandeville, are almost always, indeed, swollen with interpolated particulars, usually of an extravagant kind, whilst in no few cases the writer has failed to understand the passages which he adopts from Odoric and professes to give as his own experiences. Thus (p. 193)[3] in appropriating a passage of Odoric about tortoises

[1] The *on* in Madabron apparently represents the Arabic nunation, though its use in such a case is very odd.

[2] This physician is called in a French MS. "Jehan de Bourgoigne dit a la Barbe." M. Michelant once saw the title of a medical or botanical treatise bearing the name of Jehan de Bourgoigne. Can he also have written these travels under a feigned name?

[3] Page indications like this refer to passages in the 1866 re-issue of Halliwell's edition, as being the most ready of access. But all these passages have also been verified as substantially occurring in the French MS. from Lord Ashburnham's library mentioned below (of 1371 A.D.), cited A, and in that numbered xxxix. of the Grenville collection (B. M.), which dates probably from the early part of the 15th century, cited G.

of great size, seen in Champa, these are described as "snails" (*lymecons*, A., *limassons*, G.) whose shells were as big as cottages.

In another place (p. 209), where Odoric has given a most curious and veracious account of the Chinese custom of employing tame cormorants to catch fish, the cormorants are converted by Mandeville into "little beasts called *loyres* (*layre*, A.), which are taught to go into the water" (the word *loyre* being apparently used here for "otter," *lutra*, for which the Provençal is *luria* or *loiria*). Where Odoric, describing the court of the Great Khan, mentions the genuine Tartar custom which forbade any man in entering to set down his foot on the threshold of the door (an etiquette which P. della Valle found still in force at Ispahan in the 17th century), Mandeville quite fails to understand the point (see p. 220).

At a very early date the coincidence of Mandeville's stories with those of Odoric was recognized, insomuch that a MS. of Odoric, which is or was in the chapter library at Mainz, begins with the words: *Incipit Itinerarius fidelis fratris Odorici socii Militis Mendavil per Indiam; licet hic* [read *ille*] *prius et alter posterius peregrinationem suam descripsit.* At a later day Sir T. Herbert calls Odoric "travelling companion of our Sir John"; and Purchas, with most perverse injustice, whilst calling Mandeville, next to Polo, "if next, . . . the greatest Asian traveller that ever the world had," insinuates that Odoric's story was stolen from Mandeville's. Mandeville himself is crafty enough, at least in one passage, to anticipate criticism by suggesting the probability of his having travelled with Odoric (see p. 282, and below).

Much again of Mandeville's matter, particularly in Asiatic geography and history, is taken bodily from the book of Hayton, an Armenian of princely family, who became a monk of the Præmonstrant order, and in 1307 dictated this work on the East in the French tongue at Poictiers, out of his own extraordinary acquaintance with Asia and its history in his own time.

It is curious that no passage in Mandeville can be plausibly traced to Marco Polo, with one exception. This is (p. 163) where he states that at Ormus the people, during the great heat, lie in water,—a circumstance mentioned by Polo, though not by Odoric. We should suppose it most likely that this fact had been interpolated in the copy of Odoric used by Mandeville; for, if he had borrowed it direct from Polo, he would have borrowed more.

A good deal about the manners and customs of the Tartars is demonstrably derived from the famous work of the Franciscan John of Plano Carpini (see CARPINI, vol. v. p. 132), though possibly the immediate source for Mandeville may have been some popular compilation. For though the passages in question are all to be found in Carpini, more or less exactly, the expression is condensed and the order changed. For examples compare Mandeville, p. 250, on the tasks done by Tartar women, with Plano Carpini, p. 643;[1] Mandeville, p. 250, on Tartar habits of eating, with Plano Carpini pp. 639-40; Mandeville, p. 231, on the titles borne on the seals of the Great Khan, with Plano Carpini, p. 715, &c.

The account of Prester John, and all the wonders of his court and realm, is taken from the famous *Epistle* of that imaginary potentate, which was so widely diffused in the 13th century, and created that renown which made it incumbent on every traveller in Asia to assume his existence, and to find some new tale to tell of him. Many fabulous stories again of monsters, such as cyclopes, sciapodes, hippopodes, monoscelides, anthropophagi, and men whose heads did grow beneath their shoulders, of the phœnix and the weeping crocodile, such as Pliny has collected, are introduced here and there, derived no doubt from the popular versions of Solinus. And interspersed, especially in the chapters about the Levant, are the stories and legends that were retailed to every pilgrim, such as the legend of Seth and the grains of paradise from which grew the wood of the cross, that of the shooting of old Cain by Lamech, that of the castle of the sparrow-hawk (which appears in the tale of Melusina), those of the origin of the balsam plants at Matariya, of the dragon of Cos, of the river Sabbation, &c.

Even in that part of the book which may be admitted with probability to represent some genuine experience, there are distinct traces that another work has been made use of, more or less, as an aid in the compilation, we might almost say as a framework to fill up. This is the itinerary of the German knight William of Boldensele, written in 1336 at the desire of Cardinal Talleyrand de Perigord.[2] A cursory comparison of this with Mandeville leaves no doubt of the fact that the latter has followed its thread, using its suggestions, and on many subjects its expressions, though digressing and expanding on every side, and too often eliminating the singular good sense of the German traveller. After such a comparison we may indicate as examples Boldensele's account of Cyprus (Mandeville, p. 28, and p. 10), of Tyre and the coast of Palestine (Mandeville, 29, 30, 33, 34), of the journey from Gaza to Egypt (34), passages about Babylon of Egypt (40), about Mecca (42), the general account of Egypt (45), the pyramids (52), some of the particular wonders of Cairo, such as the slave-market, the chicken-hatching stoves, and the apples of paradise, *i.e.*, plantains (49), the Red Sea (57), the convent on Sinai (58, 60), the account of the church of the Holy Sepulchre (74-76), &c. The following may be quoted as a specimen, showing how Mandeville has at once followed Boldensele and deviated from his good sense:—

Boldensele (ed. Basnage, p. 342).	*Mandeville* (p. 52).
"Sunt plura antiquorum monumenta, figuræ pyramidalis, inter quæ sunt duo miræ magnitudinis et altitudinis, de maximis lapidibus et politis, in quibus inveni scripturas diversorum idiomatum. . . . Dicunt simplices hæc maxima monumenta fuisse granaria Pharaonis, et sic ea appellant, quod verum nullo modo est; quia nec ad imponendam nec ad servandam annonam . . . locus in ipsis pyramidibus aptus deprehenditur . . . verum quod monumenta sunt," &c.	"Now also I shall speak of another thing . . . that is to say of the Garners of Joseph that he caused to be made. . . . And they be made of stone, full well made of mason's craft; of which two be marvellously great and high, and the other is not so great. . . . And above the Garners, without, be many scriptures of divers languages. And some say that they are sepulchres of great Lords . . . but that is not true; for all the common rumour and speech is . . . that they be the Garners of Joseph."

It will be seen from these indications, and more particularly from the specific analysis given below, that there is only a small residuum of the book to which genuine character, as containing the experiences of the author, can possibly be attributed. Yet, as has been intimated, the borrowed stories are frequently claimed as such experiences. We have already alluded to Mandeville's claim (p. 4) to have visited distant parts of Asia; to have drunk of the Fountain of Youth, a favourite mediæval fable which he interpolates in Odoric's account of Malabar (169); to his assertion that he had visited Lamary (Sumatra), and indeed that he had gone beyond it to 33° 16′ of S. lat. (181-82); and that he had been at a certain other island in the Indian Archipelago (190). He alleges also that he had witnessed the curious exhibition of the garden of transmigrated souls (described by Odoric) at Cansay, *i.e.*, Hangchow-fu (211). He and his fellows with their valets had remained fifteen months in service with the emperor of Cathay in his wars against the king of Manzi,—Manzi, or Southern China, having ceased to have any existence as a separate kingdom some seventy years before the time referred to. Similar false statements are found at pp. 219, 235, 248, 271. But the most notable of these passages occurs in his adoption from Odoric of the story of the Valley Perilous (282). This is, in its original form, apparently founded on real experiences of Odoric viewed through a haze of excitement and superstition. Mandeville, whilst swelling the wonders of the tale with a variety of extravagant touches, appears to safeguard himself from the reader's possible discovery that the tale was stolen by the interpolation: "And some of our fellows accorded to enter, and some not. So there were with us two worthy men, Friars Minor, that were of Lombardy, who said that if any man would enter they would go in with us. And when they had said so, upon the gracious trust of God and of them, we caused mass to be sung, and made every man to be shriven and houselled; and then we entered, fourteen persons: but at our going out we were but nine," &c.

In referring to this passage it is only fair to recognize that the description (though the suggestion of the greatest part exists in Odoric) displays a good deal of imaginative power; and there is much in the account of Christian's passage through the Valley of the Shadow of Death, in Bunyan's famous allegory, which indicates a possibility that John Bunyan may have read and remembered this episode either in Mandeville or in Hakluyt's Odoric.

Such a passage, however, as that which we recently quoted, and which appears to exist in all the MSS. and versions that have been examined, leaves no room for the rehabilitation of Mandeville's character as regards conscious mendacity. But it does not necessarily follow that the whole work is borrowed or fictitious. There are other examples in mediæval works of travel in which fiction has been linked to true experiences. Even the great Moorish traveller Ibn Batuta, accurate and veracious in the main, seems, in one part at least of his narrative, to invent experiences; and in such works as those of John of Hese and Arnold von Harff, we have examples of pilgrims to the Holy Land whose narratives begin apparently in sober truth, and gradually pass into flourishes of fiction and extravagance. So in Mandeville also we find various particulars which we are unable to trace to other writers, and which may therefore be, provisionally at least, assigned to the writer's own experience, or to knowledge acquired by colloquial intercourse in the East.

It is difficult to decide on the character of his statements as to recent Egyptian history. In his account of that country (pp. 37, 38) though the series of the Comanian (*i.e.*, of the Bahri Mameluke) sultans is borrowed from Hayton down to the accession of *Melechnasser*, *i.e.*, El-Malik el-Nâṣir Mohammed ibn Kalâûn, who came first to the throne in 1299, Mandeville appears to speak from his own knowledge when he adds that this "*Melechnasser* reigned long and governed wisely." In fact, though twice displaced in the early part of his life, Malik Nâṣir reigned till 1341, a duration un-

[1] Viz., in D'Avezac's ed. in tom. iv. of *Rec. de Voyages et de Mémoires*, pub. by the Soc. de Géog., 1839.

[2] It is found in the *Thesaurus* of Canisius, 1604, v. pt. ii. p. 95, and in ed. of same by Basnage, 1725, iv. 337.

paralleled in Mohammedan Egypt, whilst we are told that during the last thirty years of his reign Egypt rose to a high pitch of wealth and prosperity. Mandeville, however, then goes on to say that his eldest son *Melechemader* was chosen to succeed, but this prince was caused privily to be slain by his brother, who took the kingdom under the name of *Melechmadabron*. "And he was Soldan when I departed from those countries." Now Malik Násir Mohammed was followed in succession by no less than eight of his sons in thirteen years, the first three of whom reigned in aggregate only a few months. The names mentioned by Mandeville appear to represent those of the fourth and sixth of the eight, viz., El-Malik el-Ṣálih '*Imádu-d-dín*, and El-Malik el-*Muzaffar* Zainu-d-dín Hájj; and these the statements of Mandeville do not fit.

Among particulars which seem to suggest personal knowledge may be instanced the very good description of the Bedouins (p. 64), starting from that of Boldensele, but largely and accurately expanded; the use of carrier pigeons in Syria (p. 118); the intimation that the Red Sea was frequented by Venetian merchants trading with India (p. 140). There are some other particulars which the author can hardly have witnessed, but which may possibly have been heard in communication with other travellers (if not borrowed from some untraced source). Such are the practice of polyandry in a certain island (p. 287), and the rite of fraternal adoption between two persons by drinking each other's blood (195). The mention of Ani in Armenia with its thousand churches (148) is probably derived from some book; the city and its thousand churches are mentioned by William of Rubrouck.

On several occasions the writer indicates some acquaintance with Arabic, though the words are not always recognizable, owing perhaps to the carelessness of copyists in such matters. Thus (p. 142) he gives the Mohammedan confession of faith as *La ellet ella Machometh rores alla* (*Rosel-alla*, A.) (Lá iláha illá 'lláh Muhammadun rasúlu 'lláh); (p. 50) the Arabic names of the wood, fruit, and sap of the balsam plant; (p. 99) the name of bitumen, "alkatran" (*al-Katrân*); (p. 131) three titles of the Koran, viz., "*Alkoran*," "*Meshaf*" (*i.e.*, *mishaf*, "written sheets or pages," "a copy of the Koran"), and *Harme* (*i.e.*, *haram*, in the sense of "sacred, inviolable"); (p. 168) the names of the three different kinds of pepper (long pepper, black pepper, and white pepper) as *sorbotin*, *fulful*, and *bano* or *bauo* (*fulful* is the common Arabic word for pepper, the others we cannot explain with any confidence); (p. 192) the name of the elephant (but in A. this runs: *Et apelle on là les oliphans vaches*).

Mandeville again, in some passages (and especially in one which is familiar from its being cited by Dr Johnson in the preface to his dictionary) shows a correct idea of the form of the earth, and of position in latitude ascertained by observation of the pole star; he knows that there are antipodes, and that if ships were sent on voyages of discovery they might sail round the world. And he tells a curious story, which he had heard in his youth, how a worthy man did travel ever eastward until he came to his own country again (p. 183). But on the other hand he repeatedly asserts the old belief that Jerusalem was in the centre of the world (79, 183), whilst he maintains in proof of this that at the equinox a spear planted erect in Jerusalem casts no shadow at noon,—which if true would only show that the city was on the equator.

Brief Analysis.—Prologue. Chaps. i.-iii. The way to Constantinople; the wonders and holy places there; the Greek islands, Greek Church, &c. Chaps. iv.-v. Constantinople and Palestine; Rhodes, Cyprus, coast of Palestine; Egypt and Babylon of Egypt; the Sinai desert and convent (these two chapters on the lines of Boldensele; succession of Ayubite and Mameluke sultans from Hayton). Chaps. v.-x. Palestine and the holy places (the most original part of the work, but based occasionally on Boldensele). Chap. xi. Syria, various routes from Western Europe; description of Tartary (the steppe country about the Volga,—very good, though expressly not from personal experience). Chap. xii. On the Saracens and their religion, Mohammed, &c. (partly based on Boldensele). Chap. xiii. Countries of Asia and Africa; journey to the East from Trebizond (this and on to chap. xx. inclusive is all based on Odoric, with interpolations *ad libitum*). Chap. xxi. The Great Khan; the history of Jenghiz and his successors (from Hayton, with something from Plano Carpini). Chap. xxii. The court and splendour of the khan, his paper-money, &c. (from Odoric). Chap. xxiii. Customs of the Tartars, &c. (chiefly from Plano Carpini). Chap. xxiv. Countries of Asia shortly described (from Hayton). Chap. xxvi. The lamb-plant (from Odoric), with much added about Alexander and the shut-up nations, griffins, and other monsters. Chap. xxvii. The royal estate of Prester John (chiefly from the "Letter" of Prester John, with something from Hayton); the Old Man of the Mountain (from Odoric). Chap. xxviii. The Valley Perilous (from Odoric, with inventions), followed by a quantity of fabulous geography of mixed and uncertain origin. Chaps. xxix., xxx. Similar hotchpotch continued (from the romance of Alexander, the letter of Prester John, Plinian fables, &c.). Chap. xxxi. The return journey from Cathay, &c. (from Odoric). The epilogue.

The oldest known MS. of the original is the earl of Ashburnham's MS. Libri xxiv., dated 1371, but nevertheless very inaccurate in proper names. The English version was made, at least as early as the beginning of the 15th century, from a French MS. defective between p. 36 l. 7 ("And there") of Halliwell's edition and p. 62 l. 25 ("And that Valey"), and is represented in this state by nearly every known English MS. It was completed and revised by two independent editors, neither of them later than the first quarter of the 15th century. One of these revisions is represented by the British Museum MS. Egerton 1982, and the very badly abbreviated Bodleian MS. e Mus. 116. The other is represented by the British Museum MS. Cotton Titus C. xvi. The first printed edition of the English version is apparently the undated edition of Pynson, which gives the version in its original defective shape. So do Wynkyn de Worde's edition of 1499 and eleven editions before 1725, except that they insert a paragraph seemingly abbreviated from the revision represented by Cotton Titus C. xvi. This latter revision was, however, followed in full by the editions of 1725 and 1727, and is, in Halliwell's editions, the text now current. The other revision seems never to have been printed.

That none of the forms of the English version can conceivably be from the same hand which wrote the original work is made patent to any critical reader by their glaring errors of translation, but the form now current asserts in the preface that it was made by Mandeville himself, and this assertion has been taken on trust by almost all modern historians of English literature. The words of the original "je eusse cest livret mis en latin . . . . mais . . . je l'ay mis en rōmant" were mistranslated as if "je eusse" meant "I had" instead of "I should have," and then (whether of fraudulent intent or by the error of a copyist thinking to supply an accidental omission) the words were added "and translated it aȝen out of Frensche into Englyssche." Schönborn and Mätzner respectively seem to have been the first to show that the current Latin and English texts cannot possibly have been made by Mandeville himself. Dr J. Vogels states the same of unprinted Latin versions which he has discovered in the British Museum, and he has proved it as regards the Italian version.

The terseness, the simplicity, and the quaintness of the English version, together with the curiosity of the subject-matter, will always make it delightful reading; but the title "father of English prose," which in its stricter sense already belonged to King Alfred, must in its looser sense be now transferred to Wickliffe.

See Schönborn's *Bibliographische Untersuchungen über die Reise-Beschreibung des Sir John Mandeville*, Breslau, 1840; Mätzner's *Altenglische Sprachproben*, I. ii. pp. 154-55; letters by E. B. Nicholson in *The Academy* of November 11, 1876, and February 12, 1881; Vogels, "Das Verhältniss der italienischen Version der Reisebeschreibung Mandeville's zur französischen" in a *Festschrift, dem Gymnasium zu Moers zur Feier seines 300jährigen Bestehens gewidmet vom Lehrer-Collegium des Crefelder Gymnasiums*, Bonn, 1882, and his forthcoming "Handschriftliche Untersuchungen über Mandeville's Reisebeschreibung," in Vollmöller's *Romanische Forschungen*; also for the bibliography of editions and translations, up to 1867, Tobler's *Bibliographia geographica Palæstinæ*. See also Yule's *Cathay and the Way Thither* (Hakluyt Society), i, 27, 28, on the sources of the book. At least two critical editions are understood to be in preparation—by Vogels (French and English), and by Michelant (French, for the Société de l'Orient Latin). On a French *Lapidaire* and other works attributed to Mandeville see Pannier's *Lapidaires français du moyen âge*, Paris, 1882, pp. 189-204. (E. B. N.—H. Y.)

MANDI, a native state in the Punjab, India, lying between 31° 23′ 45″ and 32° 4′ N. lat., and between 76° 40′ and 77° 22′ 30″ E. long., and bounded on the N. and E. by Kullu, on the S. by Suket, and on the W. by Kángrá. The country is very mountainous, being intersected by two great parallel ranges, reaching to an average height of from 5000 to 7000 feet above sea. The valleys between the hill ranges are very fertile, and produce all the ordinary grains, besides more valuable crops of rice, maize, sugarcane, poppy, and tobacco. Salt-mines contribute about one-third of the state revenue. Iron is found in places, and also gold in small quantities. The area of the state is estimated at about 1200 square miles, and a census in 1881 gives the population as 147,017. The chief, a Rájput by caste, enjoys an approximate income of £36,500, and the state pays a tribute to the British Government of £10,000 a year. Mandi town, the capital, is situated on the Biás, in 31° 43′ N. lat. and 76° 58′ E. long.

MANDINGOES, otherwise known as WANGARAWA, MALINKES, or WAKORE (the last probably their primitive designation), are one of the most widely distributed and important peoples of Western Africa to the north of the equator, and perhaps form the best representatives of the Negro stock. The country of Manding, from which their ordinary name is derived, is a comparatively small district on both banks of the Niger, about the intersection of 12° N. lat. with 9° E. long. A Mandingo empire, usually called after Mali, the chief town, which stood on the bank of the Niger to the north of Buré, was founded by a certain prince Baramindana or Baramangole in the 12th century; and its power was gradually extended till, in the reign of Mansa Musa (1311–31), Songhai, Timbuctoo, and, in fact, the whole of the Sudan with the exception of Genné on the Niger, were more or less thoroughly subjugated. Timbuctoo finally fell into the hands of the Berbers about 1433; but Mali remained a leading state and its capital a great commercial centre till the beginning of the 16th century, when Omar Askia, prince of Songhai, captured the city. The Mali dynasty was a Mohammedan one; and, though some sections of the Mandingo race are still pagans, the greater number are ardent supporters of Islam. Of the present grouping and relations of the states in which they are the dominant element detailed information does not exist; but such accounts as those of Benjamin Anderson (*Journey to Musardu, the capital of the Western Mandingoes*, New York, 1870) show that some of them are possessed of a considerable share of barbaric civilization. According to Dr Quintin, the leading areas of Mandingo occupation are the country watered by the great head-streams of the Senegal (the Faleme, the Bafing, &c.), the district to the south of the lower course of the Gambia, and the coast region of Susu to the north of Sierra Leone. The Mandingoes are generally tall and strongly built; black in complexion, and harsh and ugly in features, but with a spirited and intellectual expression. They are great traders, work in iron and gold, weave cotton cloth, tan excellent leather, and regularly cultivate a considerable variety of crops—rice, cotton, tobacco, kola, potatoes. Their clay-built walled towns often contain 8000 to 10,000 inhabitants, and villages and hamlets are thickly scattered over the country.

Besides Park's *Travels* (in which the Mandingoes play a prominent part) see Barth, *Travels in Central Africa*, and Dr L. Quintin, "Etude ethnogr. sur les pays entre le Sénégal et le Niger," in *Bull. de la Soc. de Géogr.*, Paris, 1881.

MANDLA, a district in the chief commissionership of the Central Provinces, India, lying between 22° 14′ and 23° 22′ N. lat., and between 80° and 81° 48′ E. long., is bounded on the N.E. by Rewah state, on the S.E. by Bilâspur, on the S.W. by Balaghat, and on the W. by Seoni and Jabalpur. It has an area of 4719 square miles, and the headquarters are at Mandla town. The district consists of a wild highland region, broken up by the valleys of numerous rivers and streams. In the lower valleys there is abundance of rich black cotton soil, while in the less favoured valleys a light friable soil is found. The Nerbudda river flows through the centre of the district, receiving several tributaries which take their rise in the Maikal Hills, a range densely clothed with *sál* forest, and forming part of the great watershed between eastern and western India. The loftiest mountain is Chaurádadar, about 3400 feet high. Tigers and wild beasts abound, and the proportion of deaths caused by wild animals is greater in Mandla than in any other district of the Central Provinces.

The census of 1872 disclosed a population of 213,018 (males, 110,473; females, 102,545). The aboriginal or hill tribes number more strongly in Mandla than in any other district of the Central Provinces, the Gonas being alone returned at 113,306. Mandla town, with a population of 4936, is the only place in the district with upwards of 2000 inhabitants. Of the total area of 4719 square miles, 556 were returned in 1881 as cultivated, and 2530 as cultivable. In the same year 54,431 acres were devoted to the production of rice, and 75,196 to wheat, while other food grains occupied 199,062 acres. Fibres and sugar-cane are produced in considerable quantities. The magnificent *sál* forests which formerly clothed the highlands of the district have suffered greatly from the nomadic system of cultivation practised by the hill tribes, who cut down and burn the wood on the hill-sides, and sow their crops in the ashes. Of late years, however, measures have been taken to prevent further damage to the forests. The only local manufacture consists in the weaving of coarse cotton cloth. The total gross revenue of the district in 1881 was returned at £21,398, of which £8999 was derived from the land. There are 46 Government and aided schools. The cost of officials and police was £6396. The district has a bad reputation for fever.

MANDOLINE. See LUTE.

MANDRAKE, *Mandragora officinarum*, L., of the potato family, order *Solanaceæ*, is a native of Spain, Sicily, Crete, Cilicia, Syria, &c., and North Africa (Benth. et Hook., *Gen. Pl.*, ii. p. 900; and DC., *Prod.*, xiii. p. 466). It has a short stem bearing a tuft of ovate leaves, with a thick fleshy and often forked root. The flowers are solitary, with a purple bell-shaped corolla. The fruit is a fleshy orange-coloured berry. The mandrake has been long known for its poisonous properties and supposed virtues. It acts as an emetic, purgative, and narcotic, and was much esteemed in old times; but, except in Africa and the East, where it is used as a narcotic and antispasmodic, it has fallen into disrepute (Pickering's *Chron. Hist. of Plants*, p. 247). In ancient times, according to Isidorus and Serapion, it was used as a narcotic to diminish sensibility under surgical operations, and the same use is mentioned by Kazwíní, i. 297, *s.v.* "Luffáh." Shakespeare more than once alludes to this plant, as when Banquo in *Macbeth* says—"Or have we eaten of the insane root that takes the reason prisoner?" and again in *Antony and Cleopatra*—"Give me to drink mandragora." The notion that the plant shrieked when touched, so that those who desired to pluck it up had to stop their ears with pitch, is alluded to in *Romeo and Juliet*—"And shrieks like mandrakes torn out of the earth, that living mortals, hearing them, run mad." The mandrake, often growing like the lower limbs of a man, was supposed to have other virtues, and was much used for love philtres (Diosc., iv. 76), while the fruit was supposed, and in the East is still supposed, to facilitate pregnancy (Aug., *C. Faust.*, xxii. 56; compare Gen. xxx. 14, where the Hebrew דּוּדָאִים is undoubtedly the mandrake). Like the mallow, the mandrake was potent in all kinds of enchantment (see Maimonides in Chwolson, *Ssabier*, ii. 459, and the notes). Dioscorides identifies it with the κιρκαία, the root named after the enchantress Circe. To it appears to apply the fable of the magical herb Baaras, which cured demoniacs, and was procured at great risk or by the death of a dog employed to drag it up, in Josephus (*B. J.*, vii. 6, § 3). The German name of the plant (Alraune; O. H. G. Alrûna) indicates the prophetic power supposed to be in little images (homunculi, Goldmännchen, Galgenmännchen) made of this root which were cherished as oracles. The possession of such roots was thought to ensure prosperity. (See Ducange, *s.v.* "Mandragora," and Littré.)

Gerard in 1597 (*Herball*, p. 280) described the male and female mandrakes. Dioscorides also recognizes two such plants apparently corresponding to the spring and autumn species (*M. vernalis*, Bert., and *M. officinarum*, L., respectively), differing as he says in the colour of the foliage and shape of fruit. He alludes to the "ridiculous tales" and "doltish dreames" about it merely to scout them. He notes that the root is often single, or with two to many branches. Even in his day, as now, the root of the wild bryony was trimmed to represent the human form, miscalled mandrake, and then sold as such to the ignorant.

MANDRILL, the name of one of the most remarkable, at all events in outward appearance, of the Baboons, *Cynocephalus maimon* or *mormon*. The general characters of the genus to which it belongs are given in the article APE, vol. ii. p. 152. The word appears to have been first introduced into our literature in a work published in 1744 called *A New Voyage to Guinea*, by William Smith, who in an account of the animals of Sierra Leone describes one "called by the white men in this country Mandrill," but adds, "why it is so called I know not."[1] Smith gives sufficiently accurate details to show that his animal is not

[1] "'Mandrill' seems to signify a 'man-like ape,' the word 'Drill' or 'Dril' having been anciently employed in England to denote an Ape or Baboon. Thus in the fifth edition of Blount's '*Glossographia*, or a dictionary interpreting the hard words of whatsoever language now used in our refined English tongue . . . very useful for all such as desire to understand what they read,' published in 1681, I find 'Dril, a stonecutter's tool wherewith he bores little holes in marble,

that now called Mandrill, but the Chimpanzee. Buffon, however, while quoting Smith's description, transferred the name to the very different species now under consideration, and to that it has been attached ever since.

The Baboons generally are distinguished from other Monkeys by the comparative equality of the length of their limbs, which with the structure of the vertebral column adapts them rather for quadrupedal progression on the ground than for climbing among the branches of trees. They are also remarkable for the great size of their face and jaws as compared with the part of the skull which encloses the brain. The Mandrill, in addition to these characters, is distinguished by the heaviness of its body, stoutness and strength of its limbs, and exceeding shortness of its tail, which is a mere stump, not 2 inches long, and usually carried erect. It is, moreover, remarkable for the prominence of its brow ridges, beneath which the small and closely approximated eyes are deeply sunk; the immense size of the canine teeth; the great development of a pair of oval bony prominences on the maxillary bones in front of the orbits, rising on each side of the median line of the face, and covered by a longitudinally-ribbed naked skin; and more especially for the extraordinarily vivid colouring of some parts of the skin.

The body generally is covered with a full soft coating of hair of a light olive-brown above and silvery-grey beneath, and the chin is furnished underneath with a small pointed yellow beard. The hair of the forehead and temples is directed upwards so as to meet in a point on the crown, which gives the head a triangular appearance. The ears are naked and of a bluish-black colour. The hands and feet are naked and black. A large space around the greatly developed ischial callosities, as well as the upper part of the insides of the thighs, is naked and of a crimson colour, shading off on the sides to lilac or blue, which, depending not upon pigment but upon injection of the superficial blood-vessels, varies in intensity according to the condition of the animal—increasing under excitement, fading during sickness, and disappearing after death. But it is in the face that the most remarkable disposition of vivid hues occur, more resembling those of a brilliantly coloured flower than what might be expected in the cutaneous covering of a mammal. The cheek prominences are of an intense blue, the effect of which is heightened by deeply sunk longitudinal furrows of a darker tint, while the central line and termination of the nose are a bright scarlet. Notwithstanding the beauty of these colours in themselves, the whole combination, with the form and expression of features, quite justifies Cuvier's assertion that "il serait difficile de se figurer un être plus hideux que le Mandrill."

It is only to fully adult males that this description applies. The female is of much smaller size, and of more slender make; and, though the general tone of the hairy parts of the body is the same, the prominences, furrows, and colouring of the face are very much less marked. The young males have black faces. At the age of three the blue of the cheeks begins to appear, and it is not until they are about five, when they cut their great canine teeth, that they acquire the characteristic red of the end of the nose.

The Mandrills, especially the old males, are remarkable for the ferocity of their disposition, as well as for other disagreeable qualities, which are fully described in Cuvier's account of the animal in *La Ménagerie du Muséum d'Histoire Naturelle* (1801), but when young they can easily be tamed. Like the rest of the Baboons, they appear to be rather indiscriminate eaters, feeding upon fruit, roots, reptiles, insects, scorpions, &c., and inhabit open rocky ground rather than forests. Not much is known of the Mandrill's habits in the wild state, nor of the exact limits of its geographical distribution. The specimens brought to Europe all come from the west coast of tropical Africa, from Guinea to the Gaboon.

An allied species, the Drill (*Cynocephalus leucophæus*), which resembles the Mandrill in size, general proportions, and shortness of tail, but wants the bright colouring of the face which makes that animal so remarkable, inhabits the same district. (W. H. F.)

&c. Also a large overgrown Ape and Baboon, so called.' 'Drill' is used in the same sense in Charlton's *Onomasticon Zoicon*, 1668. The singular etymology of the word given by Buffon seems hardly a probable one."—Huxley's *Man's Place in Nature*, p. 10, 1863.

MANDURIA, a city of Italy in the province of Lecce, 22 miles east of Taranto on the road to Lecce, in the midst of a wide open country. It had 7948 inhabitants at the census of 1871, is the seat of two pretty important fairs, and contains a spacious palace of the Francavilla family, and a fine old church with campanile and rose window; but the main interest of the place attaches to the ruins of the ancient city in the neighbourhood. The whole circuit of the double line of ancient walls, built of large rectangular stones without mortar, can still be traced, the outer wall and ditch measuring 23 feet in breadth, and the inner passage with the inner wall about 50 feet. At Scegno, just outside the walls, the visitor may still see the fountain of Manduria, the level of which, according to Pliny, it was impossible to alter by any drawing out or pouring in of water.

Manduria is first mentioned in connexion with the death of Archidamus, king of Sparta, who perished in a battle fought under its walls in 338 B.C.; and the only other fact of importance in its ancient annals is the capture by Fabius Maximus in 209. Though omitted from Pliny's list of towns in this region, it appears in the Tabula Peutingeriana. After the destruction of the old town by the Saracens the inhabitants removed to the present site, and the name Casalnuovo, which they at first applied to the new settlement, was exchanged by Ferdinand I. for the original Manduria.

MANES. This term, which is clearly euphemistic, meaning "goodies" or "good fellows," was applied by the Romans to the spirits of the departed. As in all nations of antiquity, and in many existing savage tribes, these spirits were held by them in great awe and veneration, as being powerful for good or for harm. The doctrine, whether imported from the Egyptian theology or of Turanian origin through the Etruscan tomb-builders, is closely allied to that of the Greek belief in the existence of the souls of heroes, ancestors, and generally of the "mighty dead," whom they called δαίμονες, but, of course, in a sense widely different from our notion of *demons*. Thus in Æschylus the spirits of Agamemnon and of Darius are invoked as δαίμονες, and in the *Suppliant Women* (24) they are appealed to as βαρύτιμοι χθόνιοι, where the notion of "heavily-punishing" seems conveyed by the compound epithet. Generally, the *dæmones* were regarded as hostile, or at least dangerous, and blood-offerings (ἐναγισμοί) were made to them to propitiate their wrath, and to induce them to send aid or material blessings from the realms below. The idea appears to have been that the spirits ranged the earth, hungry and forlorn, and seeking whom they might devour. Hence pestilences and sudden deaths were attributed to them, and in this sense they came to be regarded as the enemies of the living. Victims were given to them, that they might not themselves make victims of whomsoever they pleased. Offerings of all kinds were placed in the tomb or burnt on the pyre, and the rites of burial were, with the lamentations of surviving friends, thought necessary for the repose of the ghost. Hesiod, however, in a remarkable passage (*Op. et D.*, 122), speaks of the δαίμονες in terms more allied to our ideas of "guardian angels." He says they were the souls or spirits of the men who lived in the golden age, and that their office now is to walk the earth unseen, and to watch the actions and conduct of man. The meaning of the word *demon* is very obscure. Some connect it with διϝ, the root of *Dis*, *Dyaus*, Ζεύς, *Juppiter*, &c., others with δαίειν, "to allot," "to distribute," (Curtius, *Gr. Etym.*, i. 230), while others, with Plato (*Cratylus*, p. 398, B), have supposed that δαήμων, "knowing," is the original sense. In a general way, δαίμων meant a man's luck or fortune in life, and hence δυσδαίμων and εὐδαίμων are common phrases for "unfortunate" and "prosperous."

The word *manes* seems referable to an old adjective, of which there were two forms, *manis* and *manus*, "good." From the former comes *immanis*, applied to things or persons of formidable size, power, dimensions, &c., and so "huge," "savage," or in any sense "uncanny." The morning is *mane*, "the good or lucky time," because there was an old proverb (Hesiod, *Op. et D.*, 578) that morning was the best time for work. It is generally used as an ablative, *mane novo*, &c., yet Virgil has *dum mane novum*, (*Georg.* iii. 325). *Manus* is found in the old Italian divinity *Genita Mana*, the "good mother," also called Mania and Larunda, the reputed mother of the Lares or household gods. To this goddess Pliny tells us (*N. H.* xxix. 58) the Romans offered in sacrifice a puppy-dog, *catulus*. In xxi. 11 he says that chaplets used to be offered to the manes, and in xxxiii. 2 he speaks of men digging mines to get wealth *in sede manium*, in the depths where the spirits reside.

There can be no doubt that food offerings were, according to a widely spread superstition, offered to the manes, as to the Lar, to Hecate, to Trivia, and to other infernal powers. Thus Virgil (who is fond of the use of the word) says in *Æn.* iii. 63, "aggeritur tumulo tellus; stant Manibus aræ." On these altars, he adds, goblets of milk and the blood of victims were offered, though he evidently has in view the Greek rite of appeasing the dæmons. Perhaps there were not such solemn propitiatory sacrifices made to the manes as to the Greek δαίμονες. But all nations have reverenced the spirits of their ancestors, and especially those nations which retain strongly patriarchal traditions and the distinctions of caste.

The *genius* was a kind of attendant on the living, the sharer of his fortunes, and perhaps to some extent regulating them, from birth to death. To indulge one's genius originally meant to please him with good cheer, an idea that lay at the root of all primitive notions of sacrifice. Of this notion there is no Greek equivalent. It seems more nearly allied to the superstition of a "double" or "wraith," a kind of *alter ego* who at once was, and was not, identical with the individual person. (See Hor., *Epist.* ii. 2, 187.)

Between the *manes* and the received idea of *souls* there was a pretty close analogy. When Virgil says (*Æn.* vi. 743), "quisque suos patimur manes," he appears to mean that the souls of all receive the reward of deeds done in life. There was, of course, a corresponding idea that the *manes* could be conjured up, and could appear as ghosts. Thus Propertius (*El.*, v. 7), commencing with the verse "Sunt aliquid manes, letum non omnia finit," describes how the ghost of his Cynthia appeared to him and upbraided him for his faithlessness. See also Virg., *Æn.* iv. 490 and v. 99. Like the δαίμονες, they were also supposed to have the power of sending dreams (*ibid.* vi. 897).

In sepulchral inscriptions, even on early Christian tombs, the dedication *dis manibus* is common, showing the strong tendency to deify which prevailed with the Romans under the empire.

MANETHO. Manetho Sebennyta (Μανέθων, Μανεθῶ, Μανεθώς, Μανεθῶθ, &c., *i.e.*, *Mai en Thoth*, "beloved by Thoth"), Egyptian priest and annalist, was a native of Sebennytus (Semmenúd) in the Delta. His name is connected by Plutarch with the reign of Ptolemy I., and he is usually stated to have written under Ptolemy II. Philadelphus, though the only authority for this is an epistle to that king of the Pseudo-Manetho, author of the forged *Book of Sothis* preserved by Syncellus. He was instructed in Greek—so Josephus tells us—and the three books of his Αἰγυπτιακά composed in that language opened to foreigners the history of Egypt from the mythical period downwards, as it was preserved in the records of the priests. Unhappily the book is now known only by some lists and fragments preserved by Josephus in his treatise *Against Apion*, by Eusebius in his *Chronica*, and by Syncellus. Syncellus used the work of Eusebius (also known to us through Jerome and the Armenian version[1]) and the lost *Pentabiblon* of Africanus. Thus the little that we know of Manetho's history has reached us through a process of transcription and retranscription very unfavourable to the correct transmission of the lists of kings and dynasties, to which Josephus alone adds any considerable narrative excerpts. It seems indeed that our authorities themselves used varying and partly corrupt recensions of the original text, and that deliberate corruptions of the Manethonic tradition were not wanting appears from the existence of the *Book of Sothis* cited by Syncellus, which was undoubtedly a spurious work. That Manetho himself made honest use of his Egyptian sources is generally recognized, since the Egyptian monuments have afforded confirmation of many, though by no means all, of his statements; but how the corrupt and varying data we now have should be used, or whether the Egyptian tradition can be made the basis of a rational chronology of the oldest historical period, is doubtful (see vol. vii. p. 729 *sq.*).

The titles of several other books ascribed to Manetho, with a mass of useful material and discussion, will be found along with the best edition of the fragments in Müller's *Fragmenta Historicorum Græcorum*, ii. 511–616. An extant astrological poem called Ἀποτελεσματικά bears the name of Manetho, but is of much later date (last edition by Koechly, Leipsic, 1858). See Boeckh, *Manetho u. die Hundssternperiode*, 1845; Gutschmid, in *Philologus* (1856), and *Rhein. Mus.*, 1859; Lauth, *Manetho und der Turiner Königs-Papyrus*, 1865; Lieblein, *Aeg. Chron.* (1863) and *Recherches sur la Chron. Ég.*, 1873; and in general the books on Egyptian history and chronology. A fuller list of relative literature is given by Engelmann, *Bibl. Scriptor. Class.* (8th ed.), i. 507.

MANFRED (*c.* 1231–1266), regent and king of the Two Sicilies, a natural son of the emperor Frederick II. by Bianca Lanzia, the daughter of a Lombard earl, was born in Sicily about 1231, and received from his father the title of prince of Tarentum in 1248. Frederick II. at his death appointed him regent of the Two Sicilies during the absence of his brother Conrad IV., and notwithstanding the hostility of Innocent IV., and the revolt of many nobles and towns in Apulia at the instigation of that pontiff, he was able in 1252 to hand over to Conrad an undivided sovereignty. On the death of the latter in 1254, Manfred was once more called to the regency in the interests of his infant nephew Conradin, and by his victory over the forces of Innocent IV. at Foggia on December 2d of that year was able to establish his authority over the entire kingdom. When in 1258 rumours had reached Sicily of the death of Conradin, Manfred, yielding to the solicitations of his prelates, barons, and people, allowed himself to be crowned at Palermo on August 11. Shortly afterwards envoys arrived from the mother of Conradin to say that he was still alive, and to demand the crown for him; but this the king, strong in the popularity which he had acquired by his brave defence of his country, by his pleasing person, and by his many accomplishments, declined to give, promising only to preserve the crown for his nephew,

[1] *Eusebi Chronicorum libri duo*, ed. A. Schoene, Berlin, 1866–75.

and faithfully to bequeath it to him on his own death. Excommunicated in 1259 by Alexander IV., Manfred again resorted to arms, and overrunning the papal states, was made master of Tuscany by the battle of Monte Aperto (September 4, 1260). Now at the height of his power, he was anew excommunicated by Urban IV. in 1261, and in 1263 his forfeited crown was offered to Charles, count of Anjou, and brother of Louis IX. of France. Towards the end of summer in 1265, giving effect to a crusade proclaimed by Urban, Charles with his army entered Piedmont, but the encounter with the Sicilians did not take place until February 1266 at Benevento, where Manfred, filled with despair by the cowardly flight of his Apulians, spurred into the thickest of the battle and fell covered with wounds. His mangled body was hastily buried under a heap of stones near the bridge, but afterwards, at the instance of Pope Clement IV., was dragged out and laid in unconsecrated ground on the frontier of the kingdom.

MANFREDONIA, a seaport and city of Italy, in the province of Foggia, the see of an archbishop, and the centre of a maritime district, lies 22 miles north-east of Foggia, with which it is connected by railway. The situation, on the shores of the Gulf of Manfredonia and at the foot of Monte Gargano, is finely sheltered, and the vegetation of the district is similar to that of Sicily. A castle dating from the 13th century protects the port, and the city is surrounded by walls and towers. The principal building is the cathedral. Though the anchorage is available only for small vessels, a fair trade is carried on in the export of grain. While in 1863 there entered in all 418 vessels with a total burden of 20,346 tons, in 1880 the burden of the 463 vessels was only 10,832 tons. The population of the commune in 1881 was 9401.

Manfredonia is the historical representative of Sipontum, a Roman municipium and colony of some mark, which lay about 1½ miles to the south. The ancient city having greatly declined, partly owing to the unhealthiness of its situation and partly to the disasters of war, Manfred transferred its inhabitants to the present site in 1261. For a time Manfredonia flourished greatly, but the ravages of the Turks in 1620 proved fatal to its development. The site of Sipontum is marked by the ancient church of Santa Maria di Siponto.

MANGALIA, a town on the coast of the Black Sea, in the south of the Dobrudja, at the head of a district in the new Roumanian province of Kustendji. In the time of Genoese supremacy in the Black Sea it was a place of 30,000 inhabitants; and its population has again risen from a few hundreds to upwards of two thousand. According to the *Corpus Inscriptionum Latinarum*, it is to be identified with the ancient Thracian city of Callatis (or Acervetis, as it was formerly called)—a colony of Miletus which continued to be a flourishing place to the close of the Roman period.

MANGALORE, the administrative headquarters of south Kánara district, Madras, is situated on the Malabar coast, in 12° 51′ 40″ N. lat., 74° 52′ 36″ E. long., with a population in 1871 of 29,667. The town is picturesque, clean, and prosperous. The native houses are laid out in good streets, and the European quarter is particularly pleasant. Mangalore clears and exports all the coffee of Coorg, and trades directly with Arabia and the Persian Gulf. In 1875 3600 ships of 264,000 tons entered. The exports in that year were valued at £505,800, and the imports at £272,704. There is a large native Roman Catholic population, with two European bishops, several churches, and a convent. The Basel Lutheran mission has its headquarters here, and has done much good in teaching trades, &c. Good cloth is woven at their establishment; the making of roof tiles, printing, and bookbinding are also taught.

MANGANESE, a metallic chemical element (symbol Mn; atomic weight 55) widely diffused throughout the mineral kingdom, being an almost constant companion of ferrous oxide, lime, and magnesia in their native carbonates and silicates. Of manganese minerals proper—which are comparatively scarce—the most important is *pyrolusite*, the native binoxide, MnO_2. This is a black crystalline or crystallized solid with semi-metallic lustre, sufficiently soft to give a (black) streak on paper; hardness, 2 to 2·5; specific gravity, 4·8 to 4·9. It is known in commerce as "black oxide of manganese" or "manganese," and is extensively used for the industrial extraction of chlorine from muriatic acid. Its most extensive beds are found at Ilmenau and Elgersburg, Thuringia; near Giessen, North Hesse; near Mährisch-Trübau, Moravia; and in Spain. Almost all pyrolusite is contaminated with more or less of the following "manganites"—general formula $MnO_2.R''O$—which besides occur (in the same localities) as independent minerals:—*braunite*, Mn_2O_3 or MnO_2MnO; *manganite*, or grey manganese ore, $Mn_2O_3.H_2O$; *hausmannite*, Mn_3O_4 or $MnO_2.2MnO$; and *psilomelan*, a complex mineral, the composition of which generally approximates to $4MnO_2.RO + xH_2O$,—the R being chiefly Ba or K_2, but including in general more or less of Ca, Mg, and Mn. These ores are not unlike pyrolusite in their general appearance, but can usually be easily distinguished from it by their greater hardness and other physical properties. Closely allied to psilomelan are those earthy, massive, or reniform mineral mixtures known as "bog-manganese," "cupreous manganese," "earthy cobalt." In the two last-named the RO is chiefly CuO and CoO respectively. We must here mention those curious formations known as "manganese nodules" which were so frequently dredged up by the "Challenger" expedition, and with which, it seems, large areas of the ocean's bed are thickly covered. The writer found in one of these, which seemed exceptionally rich in manganese, 20·12 per cent. of binoxide of manganese (fully oxidized), 0·4 of oxide of nickel, 0·25 of cobalt, and 0·27 of copper,—a total of 21·04 per cent. of the psilomelanic part, not reckoning the CaO, MgO, &c., belonging to it. All the manganese ores named are available for the manufacture of chlorine, and indeed are so used, as components of what goes in the arts as "manganese."

The industrial value of a "manganese" depends, of course, on its actual or virtual percentage of binoxide. A convenient method for its determination was worked out by Fresenius and Will, on the basis of a reaction long before discovered by Turner. When MnO_2 is brought in contact with aqueous sulphuric and oxalic acids, it is reduced to MnO (-salt) with formation of carbonic acid; thus: $MnO_2 + C_2O_4H_2 + H_2SO_4 = 2H_2O + MnOSO_3 + 2CO_2$. It is easy so to arrange matters that all the CO_2 leaves the apparatus and nothing else, so that the weight of CO_2 formed identifies itself with the loss of weight suffered by the co-reagents; and obviously every one gramme of CO_2 formed indicates $\frac{MnO_2}{2CO_2} = \frac{87}{88} = 0{\cdot}9986$ gramme of real MnO_2. A determination of the free water (loss of weight suffered by the powdered ore at 120° C.) must accompany the assay to enable one to compare two analyses made at different times.

For the making of manganese preparations, high class pyrolusite is the most convenient raw material.

Metallic manganese may be prepared by intimately mixing it with lamp-black and heating the mixture to whiteness in a blast furnace. But the regulus thus obtained contains a large percentage of combined carbon. A purer metal was obtained by Deville, who started with perfectly pure "red oxide," Mn_3O_4, and heated it along with a proportion of sugar-charcoal insufficient for complete reduction in a double crucible made of quicklime. The unreduced oxide (MnO) and part of the lime fuse together into a violet slag, from which the regulus is easily separated. Brunner's manganese (obtained by the reduction of the fluoride with sodium in a clay crucible) is not manganese at all, but a silicide of the metal.

Hugo Tamm, who endeavoured to work out a process for the manufacture of the metal, gives the following process:—11 parts of good pyrolusite is mixed with 1 part of lamp-black and 6 parts of a flux consisting of 20 parts of lead-free bottle-glass, 7 parts of quicklime, and 7 of fluor-spar; and the mixture is strongly heated, in a graphite crucible coated over with a mixture of 3 parts of graphite and 1 part of clay, by means of a blast-furnace. There is formed a regulus covered by a green silicious slag containing much protoxide of manganese. The "raw" manganese thus produced is contaminated with about 1 per cent. each of iron, silicon, and carbon, and traces of sulphur, phosphorus, calcium, and aluminium. The green slag in subsequent operations is substituted for part of the white flux. The raw metal, when re-fused with about one-third of its weight of manganous carbonate, yielded a regulus which contained 99·9 per cent. of the metal,—the remaining $\frac{1}{10}$ per cent. consisting of carbon, silicon, and iron.

Manganese metal is grey, like cast iron (Deville's had a reddish hue like bismuth); its specific gravity is about 8; it is hard and brittle, and about as difficult to fuse as wrought iron. It readily tarnishes in ordinary air; even pure water, and much more dilute acid, attack it with evolution of hydrogen and formation of manganous (MnO) hydrate or salt. It is worth stating that neither MnO nor $MnCl_2$ is reducible at a red heat by hydrogen gas; yet Bunsen succeeded in obtaining metallic manganese by the electrolysis of a concentrated solution of the chloride, using a strong current and a negative electrode of very small area.

Oxides.—Pure peroxide can be obtained artificially by keeping the pure nitrate at 200° C. But really pure nitrate is hard to procure. Perhaps the only method for obtaining a really pure preparation is Volhard's: 10 grammes of "pure" (iron- and cobalt-free) manganous sulphate is dissolved in half a litre of water and 100 cm. of nitric acid of 1·2 specific gravity; the solution is heated to boiling, and strong solution of permanganate of potash added until the MnO is nearly but not quite down, and the mixture kept for a while on a water-bath. The precipitate of binoxide formed (according to equation $Mn_2O_7 + 3MnO = 5MnO_2$) is washed, first with dilute nitric acid, then with water, and dried (when it retains some combined water).

When binoxide of manganese is heated to redness—in vacuum, air, oxygen, nitrogen—it loses oxygen with formation of lower oxides. This phenomenon was investigated by W. Dittmar, who found that, when the binoxide is heated in a constantly renewed atmosphere, the result, for a given temperature, depends only on the partial tension of the oxygen in that atmosphere. Pure (brown-red) Mn_3O_4 remains when this tension is less, while (black) Mn_2O_3 remains when the tension is greater than a certain limit value p. In Dittmar's experiments (which were all made at a temperature somewhat above the melting point of sterling silver), the value p was found to lie close to 26 cm. of mercury. An exact determination of this critical point was not possible, because the temperature was not perfectly constant, and an increase in temperature is equivalent to a diminution in the partial tension of the oxygen. Hence, supposing the oxide Mn_2O_3 to be heated, say in vacuum and within a close apparatus, it will give off oxygen at any temperature greater than a certain minimum t_0, and at any temperature $t_0 + \Delta t$ the gas-evolution will come to a stop as soon as the tension of the gas has come up to the critical value p corresponding to this $t_0 + \Delta t$,—p increasing with Δt.

The protoxide, MnO, is most readily obtained by heating any higher oxide to redness in a current of hydrogen gas, as a dull green powder which gets readily discoloured by oxidation in ordinary air. It is not acted on by water, but readily dissolves in aqueous acids, with formation of manganous salts.

The *sulphate*, $MnSO_4$, is prepared by making pyrolusite into a paste with concentrated sulphuric acid and then heating in a crucible to dull redness until vapours of the acid cease to come off. The ferric and aluminic sulphates (originally present) are now, at least mostly, decomposed and reduced to insoluble basic salts, so that the residue when treated with water and filtered may yield a solution free of these impurities, and, of course, of baryta.

Should any iron or alumina be left it is easily eliminated by digestion with a little carbonate of manganese (prepared from a small portion of the solution by precipitation with carbonate of soda) and filtration. Cobalt and nickel, if present, can be removed by fractional precipitation with sulphide of sodium (or H_2S in the presence of $MnCO_3$?); the black sulphide of Co or Ni comes down first, the (flesh-coloured) MnS afterwards. But lime, magnesia, and alkalies (which are frequently present) are very difficult to get rid of. Compare the section on binoxide. The salt, according to the temperature at which it crystallizes, takes up 7 or 5 or 4 or even 3 or 1 H_2O. Crystallized sulphate of manganese generally exhibits a rose-red tint; but this is owing to the presence of a trace of manganic salt (if not to cobalt salt). The pure salt is colourless.

The chloride, $MnCl_2$.—The crude chloride contained in the preparation of chlorine from the binoxide and muriatic acid is purified by methods analogous to those explained for the sulphate. This (very soluble) salt crystallizes at 15°–20° C., with $4H_2O$. To obtain real $MnCl_2$, the salt must be dehydrated in a current of dry hydrochloric acid gas.

The *carbonate*, $MnCO_3$, is obtained by precipitating the solution of the sulphate or chloride by excess of carbonate of soda on boiling. It is a white precipitate, soluble in 8000 parts of water, which, when dried in the air, gets slightly oxidized with discoloration.

Far more oxidizable is the *hydrate*, $Mn(OH)_2$, as obtained by precipitation of manganous solution by caustic alkalies. In the presence of an excess of alkali or other strong soluble base (such as lime, for instance) the oxidation progresses very rapidly, with formation, ultimately, of a black manganite $MnO_2.RO$ (*e.g.*, MnO_2CaO). This is the rationale of the famous "Weldon Process" for the recovery of the "manganese" from chlorine liquors (see BLEACHING POWDER). A mixed solution of chloride of manganese and sal-ammoniac, when mixed with ammonia, gives no precipitate; but the alkaline liquor readily absorbs oxygen from the atmosphere with formation of a brown precipitate of a higher oxide. If, immediately after addition of the ammonia, the excess of volatile alkali is chased away by boiling, the resulting (neutral or slightly acid) liquor remains clear, even in air. Hereupon is founded a method for the separation of ferric iron and alumina from manganese.

Manganic salts, *i.e.*, salts of Mn_2O_3, are produced only under very special conditions. Solutions containing the sulphate and a phosphate respectively are obtained by heating finely divided pyrolusite with strong sulphuric or phosphoric acid. Both products dissolve in water with formation of intensely purple solutions, which, however, are very unstable, showing a great tendency to pass into the manganous condition. Any manganic salt when boiled with hydrochloric acid gives manganous salt with evolution of chlorine. This tendency separates them sharply from the corresponding compounds of iron.

Manganates and permanganates (compounds with bases of the hypothetical oxides MnO_3 and Mn_2O_7).—The most important of these is the *manganate of potash*, K_2MnO_4. Four parts of very finely divided binoxide of manganese and $3\frac{1}{2}$ parts of chlorate of potash are evaporated to dryness with the solution of 5 parts of caustic potash, and the residue ignited (not fused) in platinum crucibles until all the chlorate is decomposed. The intensely green mass, containing large excess of caustic alkali, dissolves in water into an intensely green solution from which crystals of the salt K_2MnO_4 can be obtained; but when the alkali is neutralized by an acid, the liquor turns intensely purple with formation of permanganate and a precipitate of alkaliferous binoxide: $2K_2MnO_4 + 2H_2O = 2KMnO_4 + 2KHO + 2H$ and $2H + K_2MnO_4 = H_2O + K_2MnO_3$. The purple solution when alkalinized with potash contaminated with organic matter reassumes its original green colour (whence its old name of "chamæleon minerale"). For the preparation of permanganate of potash it is best to pass chlorine into the green solution, when the whole of the manganese assumes the permanganate form: $K_2MnO_4 + Cl = KCl + KMnO_4$.

From the purple liquid crystals of permanganate are easily obtained by evaporation. The crystals (long prisms) are isomorphous with perchlorate of potash, $KClO_4$. They are soluble in 16 parts of cold and far less of hot water. They are almost black, and endowed with a peculiar greenish or bluish metallic lustre. Their powder is red. Their aqueous solution is most intensely purple, one milligramme of the salt giving a perceptible colour to a whole litre and more of water. On addition of acid the solution, through liberation of Mn_2O_7, becomes pink.

Of all wet-way reagents, manganates and permanganates are the most powerful oxidizing agents, especially when they are employed in conjunction with free alkali, or (the permanganates) along with free mineral acid. By one or the other of the two combinations most oxidizable inorganic and almost all organic substances are promptly oxidized. Hence both manganates and permanganates are extensively employed as disinfectants, and, in chemical laboratories, as oxidizing agents. For the former purpose impure forms of the soda salts are generally used, while pure permanganate of potash, nowadays, is exclusively employed for scientific or analytical laboratory work.

The ultimate fate of the reagent depends on whether alkali or acid was used as an auxiliary agent. In the former case the salt passes successively into (green) manganate and (insoluble brown) hydrated binoxide of manganese,—three-sevenths of the oxygen in the Mn_2O_7 being utilized. In the presence of free acid (sulphuric works best) the Mn_2O_7 loses five-sevenths of its oxygen with formation of a *colourless* solution of manganous (MnO) salt. Hence, supposing such a change to take place promptly, and the reagent to be added gradually, the exact point of completed oxidation is reached when the liquid, by the addition of another drop of the permanganate, assumes a permanent pink colour. This is the principle of a number of processes for the determination of certain reducing agents by means of a standard solution of permanganate.

Analysis.—A manganiferous substance when fused up with carbonate of soda on platinum in the presence of air yields a green mass (manganate), the colour being more distinct after cooling. Manganese oxides, when fused up with a borax bead in the oxidizing flame, impart to it an intense amethyst colour, which disappears in the reducing flame. To detect manganese in a solution of mineral salts, we first eliminate what can be precipitated by sulphuretted hydrogen in the presence of mineral acid. In the filtrate the iron (if present) is oxidized by boiling with a granule of chlorate of potash, and the ferric oxide precipitated along with the alumina by addition of sal-ammoniac and excess of ammonia, and boiling off the free volatile alkali. From the filtrate the manganese is precipitated by sulphide of ammonium, as a sulphide which, when pure, exhibits a delicate flesh-red colour but is readily discoloured, by oxidation, when in contact with air. Cobalt, nickel, and zinc, if present, go down with the manganese, but can be eliminated by treatment of the washed sulphides with acetic acid, which dissolves the manganese only. (W. D.)

MANGEL WURZEL. See AGRICULTURE, vol. i. p. 368.

MANGO. The mango-tree (*Mangifera indica*, L., natural order *Anacardiaceæ* or *Terebinthaceæ*) is a native of tropical Asia, but during the last hundred years has been extensively cultivated in the tropical and subtropical regions of the New as well as the Old World. It grows rapidly to a height of 30 to 40 feet, and its dense, spreading, and glossy foliage would secure its cultivation for the sake of its shade and beauty alone. Its fruit, a drupe, though in the wild variety (not to be confused with that of *Spondias mangifera*, Pers., belonging to the same order, also called wild mango in India) stringy and sour from its containing much gallic acid, and with a disagreeable flavour of turpentine, has become sweet and luscious through culture and selection, to which we owe many varieties, differing not only in flavour but also in size, from that of a plum to that of an apple. When unripe, they are used to make pickles, tarts, and preserves; ripe, they form a wholesome and very agreeable dessert. In times of scarcity, the kernels also are eaten. Not only the flesh and kernel of the fruit, but also the bark and resin are of some medicinal value; and the timber, although soft and liable to decay, serves for common purposes, and, mixed with sandal wood, is employed in cremation by the Hindus. It is usually propagated by grafts, or by layering or inarching, rather than by seed. See Drury's *Useful Plants of India.*

MANGOSTEEN, *Garcinia Mangostana*, L., is a tree belonging to the gamboge order (*Clusiaceæ* or *Guttiferæ*). It is a native of the Molucca Islands, but has been introduced into the other islands of the eastern archipelago, Ceylon, and southern Asia, and even the Antilles, though not without difficulty. It grows about 20 feet high, and is somewhat fir-like in general form, but the leaves are large, oval, entire, coriaceous, and glistening. Its fruit, the much-valued mangosteen, is about the size and shape of an orange, and is somewhat similarly partitioned, but is of a reddish-brown to chestnut colour. Its thick rind yields a very astringent juice, rich in tannin, and containing a gamboge-like resin. The soft and juicy pulp is snow-white or rose-coloured, and of exceedingly delicious and subtle flavour and perfume. Being perfectly wholesome, it may be eaten freely, and administered in fever. *G. purpurea* is known in India as mate mangosteen, and *Embryopteris glutinifera*, an ebenaceous tree, as wild mangosteen. See Drury's *Useful Plants of India.*

MANGROVE. The remarkable "mangrove forests" which fringe tidal estuaries, overrun salt marshes, and line muddy coasts in the tropics of both Old and New Worlds, are composed of trees and shrubs belonging to the *Rhizophoraceæ*, a small order of calycifloral exogens, mixed, however, with the "white mangrove," *Avicennia*, a verbenaceous plant. Their trunks and branches constantly emit adventitious roots, which, descending in arched fashion, strike at some distance from the parent stem, and send up new trunks, the forest thus spreading like a banyan grove. The roots and stems afford lodgment and shelter to innumerable bivalves, crabs, and other marine animals, while the branches are inhabited by aquatic birds. A further advantage in dispersal, very characteristic of the order, is afforded by the seeds, which have a striking peculiarity of germination. While the fruit is still attached to the parent branch, the long radicle emerges from the seed and descends rapidly towards the mud, where it may even establish itself before falling off. Owing to its clubbed shape, this is always in the right position, the plumule then making its appearance. The wood of some species is hard and durable, and the astringent bark is employed in tanning. The fruit of the common mangrove, *Rhizophora Mangle*, L., is sweet and wholesome, and yields a light wine. See *Treasury of Botany*, and Lindley's *Vegetable Kingdom.*

MANICHÆISM. At the close of the 3d century three great religious systems stood opposed to one another in western Asia and the south of Europe; these were Neo-Platonism, Catholicism, and Manichæism. All three may be described as the final results reached, after a history of more than a thousand years, by the religious development of the civilized nations stretching from Persia to Italy. Each had put off the national and particular character of the ancient religions, and had become a world-religion, with universalizing tendencies, and with demands which in their effect transformed the whole of human life, both public and private. The place of national worship was taken by a system which not only aimed at being a philosophy of God, the world, and history, but at the same time embraced a definite code of ethics and a religious ritual. In point of form, then, the three religions were like each other, as they also were in this, that each had appropriated elements of older and widely different religions. Their mutual resemblance becomes still further apparent when we observe that in all three the ideas of revelation, redemption, ascetic virtue, and immortality come into the foreground. Neo-Platonism, however, was the spiritualized religion of nature, Greek polytheism transfigured and developed into Pantheism through Oriental influences and philosophical speculations; Catholicism was the monotheistic universal religion, based upon the Old Testament and the Gospel, but built up with the resources of Hellenic speculation and ethics; Manichæism was the dualistic and universal religion, founded on Chaldaism, but charged with Christian, Parsic, and perhaps Buddhistic ideas. In Manichæism the Hellenic element was wanting, in Catholicism the Chaldæo-Persian. These three universal religions were developed in the course of two centuries (*c.* 50–250 A.D.), Catholicism being the earliest and Manichæism the latest creation. To both of these, however, Neo-Platonism was from the outset inferior, because it did not possess a founder, and consequently did not develop elemental force, but retained the character of an artificial creation. Attempts were made to invent a founder for it, but these, of course, entirely failed. Catholicism, again, appears as superior to Manichæism, even if we do not look at the contents of the two religions, because it honoured its founder, not only as a bearer of revelation, but as Redeemer in His own person, and as the Son of God. The struggle of Catholicism with Neo-Platonism had been already decided by about the middle of the 4th century, though the latter maintained itself in the Greek empire for nearly two centuries longer. In its contest with Manichæism, the Catholic Church was from the outset certain of victory, being at the time the privileged church of the empire. But this rival could not be annihilated; it maintained itself both in the East and in the West, though in various forms and modifications, until far on in the Middle Ages.

Mani's life. Mani (Μάνης, Manes, Μανιχαῖος, Manichæus[1]) is said, in the *Acta Archelai*, to have originally been called "Cubricus" (according to Kessler, a corruption of "Shuraik"). Nothing reliable about his life was ever known in the Græco-Roman empire; for the account in the *Acta Archelai* is quite incredible, and shaped by the objects of its author. If criticism may succeed in showing the sources from which this account has flowed, in ascertaining the tendencies which have been at work in it, and thus in extracting some solid matter, it can only do so by starting from the Oriental, the Mohammedan, tradition, which is comparatively worthy of credence. It is therefore to the latter alone that we must apply for information. According to it, Mani was a high-born Persian of Ecbatana. The year of his birth is uncertain, but Kessler accepts as reliable the statement made by Bírúní, that Mani was born in the year 527 of the astronomers of Babylon (215–216 A.D.). He received a careful education at Ctesiphon from his father Fúták (Πατέκιος). As the father connected himself at a later period with the confession of the *Moghtasilah*, or "Baptists," in southern Babylonia, the son also was brought up in the religious doctrines and exercises of this sect. These Baptists (see the *Fihrist*) were apparently connected with the Elkesaites and the Hemerobaptists, and certainly with the Mandæans. It is not improbable that this Babylonian sect had absorbed Christian elements. Thus the boy early became acquainted with very different forms of religion. If even a small part of the stories about his father is founded on fact,—and there is no doubt that most of them are mere Manichæan legends,—it was he who first introduced Mani to that medley of religions out of which his system arose. Manichæan tradition relates that Mani received revelations while yet a boy, and assumed a critical attitude towards the religious instruction that was being imparted to him. This is the more incredible since the same tradition informs us that the boy was as yet prohibited from making public use of his new religious views. It was only when Mani had reached the age of twenty-five or thirty years that he began to proclaim his new religion. This he did at the court of the Persian king, Sapor I., and according to the story, on the coronation-day of that monarch (241–42). A Persian tradition says that he had previously been a Christian presbyter; but this is certainly incorrect. Mani did not remain long in Persia, but undertook long journeys for the purpose of spreading his religion, and also sent forth disciples. According to the *Acta Archelai*, his missionary activity extended westwards into the territory of the Christian church; but from Oriental sources it is certain that Mani rather went into Transoxania, western China, and southwards as far as India. His labours there as well as in Persia were not without result. Like Mohammed after him and the founder of the Elkesaites before him, he gave himself out for the last and highest prophet, who was to surpass all previous divine revelation, which only possessed a relative value, and to set up the perfect religion. In the closing years of the reign of Sapor I. (*c.* 270) Mani returned to the Persian capital, and gained adherents even at court. But the dominant priestly caste of the Magians, on whose support the king was dependent, were naturally hostile to him, and after some successes Mani was made a prisoner, and had then to flee. The successor of Sapor, Hormuz (272–273), appears to have been favourably disposed towards him, but Bahrám I. abandoned him to the fanaticism of the Magians, and caused him to be crucified in the capital in the year 276–7. The corpse was flayed, and Mani's adherents were cruelly persecuted by the king.

Mani's writings. Mani himself composed a large number of works and epistles, which were in great part still known to the Mohammedan historians, but are now lost. The later heads of the Manichæan churches also wrote religious treatises, so that the ancient Manichæan literature must have been very extensive. According to the *Fihrist*, Mani made use of the Persian and Syriac languages; but, like the Oriental Marcionites before him, he invented an alphabet of his own, which the *Fihrist* has handed down to us. In this alphabet the sacred books of the Manichæans were written even at a later period. The *Fihrist* reckons seven principal works of Mani, six being in the Syriac and one in the Persian language; regarding some of these we also have information in Epiphanius, Augustine, Titus of Bostra, and Photius, as well as in the formula of abjuration (Cotelerius, *PP. Apost. Opp.*, i. 543) and in the *Acta Archelai*. They are (1) *The Book of Secrets* (see *Acta Archel.*), containing discussions bearing on the Christian sects spread throughout the East, especially the Marcionites and Bardesanites, and dealing also with their conception of the Old and New Testaments; (2) *The Book of the Giants* (Demons?); (3) *The Book of Precepts for Hearers* (probably identical with the *Epistola Fundamenti* of Augustine, and with the *Book of Chapters* of Epiphanius and the *Acta Archelai*; this was the most widely spread and most popular Manichæan work, having been translated into Greek and Latin; it contained a short summary of all the doctrines of fundamental authority); (4) *The Book Sháhpúrakán* (Flügel was unable to explain this name; according to Kessler it signifies "epistle to King Sapor"; the treatise was of an eschatological character); (5) *The Book of Quickening* (Kessler identifies this work with the "Thesaurus [vitæ]" of the *Acta Archelai*, Epiphanius, Photius, and Augustine, and if this be correct, it also must have been in use among the Latin Manichæans); (6) *The Book* πραγματεία (of unknown contents); (7) a book in the Persian language, the title of which is not given in our present text of the *Fihrist*, but

[1] The name has not as yet been explained, nor is it even known whether it be of Persian or Semitic origin.

which is in all probability identical with the "holy gospel" of the Manichæans (mentioned in the *Acta Archel.* and many other authorities). It was this work which the Manichæans set up in opposition to the Gospels. Besides these principal works, Mani also wrote a large number of smaller treatises and epistles. The practice of writing epistles was continued by his successors. These Manichæan dissertations also became known in the Græco-Roman empire, and existed in collections.[1] There also existed a Manichæan book of memorabilia, and of prayers, in Greek, as well as many others,[2] all of which were destroyed by the Christian bishops acting in conjunction with the authorities. A Manichæan epistle, addressed to one Marcellus, has, however, been preserved for us in the *Acta Archelai.*[3]

ni- æan stem.

Though the leading features of Manichæan doctrine can be exhibited clearly even at the present day, and though it is undoubted that Mani himself drew up a complete system, many details are nevertheless uncertain, since they are differently described in different sources, and it often remains doubtful which of the accounts that have been transmitted to us represents the original teaching of the founder.

The Manichæan system is one of consistent, uncompromising dualism, in the form of a fantastic philosophy of nature. The physical and the ethical are not distinguished, and in this respect the character of the system is thoroughly materialistic; for when Mani coordinates good with light, and evil with darkness, this is no mere figure of speech, but light is actually the only good, and darkness the only evil. From this it follows that religious knowledge can be nothing else than the knowledge of nature and her elements, and that redemption can only consist in a physical process of freeing the element of light from the darkness. Under such circumstances ethics becomes a doctrine of abstinence in regard to all elements which have their source within the sphere of darkness.

The self-contradictory character of the present world forms the point of departure for Mani's speculations. This contradiction presents itself to his mind primarily as elemental, and only in the second instance as ethical, inasmuch as he considers the sensual nature of man to be the outflow of the evil elements in nature. From the contradictory character of the world he concludes the existence of two beings, originally quite separate from each other—light and darkness. Each is to be thought of according to the analogy of a kingdom. Light presents itself to us as the good primal spirit (God, radiant with the ten [twelve] virtues of love, faith, fidelity, high-mindedness, wisdom, meekness, knowledge, understanding, mystery, and insight), and then further as the heavens of light and the earth of light, with their guardians the glorious æons. Darkness is likewise a spiritual kingdom (more correctly, it also is conceived of as a spiritual and feminine personification), but it has no "God" at its head. It embraces an "earth of darkness." As the earth of light has five tokens (the mild zephyr, cooling wind, bright light, quickening fire, and clear water), so has the earth of darkness also five (mist, heat, the sirocco, darkness, and vapour). Satan with his demons was born from the kingdom of darkness. These two kingdoms stood opposed to each other from all eternity, touching each other on one side, but remaining unmingled. Then Satan began to rage, and made an incursion into the kingdom of light, into the earth of light. The God of light, with his syzygy, "the spirit of his right hand," now begot the primal man, and sent him, equipped with the five pure elements, to fight against Satan. But the latter proved himself the stronger, and the primal man was for a moment vanquished. And, although the God of light himself now took to the field, and with the help of new æons (the spirit of life, &c.), inflicted total defeat upon Satan, and set the primal man free, the latter had already been robbed of part of his light by the darkness, and the five dark elements had already mingled themselves with the generations of light. It only remained now for the primal man to descend into the abyss, and prevent the further increase of the generations of darkness by cutting off their roots; but he could not immediately separate again the elements that had once mingled. These mixed elements are the elements of the present visible world, which was formed from them at the command of the God of light. The forming of the world is in itself the beginning of the deliverance of the imprisoned elements of light. The world is represented as an orderly structure of various heavens and various earths, which is borne and supported by the æons, the angels of light. It possesses in the sun and moon, which are in their nature almost quite pure, large reservoirs, in which the portions of light that have been rescued are stored up. In the sun dwells the primal man himself, as well as the glorious spirits which carry on the work of redemption; in the moon the mother of life is enthroned. The twelve constellations of the zodiac form an ingenious machine, a great wheel with buckets, which pour into the sun and moon, those shining ships that sail continually through space, the portions of light set free from the world. Here they are purified anew, and attain finally to the kingdom of pure light and to God Himself. The later Western Manichæans termed those portions of light which are scattered throughout the world—in its elements and organisms—awaiting their deliverance, the *Jesus patibilis.*

It is a significant mark of the materialistic and inhuman character of the system that, while the formation of the world is considered as a work of the good spirits, the creation of man is referred to the princes of darkness. The first man Adam was engendered by Satan in conjunction with "sin," "cupidity," "desire." But the spirit of darkness drove into him all the portions of light he had stolen, in order to be able to dominate them the more securely. Hence Adam is a discordant being, created in the image of Satan, but carrying within him the stronger spark of light. Eve is given him by Satan as his companion. She is seductive sensuousness, though also having in her a small spark of light. But if the first human beings thus stood entirely under the dominion of the devil, the glorious spirits took them under their care from the very outset, sending æons down to them (including Jesus), who instructed them regarding their nature, and in particular warned Adam against sensuality. But this first man fell under the temptation of sexual desire. Cain and Abel indeed are not sons of Adam, but of Satan and Eve; Seth, however, who is full of light, is the offspring of Adam by Eve. Thus did mankind come into existence, its various members possessing very different shares of light, but the men having uniformly a larger measure of it than the women. In the course of history the demons sought to bind men to themselves by means of sensuality, error, and false religions (among which is to be reckoned above all

[1] A βιβλίον ἐπιστολῶν is spoken of in the formula of abjuration, and an *Epistola ad virginem Menoch* by Augustine. Fabricius has collected the "Greek fragments of Manichæan Epistles" in his *Bibliotheca Græca* (vii. p. 311 *sq.*).

[2] The *Canticum amatorium* is cited by Augustine.

[3] Zittwitz assumes that this epistle was in its original form of much larger extent, and that the author of the *Acts* took out of it the matter for the speeches which he makes Mani deliver during his disputation with Bishop Archelaus. The same scholar traces back the account by Turbo in the *Acts*, and the historical data given in the fourth section, to the writings of Turbo, a Mesopotamian, who is assumed to have been a Manichæan renegade and a Christian. But as to this difference of opinion is at least allowable.

the religion of Moses and the prophets), while the spirits of light carried on their process of distillation with the view of gaining the pure light which exists in the world. But these good spirits can only save men by imparting to them the true *gnosis* concerning nature and her forces, and by calling them away from the service of darkness and sensuality. To this end prophets, preachers of true knowledge, have been sent into the world. Mani, following the example of the gnostic Jewish Christians, appears to have held Adam, Noah, Abraham (perhaps Zoroaster and Buddha) to be such prophets. Probably Jesus was also accounted a prophet who had descended from the world of light,—not, however, the historical Jesus, the devilish Messiah of the Jews, but a contemporaneous phantom Jesus, who neither suffered nor died (*Jesus impatibilis*). According to the teaching of some Manichæans, it was the primal man who disseminated the true gnosis in the character of Christ. But at all events Mani himself, on his own claim, is to be reckoned the last and greatest prophet, who took up the work of Jesus impatibilis and of Paul (for he too finds recognition), and first brought full knowledge. He is the "leader," the "ambassador of the light," the "Paraclete." It is only through his agency and that of his imitators "the elect," that the separation of the light from the darkness can be completed. The system contains very fantastic descriptions of the processes by which the portions of light when once set free finally ascend even to the God of light. He who during his lifetime did not become one of the elect, who did not completely redeem himself, has to go through a severe process of purification on the other side of the grave, till he too is gathered to the blessedness of the light. It is erroneous, however, to ascribe, as has been done, a doctrine of transmigration to the Manichæans. Of course men's bodies as well as the souls of the unsaved, who according to the oldest conception have in them no light whatever, fall under the sway of the powers of darkness. A later view, adapted to the Christian one, represents the portions of light in the unsaved as actually becoming lost. When the elements of light have at last been completely, or as far as possible, delivered from the world, the end of all things comes. All glorious spirits assemble, the God of light himself appears, accompanied by the æons and the perfected just ones. The angels supporting the world withdraw themselves from their burden, and everything falls in ruins. A tremendous conflagration consumes the world; the perfect separation of the two powers takes place once more; high above is the kingdom of light, again brought into a condition of completeness, and deep below is the (? now powerless) darkness.

Ethics, social polity, and worship of the Manichæans.

On the basis of such a cosmical philosophy, ethics can only have a dualistic ascetic character. Manichæan ethics is not merely negative, however, since it is necessary to cherish, strengthen, and purify the elements of light, as well as free oneself from the elements of darkness. The aim is not self-destruction, but self-preservation; and yet the ethics of Manichæism appears in point of fact as thoroughly ascetic. The Manichæan had above all to refrain from sensual enjoyment, shutting himself up against it by three seals, the *signaculum oris*, *manus*, and *sinus*. The *signaculum oris* forbids all eating of unclean food (which included all bodies of animals, wine, &c.,—vegetable diet being allowed because plants contained more light, though the killing of plants, or even plucking their fruit and breaking their twigs, was not permitted), as well as all impure speech. The *signaculum manus* prohibits all traffic with things generally, in so far as they carry in them elements of darkness. Finally by the *signaculum sinus* every gratification of sexual desire, and hence also marriage, is forbidden. Besides all this, life was further regulated by an exceedingly rigorous system of fasts. Certain astronomical conjunctions determined the selection of the fast-days, which in their total number amounted to nearly a quarter of the year. Sunday was regularly solemnized as one, and the practice was also generally observed on Monday. Hours of prayer were determined with equal exactness. The Manichæan had to pray four times a day, each prayer being preceded by ablutions. The worshipper turned towards the sun, or the moon, or the north, as the seat of light; but it is erroneous to conclude from this, as has been done, that in Manichæism the sun and moon were themselves objects of worship. Forms of prayer used by the Manichæans have been preserved to us in the *Fihrist*. The prayers are addressed to the God of light, to the whole kingdom of light, to the glorious angels, and to Mani himself, who is apostrophized in them as "the great tree, which is all salvation." According to Kessler, these prayers are closely related to the Mandæan and the ancient Babylonian hymns. An asceticism so strict and painful as that demanded by Manichæism could only be practised by few; hence the religion must have abandoned all attempts at an extensive propaganda, had it not conceded the principle of a twofold morality. A distinction was made in the community between the *Electi* (*Perfecti*), the perfect Manichæans, and the *Catechumeni* (*Auditores*), the secular Manichæans. Only the former submitted themselves to all the demands made by their religion; for the latter the stringency of the precepts was relaxed. They had to avoid idolatry, sorcery, avarice, falsehood, fornication, &c.; above all, they were not allowed to kill any living being (the ten commandments of Mani). They had also to free themselves as much as possible from the world; but in truth they lived very much as their non-Manichæan fellow-citizens. We have here essentially the same condition of things as in the Catholic Church, where a twofold morality was also in force, that of the religious orders and that of secular Christians,—only that the position of the electi in Manichæism was a more distinguished one than that of the monks in Catholicism. For, after all, the Christian monks never quite forgot that salvation is given by God through Christ, whereas the Manichæan electi were actually themselves redeemers. Hence it was the duty of the auditores to pay the greatest respect and most assiduous attention to the electi. These "perfect ones," wasting away under their asceticism, were objects of admiration, and of the most elaborate solicitude.[1] Food was presented to them in abundance, and by their eating it the electi set free the portions of light from the vegetables. They prayed for the auditores, they blessed them and interceded for them, thereby shortening the process of purification the latter had to pass through after death. It was only the electi, too, who possessed full knowledge of religious truths, a point of distinction from Catholicism.

The distinction between electi and auditores, however, does not exhaust the conception of the Manichæan Church; on the contrary, the latter possessed a hierarchy of three ranks, so that there were altogether five gradations in the community. These were regarded as a copy of the ranks of the kingdom of light. At the head stood the *teachers* ("the sons of meekness," Mani himself and his successors); then follow the *administrators* ("the sons of knowledge," the bishops); then the *elders* ("the sons of understanding," the presbyters); the *electi* ("the sons of mystery"); and finally the *auditores* ("the sons of

[1] Analogous to this is the veneration in which the Catholic monks and the Neo-Platonic "philosophers" were held, but the prestige of the Manichæan electi was greater than that of the monks and the philosophers.

insight"). The number of the electi must always have been small. According to Augustine the teachers were twelve, and the bishops seventy-two in number. One of the teachers appears to have occupied the position of superior at the head of the whole Manichæan Church. At least Augustine speaks of such a personage, and the *Fihrist* also has knowledge of a chief of all Manichæans. The constitution, therefore, had a monarchic head.

The worship of the Manichæans must have been very simple, and must have essentially consisted of prayers, hymns, and ceremonies of adoration. This simple service promoted the secret dissemination of their doctrines. The Manichæans too, at least in the West, appear to have adapted themselves to the church's system of festivals. The electi celebrated special feasts; but the principal festival with all classes was the "Bema" (βῆμα) the feast of the "teacher's chair," held in commemoration of the death of Mani in the month of March. The faithful prostrated themselves before an adorned but empty chair, which was raised upon a podium of five steps. Long fasts accompanied the feasts. The Christian and Mohammedan historians could learn little of the Manichæan mysteries and "sacraments," and hence the former charged them with obscene rites and abominable usages. It may be held as undoubted that the later Manichæans celebrated mysteries analogous to Christian baptism and the Lord's Supper, which may have rested upon ancient consecration rites and other ceremonies, instituted by Mani himself and having their origin in nature worship.

torical ition Mani- ism.

From the foregoing account it will be evident, as indeed from modern investigation it is certain, that Manichæism did not originate on Christian ground. It would be more proper to speak of Mohammedanism than of Manichæism as a Christian sect; for Mohammed stands in a far closer relation to the Jewish and Christian religions than did Mani. It is Kessler's merit to have shown that the ancient Babylonian religion, the original source of all the gnosis of western Asia, was the basis of the Manichæan system. Hence the erroneousness of the assumption, which formerly prevailed, that Manichæism was a reform movement of Parsism, a modification of Zoroastrianism under the influence of Christianity. Manichæism is a system which rather belongs to the Semitic group of religions. It is the Semitic religion of nature, withdrawn from national limits, modified by Christian and Persian elements, elevated into a gnosis, and transforming human life by the influence of stringent regulations. But the recognition of this fact only supplies us with a very general explanation of the origin of Manichæism. The question still remains, through what channels and to what extent Mani adopted those Persian and Christian elements, and further, in what form the ancient nature religion of Babylonia was utilized by him. As far as the latter point is concerned it is known that, two centuries before Mani, the Semitic nature-religions had already been taken up by various enthusiastic or speculative spirits, who had given them philosophic depth and moulded than into "systems," which were propagated with the aid of mysterious rites. Mani's undertaking, then, was by no means a novel one, but was rather the last in a long series of similar efforts. Again, even in the earlier of these attempts, from that of Simon Magus onward, Christian elements had been adopted to a greater or less extent; and the sects of the Christian gnostic schools of Syria and western Asia may all be traced back to the nature-religions of ancient Semitism, transformed into a philosophy of the world and of life. It is the Babylonian sect of the Moghtasilah that seems to have furnished Mani with the matter of his religious philosophical speculations, and the religion of this sect was purely Semitic (see MANDÆANS; the Mandæans were related to the Moghtasilah). This was the source of the thorough-going dualism which forms the basis of Mani's system; for the ancient Persian religion was not essentially dualistic, but was at bottom monistic, since Ahriman is created by Ormuzd. At the same time Mani turned the theologumena of ancient Persia also to account. The fact that the two opposed elements are called "light" and "darkness" can hardly be independent of Parsism, and Manichæism uses other *termini technici* of the Persian religion. Whether Mani's idea of redemption is to be traced to the ancient Babylonian or to the Zoroastrian religion we do not venture to decide. The idea of "the prophet" and "the primal man" is at all events Semitic.

It is very difficult to determine what was the extent of Mani's knowledge of Christianity, how much he himself borrowed from it, and through what channels it reached him. In any case it is certain that Manichæism, in those districts where it was brought much into contact with Christianity, became additionally influenced by the latter at a very early period. The Western Manichæans of the 4th and 5th centuries are much more like Christians than their Eastern brethren. In this respect Manichæism experienced the same kind of development as Neo-Platonism. As regards Mani himself, it is safest to assume that he held both Judaism and Catholic Christianity to be entirely false religions. It is indeed true that he not only described himself as the promised Paraclete—for this designation probably originated with himself—but also conceded a high place in his system to "Jesus;" we can only conclude from this, however, that he distinguished between Christianity and Christianity. The religion which had proceeded from the historical Jesus he repudiated together with its founder, and Catholicism as well as Judaism he looked upon as a religion of the devil. But he distinguished between the Jesus of darkness and the Jesus of light who had lived and acted contemporaneously with the former. This distinction agrees with that made by the gnostic Basilides no less strikingly than the Manichæan criticism of the Old Testament does with that propounded by the Marcionites (see the *Acta Archelai*, in which Mani is made to utter the antitheses of Marcion). Finally the Manichæan doctrines exhibit points of similarity to those of the Christian Elkesaites; but, as it is possible, and even probable, that such resemblances are to be ascribed to a common ancient Semitic source, they do not here call for further consideration. The historical relation of Mani to Christianity is then as follows. From Catholicism, which he very probably had no detailed knowledge of, he borrowed nothing, rejecting it as devilish error. On the other hand, he looked upon what he considered to be Christianity proper, that is, Christianity as it had been developed among the sects of Basilidians, Marcionites, and perhaps Bardesanites, as a comparatively valuable and sound religion. He took from it, however, as from the Persian religion, hardly anything but names, and, perhaps we may add, a criticism of the Old Testament and of Judaism so far as he required it. Indications of the influence of Marcionitism are found in the high estimation in which Mani held the apostle Paul, and in the fact that he explicitly rejects the Book of Acts. Mani appears to have given recognition to a portion of the historical matter of the Gospels, and to have interpreted it in accordance with his own doctrine. In conclusion, it remains to be asked whether Buddhistic elements can also be detected in Manichæism. Most modern scholars since F. C. Baur have answered this question in the affirmative. According to Kessler, Mani made use of the teaching of Buddha, at least as far as ethics was concerned. It cannot be doubted that Mani, who undertook long journeys as far as India, knew of Buddhism. The name Buddha (Buddas) which occurs in the legendary account of Mani, and perhaps in the latter's own writings, indicates further that he had occupied his attention with Buddhism when engaged in the work of founding his new religion. But his borrowings from this source must have been quite insignificant. A detailed comparison shows the difference between Buddhism and Manichæism in all their principal doctrines to be very great, while it becomes evident that the points of resemblance are almost everywhere accidental. This is also true of the ethics and the asceticism of the two systems. There is not a single point in Manichæism which demands for its explanation an appeal to Buddhism. Such being the case, the relationship between the two religions remains a mere possibility, a possibility which the inquiry of Geyler (*Das System des Manichæismus und sein Verhältniss zum Buddhismus*, Jena, 1875) has not been able to elevate into a probability.

How are we to explain the rapid spread of Manichæism, and the fact that it really became one of the great religions? One answer is that Manichæism was the most complete gnosis, the richest, most consequent, and most artistic system formed on the basis of the ancient Babylonian religion (so Kessler). This explanation is insufficient, for no religion operates mainly through the perfection of its system of doctrine; and it is not strictly correct, for the older gnostic systems were not less richly equipped than the Manichæan. What gave strength to Manichæism was rather that it united an ancient mythology and a thoroughgoing materialistic dualism with an exceedingly simple spiritual worship and a strict morality. On comparing it with the Semitic religions of nature, we perceive that it retained their mythologies, after transforming them into "doctrines," but abolished all their sensuous cultus, substituting instead a spiritual worship as well as a strict morality. Manichæism was thus able to satisfy the new wants of an old world. It offered revelation, redemption, moral virtue, and immortality, spiritual benefits on the basis of the religion of nature. A further source of strength lay in the simple yet firm social organization which was given by Mani himself to his new institution. The wise man and the ignorant, the enthusiast and the man of the world, could all find acceptance here, and there was laid on no one more than he was able and willing to bear. Each one, however, was attached and led onward by the prospect of a higher rank to be attained, while the intellectually gifted had an additional inducement in the assurance that they did not require to submit themselves to any authority, but would be led to God by pure reason. Thus adapted from the first to individual requirements, this religion also showed itself able to appropriate from time to time foreign elements. Originally furnished from fragments of various religions, it could increase or diminish this possession without rupturing its own elastic framework. And, after all, great adaptability is just as necessary for a universal religion as a divine founder in whom the highest revelation of God Himself may be seen and reverenced. Manichæism indeed, though it applies the title "redeemer" to Mani, has really no knowledge of a redeemer, but only of a physical and gnostic process of redemption; on the other hand, it possesses in Mani the supreme prophet of God. If we consider in conclusion that Manichæism gave a simple, apparently profound and yet convenient solution of the problem of good and evil, a problem that had become peculiarly oppressive to the human race in the 2d and 3d centuries, we shall have named the most important factors which account for the rapid spread of the system.

Manichæism first gained a firm footing in the East, *i.e.*, in Persia, Mesopotamia, and Transoxania. The persecutions it had to endure did not hinder its extension. The seat of the Manichæan pope was for centuries in Babylon, at a later period in Samarkand. Even after the conquests of Islam the Manichæan Church continued to maintain itself, indeed it seems to have become still more widely diffused by the victorious campaigns of the Mohammedans, and it frequently gained secret adherents among the latter themselves. Its doctrine and discipline underwent little change in the East; in particular, it drew no nearer to the Christian religion. More than once, however, Manichæism experienced attempts at reformation; for of course the auditores very easily became worldly in character, and movements of reformation led temporarily to divisions and the formation of sects. Towards the close of the 10th century, at the time the *Fihrist* was written, the Manichæans in Mesopotamia and Persia had already been in large measure ousted from the towns, and had withdrawn to the villages. But in Turkestan, and as far as the Chinese frontier, there existed numerous Manichæan communities, and even whole tribes that had adopted the name of Mani. Probably it was the great migrations of the Mongolian race that first put an end to Manichæism in Central Asia. But even in the 15th century there were Manichæans living beside the Thomas-Christians on the coast of Malabar in India (see Germann, *Die Thomas-Christen*, 1875). Manichæism first penetrated the Greek-Roman empire about the year 280, in the time of the emperor Probus (see the *Chronicon* of Eusebius). If we may take the edict of Diocletian against the Manichæans as genuine, the system must have gained a firm footing in the West by the beginning of the 4th century, but we know that as late as about the year 325 Eusebius had not any accurate knowledge of the sect. It was only subsequent to about 330 that Manichæism spread rapidly in the Roman empire. Its adherents were recruited on the one hand from the old gnostic sects (especially from the Marcionites,—Manichæism exerted besides this a strong influence on the development of the Marcionite churches of the 4th century), on the other hand from the large number of the "cultured," who were striving after a "rational" and yet in some manner Christian religion. Its polemics and its criticism of the Catholic Church now became the strong side of Manichæism, especially in the West. It admitted the stumbling-blocks which the Old Testament offers to every intelligent reader, and gave itself out as a Christianity without the Old Testament. Instead of the subtle Catholic theories concerning divine predestination and human freedom, and instead of a difficult theodicæa, it offered an exceedingly simple conception of sin and goodness. The doctrine of the incarnation of God, which was especially objectionable to those who were going over to the new universal religion from the old cults, was not proclaimed by Manichæism. In its rejection of this doctrine Manichæism agreed with Neo-Platonism; but, while the latter, notwithstanding all its attempts to conform itself to Christianity, could find no formula by which to inaugurate within its own limits the special veneration of Christ, the Western Manichæans succeeded in giving their teaching a Christian tinge. The only part of the Manichæan mythology that became popular was the crude, physical dualism. The barbaric elements were judiciously screened from view as a "mystery;" they were, indeed, here and there explicitly disavowed even by the initiated. The further Manichæism advanced into the West, the more Christian and philosophic did it become. In Syria it maintained itself in comparative purity. In North Africa it found its most numerous adherents, gaining secret support even among the clergy. The explanation of this perhaps lies in the fact that one part of the population of North Africa was of Semitic origin. Augustine was an

Sketch of the histor of Ma chæis

auditor for nine years, while Faustus was at that time the most esteemed Manichæan teacher in the West. Augustine in his later writings against the Manichæans deals chiefly with the following problems:—(1) the relation between knowledge and faith, and between reason and authority; (2) the nature of good and evil, and the origin of the latter; (3) the existence of free will, and its relation to the divine omnipotence; (4) the relation of the evil in the world to the divine government.

The Christian Byzantine and Roman emperors, from Valens onwards, enacted strict laws against the Manichæans. But at first these bore little fruit. The auditores were difficult to trace out, and besides they really gave little occasion for persecution. In Rome itself between 370 and 440 Manichæism gained a large amount of support, especially among the scholars and public teachers. It also made its way into the life of the people by means of a popular literature in which the apostles were made to play a prominent part (*Apocryphal Acts of the Apostles*). Manichæism in the West had also some experience of attempts at reformation from the ascetic side, but of these we know little. In Rome Leo the Great was the first who took energetic measures, along with the state authorities, against the system. Valentinian III. decreed banishment against its adherents, Justinian the punishment of death. In North Africa Manichæism appears to have been extinguished by the persecution of the Vandals. But it still continued to exist elsewhere, both in the Byzantine empire and in the West, and in the earlier part of the Middle Ages it gave an impulse to the formation of new sects, which remained related to it. And, if it has not been quite proved that so early as the 4th century the Priscillianists of Spain were influenced by Manichæism, it is at least undoubted that the Paulicians and Bogomiles as well as the Catharists and the Albigenses are to be traced back to Manichæism (and Marcionitism). Thus the system, not indeed of Mani the Persian, but of Manichæism as modified by Christian influences, accompanied the Catholic Church until the 13th century.

Sources.—(*a*) Oriental. Among the sources for a history of Manichæism, the most important are the Oriental. Of these the Mohammedan, though of comparatively late date, are distinguished by the excellent manner in which they have been transmitted to us, as well as by their impartiality. They must be named first, because ancient Manichæan writings have been used in their construction, while, with the exception of some small and rather unimportant pieces, we possess no other original Manichæan works dating from the 3d century. At the head of all stands En-Nedím, *Fihrist* (*circa* 980), edited by Flügel (1871–72); comp. the latter's work *Mani, seine Lehre u. seine Schriften*, 1862. See also Shahrastání, *Kitáb al-milal wan-nuhal* (12th cent.), edited by Cureton (1846) and translated into German by Haarbrücker, 1851, and individual notes and excerpts by Tabarí (10th cent.), Al-Bírúní (11th cent.), and other Arabian and Persian historians.

Of the Christian Orientals those that afford most information are Ephraem Syrus (ob. 373), in various writings; the Armenian Esnik (see *Zeitsch. f. hist. Theol.*, 1840, ii.; Langlois, *Collection*, ii. 375 *sq.*), who wrote in the 5th century against Marcion and Mani; and the Alexandrian patriarch Eutychius (*ob.* 916), *Annales*, ed. Pococke, 1628. There are besides scattered pieces of information in Aphraates (4th cent.), Barhebræus (13th cent.), and others.

(*b*) Greek and Latin. The earliest mention of the Manichæans in the Græco-Roman empire is to be found in an edict of Diocletian (see Hänel, *Cod. Gregor.*, tit. xv.), which is held by some to be spurious, while others assign it to one or other of the years 287, 290, 296, 308 (so Mason, *The Persec. of Diocl.*, p. 275 *sq.*). Eusebius gives a short account of the sect (*H. E.*, vii. 31). It was the *Acta Archelai*, however, that became the principal source on the subject of Manichæism for Greek and Roman writers. These *Acta* are not indeed what they give themselves out for, viz., an account of a disputation held between Mani and the bishop Archelaus of Cascar in Mesopotamia; but they nevertheless contain much that is trustworthy, especially regarding the doctrine of Mani, and they also include Manichæan documents. They consist of various distinct pieces, and originated in the beginning of the 4th century, probably at Edessa. They were translated as early as the first half of the same century from the Syriac (as is maintained by Jerome, *De Vir. Illust.*, 72; though this is doubted by modern scholars) into Greek, and soon afterwards into Latin. It is only this secondary Latin version that we possess (edited by Zacagni, 1698; Routh, *Reliq. Sac.*, vol. v., 1848; translated in Clark's *Ante-Nicene Library*, vol. xx.); small fragments of the Greek version have been preserved. Regarding the *Acta Archelai*, see Zittwitz in *Zeitschr. f. d. histor. Theol.*, 1873, and Oblasinski, *Acta disp. Arch. et Manetis*, 1874. In the form in which we now possess them, they are a compilation after the pattern of the *Clementine Homilies*, and have been subjected to manifold redactions. These *Acta* were used by Cyril of Jerusalem (*Catech.*, 6), Epiphanius (*Hær.*, 66), and a great number of other writers. All the Greek and Latin heresiologists have included the Manichæans in their catalogues; but they seldom adduce any independent information regarding them (see Theodoret, *Hær. fab.*, i. 26). Important matter is to be found in the resolutions of the councils from the 4th century onwards (see Mansi, *Acta Concil.*, and Hefele, *Conciliengeschichte*, vol. i.–iii.), and also in the controversial writings of Titus of Bostra (6th cent.), Πρὸς Μανιχαίους (ed. Lagarde, 1859), and of Alexander of Lycopolis, Λόγος πρὸς τὰς Μανιχαίου δόξας (ed. Combefis; transl. in *Ante-Nic. Lib.*, vol. xiv. Of the Byzantines, the most worthy of mention are John of Damascus (*De Hæres.* and *Dialog.*) and Photius (*cod.* 179 *Biblioth.*). The struggle with the Paulicians and the Bogomiles, who were often simply identified with the Manichæans, again directed attention to the latter. In the West the works of Augustine are the great repertory for information on the subject of Manichæism (*Contra epistolam Manichæi, quam vocant fundamenti*; *Contra Faustum Manichæum*; *Contra Fortunatum*; *Contra Adimantum*; *Contra Secundinum*; *De actis cum Felice Manichæo*; *De Genesi c. Manichæos*; *De natura boni*; *De duabus animabus*; *De utilitate credendi*; *De moribus eccl. cathol. et de moribus Manichæorum*; *De hæres.*). The more complete the picture, however, which may here be obtained of Manichæism, the more cautious must we be in making generalizations from it, for it is beyond doubt that Western Manichæism adopted Christian elements which are wanting in the original and in the Oriental Manichæism.

Literature.—The most important works on Manichæism are Beausobre, *Hist. critique de Manichée et du Manichéisme*, 2 vols., 1734 *sq.* (the Christian elements in Manichæism are here strongly, indeed too strongly, emphasized); Baur, *Das manich. Religionssystem*, 1831 (in this work Manichæan speculation is exhibited from a speculative standpoint); Flügel, *Mani*, 1862 (a very careful investigation on the basis of the *Fihrist*); Kessler, *Untersuchung zur Genesis des manich. Religionssystems*, 1876; and the article "Mani, Manichäer," by the same writer in Herzog-Plitt's *R.E.*, ix. 223–59. This article is very thorough, and leads to most favourable expectations regarding the author's forthcoming work. The accounts of Mosheim, Lardner, Walch, and Schröckh, as well as the monograph by Trechsel, *Ueber Kanon, Kritik, und Exegese der Manichäer*, 1832, may also be mentioned as still useful. The various researches which have been made regarding Parsism, the ancient Semitic religions, Gnosticism, &c., are of the greatest importance for the investigation of Manichæism. (A. HA.)

MANILA (less correctly MANILLA), the capital of Luzon and the Philippine Islands, and the centre of Spanish commerce in the East, was founded by Legaspí in 1571, and is situated on the eastern shore of a circular bay 120 nautical miles in circumference, 14° 36′ N. lat. and 120° 52′ E. long. The country around the bay is more or less flat in character, and in the dry season almost bare of vegetation, so that, excepting the Mafonso and Matéo mountains behind Manila, and the chains of mountains running north and south of the entrance to the bay, there is really nothing attractive about the harbour. It is unsafe in the north-east and south-west monsoons, and vessels over 300 tons have to run for shelter to the naval port of Cavité, the smaller craft finding a safe anchorage behind a breakwater facing the mouth of the Pasig. A new breakwater, however, was commenced in 1880 for large vessels. This river Pasig, which is about 14 miles long, is fed by an inland lake called the Laguna de Bayo, and on its way into the harbour it divides Manila into two parts. On its northern bank are large commercial warehouses, a bazaar occupied chiefly by Chinese, known as the Escolta, and trending eastwards an extensive suburb of native dwellings extending some miles up the Pasig. Beyond the Escolta lie Binondo, the business part of Manila, and San Miguel, the fashionable quarter where Spaniards and foreigners have their residence, and where since the earthquake of 1880 two palaces have been erected for the governor or captain-general and for the admiral of the fleet. There are numerous churches and barracks in this part of the town, and several public buildings, of which the following may be mentioned,—the hospital of St Lazarus, the *garnero* or large military storehouse, and the famous cigar factory, covering a space of about 6 acres, and employing daily 10,000 women. Beyond and blending as it were with Binondo are villages in which the governor has his country house, and where Europeans have built pretty villa residences. A stone bridge and a new suspension bridge connect Binondo or modern Manila with the suburb opposite and the old fort of St Iago, situated on the south bank and about a mile from the mouth of the Pasig. Within the fort wall lies the old city, or, as it is commonly called, the Plaza de Manila. It is approached by several gates—the principal being the Entrada, near which stands the custom-house. It has several squares, and the streets running at right angles with each other are fairly broad and clean, but, as no trade is carried on in this part of the town, they are dull by day, and, as only oil lamps are used, gloomy by night. The public edifices, such as the governor's palace, the town-hall, and the cathedral, are in a large square, in the centre of which is a statue of Charles IV. surrounded by a garden of flowers. To these may be added the civil and military hospitals, the mint and museum, the university and the academy of arts, the arsenal, the prison, and numerous barracks, convents, and monasteries. Beyond the walls is the *calzada* or esplanade, with a small *paseo* or promenade facing the bay, where three or four military bands play twice a week to a large concourse of people. This forms the chief out-door attraction for the élite of Manila. There are two theatres—occasionally visited by European companies; but there is a want of the cafés and bull fights so associated with Spanish life. Evening receptions are given by the Spaniards, where cards and music serve to while away the time, and the well-to-do *Tagalo*, besides imitating his masters in all their amusements, has another to which he is passionately addicted, viz., cock-fighting. This is under Government control, and in town can only be held in licensed cockpits, which in 1878 yielded above £33,000 to the revenue. The native officials may sometimes be a little officious and overbearing; but the natives generally, especially those out of Manila, are as hospitable to the stranger as the Spaniard.

The population in the walled town, inclusive of the garrison, is given in the consular reports for 1880 as 12,000, and that of Binondo and the suburbs as 250,000 to 300,000. In 1842 the total was rather more than 150,000.

The climate is healthy, and though hot is not unbearably so, the mean temperature being about 82°·6 Fahr. The hot season prevails from March to the end of June; the rest of the year may be said to be showery and stormy. The chief climatic drawbacks to a residence in Manila are hurricanes, earthquakes, and fearful thunderstorms. Great damage was done to property by a tornado of exceptional severity in October 1882.

The cemetery of Manila is well suited for a hot climate and the backward condition of its sanitary arrangements. It is a large circular area, surrounded by an outer and an inner wall, with horizontal recesses between them placed one above another in tiers. On the arrival of a body for sepulture it is taken out of its coffin and put into one of these recesses; quicklime is then spread upon it and the mouth of the recess bricked up. If the recess is the property of the relatives of the dead, the body remains undisturbed for ever. If otherwise, it remains until the recess is absolutely required for another inmate, when the bones, the only remains left of the deceased, are collected and carefully deposited in a large hollow or fosse kept for that purpose.

For two centuries after the Spanish settlement the trade of Manila with the Western world was carried on *via* Acapulco and Mexico; and it was not till 1764 that even the Spanish vessels began to come round by the Cape. The port, however, was opened with some restrictions to foreign vessels in 1789; permission for the establishment of an English commercial house was granted in 1809; the same liberty was before long extended to other nationalities; and in 1834 the privileges of the Royal Company of the Philippines expired and left the commercial movement to its natural tendencies. Since that time the trade of Manila has greatly increased. While in 1840 the port was entered by 187 vessels with a burden of about 57,000 tons, the corresponding figures for 1881 are, including 182 steamers, 317 vessels (British, 118; Spanish, 95; German, 38), with a burden of 244,000 tons. Manila hemp (*abaca*), sugar, cigars, and coffee are the chief articles of export; and sapan wood, mother of pearl, and gum are regular though secondary items. The quantity of hemp shipped at Manila has increased from 528,206 piculs (1 picul=139 lb) in 1877 to 662,886 in 1881, and in the same period the quantity of sugar has risen from 1,215,066 piculs to 2,001,310. Britain and the United States are the great markets for both. The average number of cigars exported is 92,620,000, the greater proportion going to Singapore and China. The total value of the exports was £5,460,000 in 1881, against £2,679,000 in 1864; and a corresponding increase has taken place in the imports.

Telegraphic communication between Manila and Hong-Kong was established in 1880.
